There is considerable variation in the size and shape of the CC between individuals. Similar to the larger volume and weight of the male brain compared with that of the female, anatomical studies at the turn of the last century revealed that the CC was larger in area in the midsagittal plane in men than in women. However, during the last few decades, several studies reported that some subregions, mainly the splenium (de Lacoste-Utamsing and Holloway, 1982) and the isthmus (Witelson, 1989), were larger in women than in men relative to total callosal size. These sex differences have been interpreted as a possible anatomical correlate of the sex differences in the pattern and degree of hemispheric functional asymmetry. The relatively larger CC subregions in women would be consistent with the greater bihemispheric representation of some aspects of language in women than in men. A larger CC could allow for more transfer of information back and forth between hemispheres. These first studies were based on direct measurement of postmortem brains. However, magnetic resonance imaging (MRI) scans provide relatively clear pictures of the CC, although not without some ambiguity of exact boundaries (Figure 3). This new technology has been used in numerous studies of CC size. The results of these studies revealed considerable inconsistency, which led to an extensive review and meta-analysis of 49 postmortem and MRI studies conducted since 1980. It was concluded that the CC is larger in absolute size in men than in women, and that subregions (when CC size is taken into account) are not significantly different in size between the sexes, with the exception of the isthmus, for which there is some consistency of evidence for a larger isthmus in women, albeit with a difference of small magnitude (Bishop and Wahlsten, 1997).

Most studies have used one of two methods to measure the subregions of the CC. The earlier method employs an arithmetic parcellation of the CC into seven subregions that are determined mainly by dividing it into halves and thirds along the maximal longitudinal CC length (Figure 4a).

Figure 3. MR image showing the midsagittal view of a normal adult brain, illustrating the clear depiction of the corpus callosum (CC) that is obtained on scans. However, some regions of the CC are difficult to distinguish from the surrounding structures in scans, such as the boundaries of the rostrum (R) of the CC, and the junction of the CC body and fornix (F). G, genu; S, splenium.

The cortical regions related to each region may be roughly estimated. As further study of CC size ensued, a more sophisticated computerized method was developed which obtained the widths (height) of 99 percentile divisions of the CC along its curved longitudinal axis (Figure 4b). Studies then measured the area of several groups of widths that approximated the subregions of the arithmetic method, or that were obtained by factor analysis. Studies of CC size raise the important issue for anatomical studies in general of how to correct or control for variation in brain size as a baseline. Different normalization techniques using ratio scores, analyses of covariance, or stereotaxic methodology which scales MRI scans into standardized space were used on the same data sets and revealed different results with regard to the differences in CC size (Bermudez and Zatorre, 2001). (*See* **Sex Differences in the Brain**)

Microscopic Anatomy

Variation in size of the CC could reflect various histological differences, such as a different total number of axons, a different proportion of thick

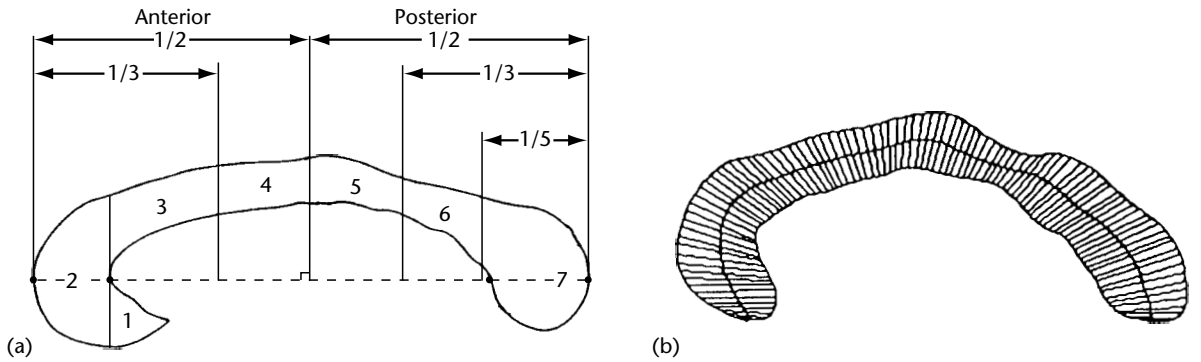

Figure 4. Sketches showing the two different methods for dividing the CC into subdivisions for measurement. (a) Arithmetic method: diagram of the midsagittal view of the CC of the human adult, showing seven subregions. The broken line is the linear axis used to subdivide the CC arithmetically into anterior and posterior halves, as well as anterior, middle and posterior thirds, and the posterior one-fifth region (region 7) which is roughly congruent with the splenium. The boundary line for the genu (region 2) is drawn perpendicular to the linear axis. Regions 3, 4, 5 and 6 constitute the body of the CC. (Adapted from Witelson SF (1989) Hand and sex differences in the isthmus and genu of the human corpus callosum: a postmortem morphological study. *Brain* **112**: 799–835.) (b) Computerized method: a tracing of a human CC showing the division into 99 minimum widths along the curved longitudinal axis. The widths are determined by dividing the dorsal and ventral CC perimeters into 99 percentiles and connecting the corresponding points. (Adapted from Denenberg *et al.* (1991) A factor analysis of the human's corpus callosum. *Brain Research* **548**: 126–132, with permission from Elsevier Science.)

(large-diameter) and thin fibers, or variation in the amount of myelination. A larger CC could have the same number of fibers as a smaller CC, but with a smaller packing density, or it could have a greater number of fibers with the same packing density. Different microscopic anatomy could have functional consequences. Using light microscopy, Aboitiz and colleagues found that the overall density of callosal fibers was not significantly correlated with callosal area, indicating that an increased CC area housed an increased total number of fibers (Aboitiz *et al.*, 1992). However, there was regional differentiation in the density of fibers of different size. Thin fibers were most dense in the anterior third of the CC, and their density decreased to a minimum in the posterior body. Thicker fibers had a complementary pattern, having a peak density in the posterior body. Thicker and more myelinated fibers have faster rates of conductivity. Relatively more thin fibers interconnect higher-order association cortex. It may be that the longer interhemispheric transfer time over thin fibers may be irrelevant for higher-order cognition compared with more direct sensory information.

Small Commissures

Fibers also cross the midline in two other commissures, namely the anterior and posterior commissures (Figure 1). Each is small, on average less than $10\,mm^2$ in cross-section. The anterior commissure houses fibers from the orbitofrontal regions and from the anterior and midregions of the temporal lobe. The posterior commissure connects the diencephalic and midbrain structures. These two commissures are important features in brain imaging, as they are readily viewed and serve as stereotactic landmarks to define the horizontal axis of the brain.

The anatomy of the anterior commissure has undergone an interesting evolutionary change which has functional relevance. Phylogenetically it is older than the neocortex. In lower mammals (e.g. the lemur), it primarily connects regions related to olfaction. Marsupials (e.g. kangaroos) are the one group of mammals that do not have a CC, and in this case the anterior commissure plays a key role in transmitting information between the hemispheres. In humans and other higher primates, the anterior commissure has anterior and posterior limbs, the anterior limb being part of the olfactory system. The posterior limb has neocortical fibers from auditory and visual association regions of the temporal lobe. In cases of agenesis or lack of development of the CC, the anterior commissure appears to play a role in functional plasticity and to mediate some information that is usually transmitted via the CC. The anterior commissure is highly variable in size, which appears to be related to gender and the pattern of hemispheric functional asymmetry. (*See* **Reorganization of the Brain**)

CORPUS CALLOSUM DEVELOPMENT OVER THE LIFESPAN

Fetal and Early Development

Early in brain development, a temporary bridge of glial cells (known as the glial sling) forms across the hemispheric midline, and commissural fibers cross supported by the sling. In some cases of abnormal development this process does not occur, resulting in callosal agenesis. The anterior commissure may then play a greater role in interhemispheric connectivity, but the pattern of hemispheric functional asymmetry is atypical. Initially in development there is an exuberance of callosal fibers, and subsequently some axons are eliminated. For example, this was demonstrated dramatically by electron microscopic analysis in the monkey (LaMantia and Rakic, 1990). In addition, axons are eliminated in a systematic pattern (e.g. in the monkey, up until 1 month before birth there are callosal axons connecting the primary and secondary somesthetic cortex, which are then eliminated, resulting in the adult pattern). Research on fetal and infant brains has been conducted via postmortem study. A review of such studies has indicated that the size of the CC doubles in fetal life and then doubles again within the next 2 years. CC size was found to correlate with gestational age, a feature that is useful for identifying normal versus abnormal brain development *in utero*. The CC is thin during the first few months of postnatal life, but the genu and splenium grow rapidly over the next few months. During this period myelination begins, and the adult shape and orientation of the CC are achieved by about 8 months of age.

There has been relatively little research on CC anatomy during childhood and adolescence. In a recent large longitudinal MRI study, it was found that the area of the CC increases substantially from 5 to about 18 years of age (Giedd *et al*., 1999), when it reaches adult size. This increase is probably due to myelination. Now that high-resolution structural MRI scans are possible, growth of the CC and its subregions can be studied in relation to cognitive development over periods of marked cognitive changes.

Adulthood

Even after the mature CC has developed, there is great variation among individuals, some of which is related to the sex of the person (see above), while some may be associated with variation in cognitive ability (see below). Age is another major factor. Both postmortem and MRI studies have demonstrated negative correlations between CC size and age, with men showing an earlier and more rapid change than women. Frontal CC regions show the greatest change with age, paralleling the more marked change in frontal lobe regions with advancing age. Table 1 summarizes the results of the studies of CC size as a function of age. As can be seen from the table, the results of the MRI studies are somewhat inconsistent with regard to the relationship between CC area and age, as well as with regard to the larger overall CC in men than in women. Although the CC is one of the most clearly visualized structures in MRI scans, the exact boundaries may be ambiguous in some regions, depending on the contrast of voxels in the surrounding structures (Figure 3). (*See* **Neuroimaging**)

Changes in the overall size of the CC must reflect some microscopic change. Only electron microscopy, whose demanding requirements for tissue preparation are problematic in non-experimental situations, can reveal all unmyelinated axons reliably. Consequently, little research has been done in this area. However, one such study reported no relationship between age and the total number of CC fibers, suggesting that the decreasing size of the CC with age may be due to loss of myelin or to a reduction in axon diameter, rather than being due to loss of axons.

Hormonal and Environmental Effects on Corpus Callosum Anatomy

Experimental research has demonstrated that sex hormones contribute to the larger overall CC in the male rat brain compared with that of the female. The rat brain is sensitive to the effects of hormones after birth. During this period of sexual differentiation of the brain, testosterone results in an increase in CC size and, in contrast, estrogen actively inhibits CC growth (Mack *et al*., 1996).

Several recent studies have documented the strong genetic component in CC size. Studies of monozygotic versus dizygotic twin pairs have shown that heritability may account for as much as 70–90% of the variation. A related issue is whether environmental/experiential factors affect callosal anatomy. Later in this article it will be noted that although left-handers or non consistent-right-handers (people who use their left hand for even a few tasks) have a larger CC than consistent-right-handers, the experience of an early forced shift from left- to right-hand writing does not appear to affect CC size (Witelson, 1989). However, there is some evidence that rats living in enriched

as opposed to deprived environmental conditions have enlarged callosa. In humans, literacy (as opposed to being illiterate) and early musical training have been associated with larger CC size. Thus environment as well as heredity may affect CC size.

RELATIONSHIP OF THE CORPUS CALLOSUM TO FUNCTIONAL ASYMMETRY AND COGNITION

The Corpus Callosum and Hemispheric Functional Asymmetry

The pattern and degree of hemispheric specialization varies between individuals. It is possible that variation in CC anatomy is related to brain lateralization. Several studies have examined the relationship between callosal anatomy and neuroanatomical asymmetries, with varying results. Studies of asymmetries of the Sylvian fissure or the posterior surface of the superior temporal gyrus (planum temporale) in relation to CC size have found that the anatomical asymmetries were correlated with posterior CC regions. Since the posterior CC houses fibers which connect right and left posterior temporo-parietal regions which are asymmetrical in function between the two hemispheres, these results support the hypothesis that the extent of callosal connectivity is related to the direction and degree of anatomical asymmetry

and possibly functional asymmetry. (*See* **Brain Asymmetry**)

One of the first behavioral measures that was found to be related to CC size was hand preference (Witelson, 1989). This result indicated that structure and function may be related in very direct ways (i.e. that the size of parts of the human brain may be correlated with behavioral measures). Since left-handers have a greater degree of bihemispheric representation of cognitive functions, it was suggested that the larger CC may provide a substrate for greater interhemispheric communication in left-handers. Subsequent studies using MRI measures of CC generally replicated and supported the finding of a larger CC and particularly some subregions in left-handers or in individuals who did not have the typical pattern of left-sided speech representation. As research progressed to address further issues, it appeared that the CC varies with both hand preference and speech lateralization independently to some degree. The CC was smaller in individuals who had what may be called 'ipsilateral' (same-sided) representation of hand preference and speech than in people who had 'contralateral' representation (e.g. left-handers with right-sided hand representation and left-sided speech representation), but it was not smaller than in left-handers with right-sided speech (also 'ipsilateral' cases) (Table 2).

The Corpus Callosum and Cognitive Correlates

Corpus callosum anatomy may provide a window on the anatomy and function of the cerebral cortex, and consequently it may reflect variation in cognitive processing. Several MRI studies have focused on CC size and its relationship to performance on verbal and spatial tasks in predominantly right-handed individuals (Table 3). In general, small but statistically significant positive correlations were observed. If larger callosa have a greater number of fibers and provide greater interhemispheric communication, these results suggest that, at least in strongly lateralized individuals, such anatomy may confer some functional advantage.

Although it seems remarkable to find relationships between ability and brain size – in this case CC area and, by inference, cortical anatomy – much further research is needed to elucidate the structure–function relationships and possible mechanisms. Such research also raises major ethical issues. MRI scans have the potential to be used as tests or indicators of ability by educational and professional bodies. Clearly caution and proactive consideration are needed with regard to such applications of basic research findings, which will likely only increase with time.

Split-brain Studies and Theoretical Implications

Commissurotomy is an operative procedure which permanently severs the CC or all tracts between the right and left hemispheres. Each hemisphere then only has access to the stimulation it receives and the neural processes that are established on that side. The neuropsychological study of split-brain patients carried out by neuroscientist Roger Sperry and colleagues yielded unambiguous information about functional lateralization of the brain. In such patients, the two sides of the brain are isolated from each other, so that neuropsychological testing can determine not only which side is dominant for specific cognitive functions, but also the limitations of each hemisphere, by determining which functions it cannot support. This has been done in a series of ingenious studies (Sperry, 1974). (*See* **Split-brain Research**)

The research with split-brain patients also raised the issue of the nature of conscious unity. For the development of this issue, in addition to

experimental neurobiological work, Dr Sperry was awarded the Nobel Prize for Medicine in 1981. More recently, it has been suggested that this tract of white matter enables the human condition. The CC may have eliminated the necessity for having two redundant systems, by linking the two hemispheres to such a degree that information can be easily shared and transmitted to appropriate sensory or motor systems. It allows for specialization of the two hemispheres, and it provides the anatomical substrate for the development of completely new functions. Gazzaniga (2000) suggested that it is processing by the left hemisphere which interprets events and allows one to attempt to find

reason or logic in life events. It may be left-hemisphere processing which is crucial for generating hypotheses to explain inexplicable events. This capacity of the left hemisphere may be what makes a person feel as if they control their own actions. Although the right hemisphere has access to what is going on in the outside world, its role may be to keep track of this information so that the left hemisphere can process and interpret it. Thus the two hemispheres may work synergistically to provide an adaptive system of experience and to interpret a person's environment and internal thoughts. Circadian Rhythms

Introductory article

Ralph E Mistlberger, Simon Fraser University, Burnaby, British Columbia, Canada

CONTENTS

Circadian rhythms are daily (about 24 h) rhythms of behavior, physiology and biochemistry that are controlled by internal clocks. These rhythms are entrained by environmental cues, and modulate cognitive performance.

INTRODUCTION

The rotation of the earth about its axis creates daily cycles of light, temperature, humidity and other geophysical variables that have had a profound impact on the evolution of life. Most living organisms, from single-celled bacteria to fungi, plants and animals, exhibit daily rhythms in their biochemistry, physiology and behavior that mirror the dramatic environmental changes that define the solar day. Some daily rhythms may represent a direct response to environmental stimuli, but most are controlled by one or more internal, 'circadian' clocks (from the Latin *circa*, 'about' and *dies*, 'day'). The primary function of these circadian clocks is to organize and synchronize the organism's cellular and behavioral activities with the outside world. By internalizing the mechanism for rhythmicity, the organism can anticipate and prepare in advance for predictable changes in its environment. Circadian clocks have been further exploited in some species to regulate seasonal reproductive cycles by measuring day length, and to enable certain cognitive operations that require internal representations of time of day.

While daily rhythms in the activity of plants and animals have undoubtedly always been recognized, the existence of endogenous circadian clocks was a matter of contention until the latter half of the twentieth century. The most compelling evidence for these clocks is the observation that daily rhythms persist (free run) when organisms are maintained in environments lacking 24 h time cues, such as in a controlled laboratory, at the poles, or in orbit aboard the space shuttle. The average duration ('period') of one complete cycle under these conditions usually deviates slightly from 24 h, hence the designation 'circadian'. The period varies both within and between species; in temporal isolation, the circadian clock of the typical mouse completes a cycle in less than a day (about 23.5 h), whereas in most humans the clock cycles at a rate slower than one solar day (the most current estimate is about 24.1 h).

Research on circadian rhythms attempts to answer the following fundamental questions. How are circadian rhythms synchronized with the environment? What are the neural and genetic mechanisms of the circadian clock? What are the consequences of circadian rhythmicity for human performance, health and welfare?

ZEITGEBERS AND ENTRAINMENT

According to the terminology used in the study of biological clocks, a rhythm is any process that repeats itself at regular intervals. A device that produces a rhythm can be said to 'oscillate'. An oscillator can be used like an hourglass to measure the passage of time. If the oscillator is synchronized to the solar day, it can also be used as a 24 h 'clock' to recognize local time, analogous to a sundial or digital wristwatch. A circadian clock is therefore an oscillator that has a mechanism by which it is synchronized to the solar day. Without such a mechanism, the circadian clock would generate daily rhythms that would drift in and out of optimal alignment with the environment. The mechanism for synchronization is therefore vital to the adaptive function of circadian clocks.

Circadian rhythms are strongly synchronized to 24 h light–dark (LD) cycles by a process of 'entrainment', defined as phase and period control of one oscillation by another. 'Phase' refers to any discrete point in the cycle, such as the wake-up time within the daily sleep–wake cycle. Thus, when the circadian sleep–wake rhythm is entrained to a

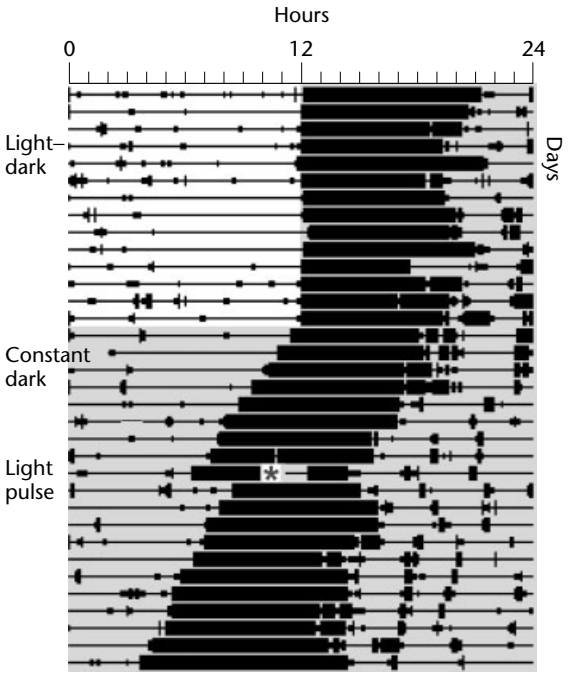

Figure 1. Wheel-running activity of a mouse in a light–dark cycle (12 h dark period indicated by shading), and in constant darkness. Each line represents one day, plotted in 10 min time bins from left to right. Vertical deflections (heavy bars) indicate time bins when wheel running occurred. In the light–dark cycle mouse activity is nocturnal and has a periodicity of exactly 24 h. In constant dark, the activity rhythm 'free runs' with a period of less than 24 h. A 30 min light pulse (asterisk) on day 10 of constant darkness induced a 'delay' phase shift of approximately 2 h.

24 h LD cycle, its period is exactly 24 h, and wake-up time occurs at about the same time within each LD cycle (e.g. when the lights come on in diurnal species, and when the lights go off in nocturnal species). Any stimulus that can entrain another periodic process is a 'zeitgeber' (from the German, 'time-giver').

The mechanism of LD entrainment has been investigated by exposing animals to brief pulses of light (from seconds to hours in duration) during prolonged recordings in constant dark. Light exposure early in the 'subjective night' (that portion of the circadian cycle when the animal acts as if it were night) resets the circadian cycle back to an earlier phase (a 'delay' phase shift; Figure 1). Light exposure late in the subjective night resets the clock forward to a later phase (an 'advance' phase shift). The brighter or longer the light pulse, the larger the shift. Light exposure during most of the 'subjective day' (when the sun would normally be up) typically has little or no effect. Entrainment is accomplished by small, light-induced phase shifts at the dawn and dusk transitions that precisely compensate for the difference between the periodicity of the LD cycle (normally exactly 24 h) and that of the circadian cycle (normally about 24 h). In humans, light during the first half of the night (before the body temperature reaches its minimum, about 2–4 h before the habitual wake-up time) induces delay shifts, while light later in the night induces advance shifts.

Although the LD cycle is the dominant zeitgeber for most species, several nonphotic zeitgebers have also been identified. Daily cycles of temperature can entrain rhythms in some species, although even in plants and poikilothermic animals this does not involve a direct effect of temperature on the rate at which the clock cycles. The biochemical machinery of the circadian clock includes a mechanism for temperature compensation, such that the circadian cycle is relatively constant across a range of tissue temperatures. If this were not the case, the 'clock' of poikilotherms would serve better as a thermometer than as a timepiece.

A number of vertebrate species can be entrained by daily schedules of food intake, and some can also be entrained or phase shifted by scheduled bouts of physical exercise or nonspecific arousal. These behavioral zeitgebers appear to be most effective at times of day when the animal would normally be asleep. The circadian timekeeping system thus appears to have the flexibility to adjust daily rhythms to important nonphotic stimuli that might be of more immediate consequence to survival than is the LD cycle.

NEURAL MECHANISMS

The biological system generating circadian rhythmicity has at its core three integrated components: a self-sustaining circadian clock, an entrainment pathway by which zeitgebers can influence the clock, and one or more output pathways by which the clock confers rhythmicity to other systems (Figure 2). In mammals, the 'master' circadian clock is located in the suprachiasmatic nucleus (SCN) in the hypothalamus. The SCN receives LD information directly from the retina, via a pathway that does not participate in form vision. Damage to the SCN disrupts or eliminates circadian rhythms in all mammals so far studied. Electrical or chemical stimulation of SCN neurons can phase shift circadian rhythms. Individual SCN neurons, grown from embryonic cells in culture, oscillate with a circadian periodicity. Remarkably, transplants of embryonic SCN tissue to adult animals

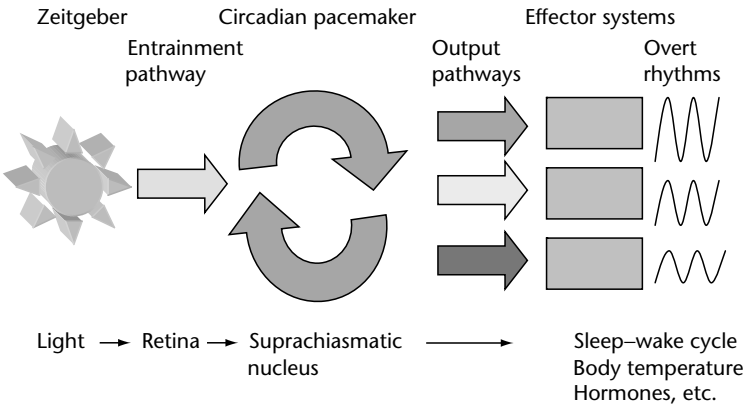

Figure 2. Conceptual model of the core elements of the system generating circadian rhythms in mammals. Overt rhythms may vary in amplitude and phase, but when entrained to light, all exhibit the same 24 h periodicity and a relative stable phase relation with other rhythms. This defines internal temporal order.

can rapidly restore circadian rhythmicity lost by SCN damage. These observations converge in support of a hypothesis that the SCN is the master circadian clock in mammals. This is an exceptional example of the use of complementary techniques to establish the function of a discrete brain structure.

Because of its importance for normal circadian organization of behavior and physiology, the SCN is accorded the status of 'master' oscillator, or 'pacemaker'. However, other circadian oscillators may also exist. One example is the retina, which contains a circadian oscillator that drives daily rhythms of its own local processes, such as photoreceptor disc renewal. In birds and reptiles, the pineal gland, retina and hypothalamus may all contain circadian oscillators, although the role of these as pacemakers or secondary oscillators varies across species.

The SCN receives major inputs from several other brain structures, some of which are important for nonphotic entrainment (e.g. inputs from the thalamic intergeniculate leaflet and pontine raphe nuclei). Neurons of the SCN in turn send axons to a limited number of structures, primarily within the hypothalamus, which presumably disperse circadian timing information more widely. The SCN may also send rhythmic signals by a diffusible factor, conveyed in the extracellular fluid, cerebrospinal fluid or blood.

GENETIC MECHANISMS

Circadian rhythms are genetically programmed and, although sensitive to environmental cycles, do not require these cycles to develop normally. Circadian phenotypes can be selected by breeding, and can be altered by gene mutations. Genetic differences are thought to underlie variability in human rhythms, such as the 'night owl' versus 'early bird' phenotypes.

In all species studied so far, circadian rhythms appear to be generated by an intracellular feedback loop involving a set of 'clock' genes and their protein products. Activation of these clock genes induces the synthesis of proteins, which then feed back upon and temporarily inhibit further clock gene expression. As clock proteins gradually degrade, clock genes are released from inhibition and protein production is renewed. Positive and negative regulators of clock gene expression are articulated in such a way as to produce an approximately 24 h cycle of cellular activity. Zeitgebers shift and entrain the clock by altering clock protein levels. Putative clock genes have been identified and cloned in fungi, fruit flies and mammals, and the feedback principle and some of the specific genes appear highly conserved across a range of phylogenetic groups. A complete molecular description of the circadian 'clockworks' can be expected soon for several species.

CONSEQUENCES OF CIRCADIAN RHYTHMS FOR COGNITION

Consistent with its ubiquitous role in physiological regulation, the circadian timing system also influences performance on cognitive tasks. This is in part secondary to circadian regulation of arousal or alertness, which in LD-entrained humans is low early in the morning and peaks in the early evening, in parallel with the circadian rhythm of body temperature. Performance speed on cognitive tasks that stress simple, repetitive throughput of information, as in tests of vigilance (e.g. detection

of an infrequent signal), serial search, card dealing, additions, and reaction times, follows the same circadian function, with the best scores achieved in the evening. Performance accuracy on some of these tasks varies inversely with body temperature. Tasks stressing short-term memory also generate better scores earlier in the day, before the body temperature reaches its maximum. In addition, performance on some tests of long-term memory is best when participants are tested at the same time of day at which they were trained, even when retest intervals are weeks apart. This implies that circadian time may be incorporated within the neural representations that mediate learning and recall.

The circadian clock has been adapted by many species to provide the sense of time necessary for foraging, navigating and migrating. These species can use timing information provided by the circadian clock to compensate for the movement of the sun and stars, and thereby use the position of these celestial landmarks to guide travel over great distances. Some species, including bees, fish, birds and at least some mammals, can learn and remember the time of day when food is available at specific places in the environment, without the aid of external time cues. According to one theory, circadian time may be encoded within all memories, for use in cognitive computations that guide the temporal aspects of many behaviors.

In humans, the ability to estimate the passage of time is also regulated in part by the circadian system. In temporal isolation, subjective estimates of hourly intervals are proportional to the duration of the circadian sleep–wake cycle. Estimation of intervals in the seconds to minutes range, however, are independent of circadian time.

Disruption of circadian rhythms, induced by transmeridian jet travel, shift-work rotation or a change in laboratory LD cycles, is associated with impaired performance on many cognitive tasks in humans and animals. Some of these effects can be attributed to the partial sleep deprivation that typically accompanies travel and shift rotation in humans, but impairments are also evident in laboratory studies that minimize sleep disruptions. Cognitive deficits that emerge across the life span may also be related to the disruptions of sleep and circadian rhythms that are a physiological hallmark of old age.

CONCLUSION

Circadian rhythmicity is a pervasive feature of life on earth. At all levels of analysis, from molecules to behavior, the daily cycles of the environment are reflected in the functions of the organism. The circadian clocks that have evolved to meet the challenges of the solar day modulate cognitive processes and mediate forms of animal behavior that require precise recognition of time of day or day length.

CONTENTS

The brain determines color from different wavelengths. Specialized cells in the retina, thalamus, primary visual cortex and higher brain areas achieve color perceptions by taking into account chromatic context, which explains various color illusions and color constancy.

INTRODUCTION

A world without color is bleak. Despite this, the benefits of color vision are difficult to quantify. Picasso said, 'When I run out of blue I use red', by which he meant that it is the brightness of a pigment and not its color that describes the three-dimensional shape of objects. Matisse demonstrated this point beautifully in his painting *Femme au Chapeau* (Figure 1). A gray-scale reproduction shows that the values of the pigments do not interfere with an accurate representation of the play of light across his subject's face. That the painting reads well as a face despite the radical color transitions shows that color is not an important cue to shape. In fact, object shapes are easily recognizable even in dim light when color vision is absent. Moreover, many people function perfectly well with impaired color perception: about 1 in 12 men are red–green color-blind and many of them are unaware of it. However, color cues are useful. In monkeys, they assist the discrimination of ripe fruit and of suitable procreative partners, and in humans, color is more than a cue for discriminating objects, for unlike shape and texture, color has emotional significance. One is 'green' with envy, 'red' with anger, 'blue' with sadness. Indeed, Matisse used this to push his portrait past mere representation. Moreover, his picture is much more appealing in color than in black and white. It is probably the emotional quality of color that has fueled color vision research, and it also helps explain the passionate controversies that fill this field's history.

COLOR VISION: WHAT IS IT?

Color vision is the ability to discriminate surfaces based on the spectral content of the light reflected from them, taking into account the light reflected from surrounding objects. Color vision, which has evolved in many animal groups such as insects and birds, is crude in most mammals except some primates, such as humans. Research has focused on color vision in Old World monkeys because their color vision is virtually identical to that in humans (De Valois *et al*., 1974).

THE ROLE OF CONES

In 1802 the English physician Thomas Young proposed that color was subserved by three classes of sensors, each maximally sensitive to a different part of the visible spectrum (Figure 2a). This trichromatic theory, extended by Helmholz in 1866, resolved a profound problem. Though we can see millions of different colors, our retinas simply do not have enough space to accommodate a separate detector for every color at every retinal location, as proposed by Newton. Given that almost all hues can be matched by the combination of three primary colors, and that the number of receptors for color at every retinal location must be small, Young's proposal of three sensors was reasonable. Moreover, it changed the way we think about color: the bottleneck imposed by the small number of sensors implied that color was a neural construction reflecting both physical properties of light and biological properties of photopigments, neurons and networks of neurons. Color is a perception, and not a property of the world.

(a) (b)

Figure 1. [*Figure is also reproduced in color section.*] (a) Henri Matisse, *Femme au Chapeau* (Paris, autumn 1905). Oil on canvas, 80.5 cm × 60 cm; San Francisco Museum of Modern Art (bequest of Elise S. Haas). The gray-scale reproduction (b) shows that the surprising color transitions do not interfere with an accurate representation of the woman's face. Yet the color reproduction is obviously more appealing – why? The dissociation of color and form, clear in this picture, shows that color is processed by the visual system separately from other stimulus attributes, like form.

We now know that color perception begins in the retina with photoreceptors called cones (Figure 2b, c). Cones are more densely packed in the portion of the retina corresponding to the center of gaze (the fovea), and become less dense in the periphery. A second type of photoreceptor, rods, are absent from the fovea. Rods function best in dim light, when the cones do not function well. Because we only have one class of rods, and a comparison between at least two classes of photoreceptor is required for color vision, rods for the most part are not involved in color perception, and we do not see color in very dim light.

Cones are divided into three classes according to their peak absorptions: the S cones absorb shorter wavelengths optimally (peak 440 nm); the M cones absorb middle wavelengths (peak 535 nm) and the L cones absorb long wavelengths (peak 565 nm). All cone classes are somewhat sensitive to wavelengths throughout most of the spectrum (Figure 2b). Thus a single class of cones is color-blind because it cannot distinguish between a dim light of optimal wavelength and an intense light of less optimal wavelength. Moreover, at any given point in the retina there is only one cone, so the retina is color-blind on a spatial scale of single cones. Despite these facts, the cones are often loosely called 'blue', 'green' and 'red', because these names are somehow more intuitive, but we must be cautious because these are not even the color names that we assign to the region of the spectrum to which each class is maximally sensitive. That single cone classes do not code the perception of single colors is proof that the simple trichromatic theory cannot fully explain color perception.

It was once assumed that cones in the primate retina would be regularly distributed (to facilitate uniform sampling of wavelength), as is the case in the goldfish. Primate S cones are distributed fairly regularly (Curcio *et al*., 1991), but L and M cones are surprisingly patchy (Roorda and Williams, 1999) (Figure 2c). The resulting clumpiness may help us detect fine-grained luminance variations, but only at the cost of color resolution. Indeed, variations in color are harder to resolve than variations in luminance (for a review see Livingstone and Hubel, 1987). Two objects that differ only in color are described as equiluminant, and you can find examples of them in the Matisse painting (equiluminant colors will come out roughly the same gray in a gray-scale copy).

The very center of the fovea (0.1° of visual angle) is devoid of S cones. Our eyes are focused for about 550 nm light, where the L and M cones have

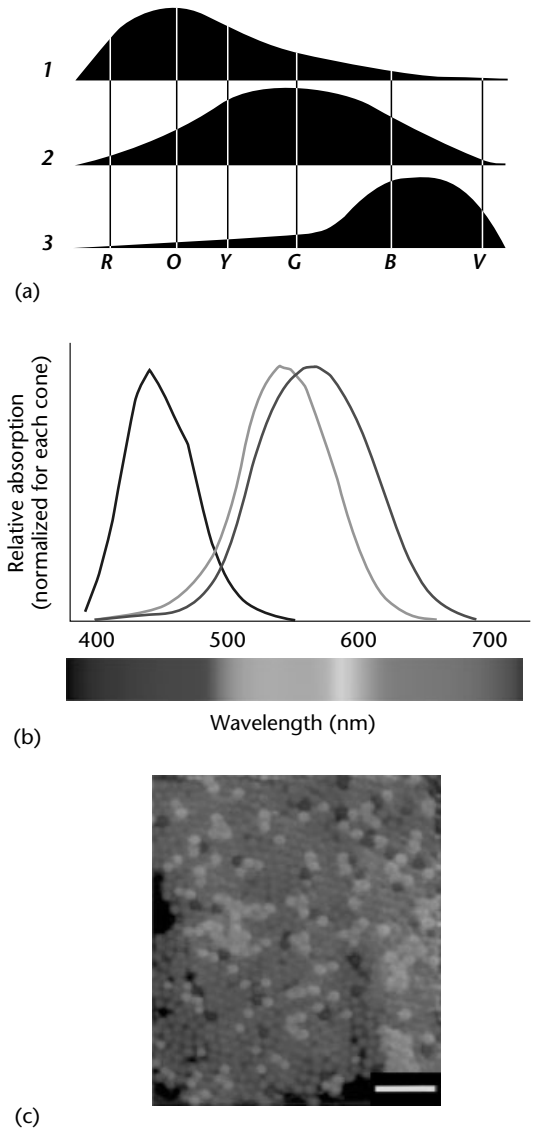

Figure 2. [*Figure is also reproduced in color section.*] Color perception begins in the retina of the eye with three classes of photoreceptors called cones. (a) The absorption spectra of the three detectors proposed by Helmholtz in 1866: shorter wavelengths (V, or violet) were represented on the right. (b) The actual cone absorption spectra of the three cone classes, L, M and S, based on the cone fundamentals of Smith and Pokorny (1972). Convention today puts shorter wavelengths on the left. Below the plot is the visible spectrum. (c) The cone mosaic of a patch of living human retina made visible with adaptive optics, from Roorda and Williams (1999). The S cones are represented by blue, M by green and L by red. Scale bar, 5 arc minutes of visual angle.

their peak sensitivities. Consequently shorter-wavelength light will be blurred. Evolution may have selected against having S cones in the center of the fovea where high spatial acuity is the goal because the short-wavelength light to which the S cones are most responsive will be an unreliable source of spatial information. The absence of S cones in the center of the fovea has surprisingly little impact on color vision, probably because the spatial extent of the S cone hole is finer than the coarse resolution of color vision.

The wavelength sensitivity of a given cone cell is attributed to the specific photopigment protein that it expresses (Nathans, 1999). The M and L photopigment genes, which are encoded on the X chromosome, are fairly similar in sequence, suggesting that the M and L photopigments arose from a common ancestral gene that duplicated not so long ago – around 30–40 million years ago, shortly after the continents of Africa and South America separated. The similarity of the M and L gene sequences predisposes them to recombination during meiosis. This has led to a polymorphism of the L and M photopigments, which is more commonly manifest in males because they only have one X chromosome on which to rely for their M and L photopigments. The polymorphism can be a complete loss of L cones (protanopia), loss of M cones (deuteranopia) or, more frequently, the expression of a mutant M/L hybrid. It is these polymorphisms that underlie the range of so-called red–green color blindness, the most famous case of which is that of Sir John Dalton (a deuteranope), who in 1794 was the first to describe the condition. The deletion of the S cone gene, on the seventh chromosome, is possible (tritanopia), but rare.

COLOR IS AN OPPONENT PROCESS

In 1880 the German psychologist Ewald Hering proposed that color was mediated not by trichromacy but by opponency. Hering observed that we cannot perceive a continuous mixture of colors as predicted by the trichromatic theory – we cannot perceive (or even conceive of) reddish-greens or bluish-yellows. Some colors are mutually exclusive of others. So, Hering argued, color must be determined by the activity of opponent mechanisms, and he proposed three: a red–green mechanism, a blue–yellow mechanism and a black–white mechanism. Today we can appreciate another reason why color must be an opponent process: the L and M cone fundamentals are so similar that to perceive long-wavelength light as distinct from middle-wavelength light (i.e. red and not yellow) the responses of the M cone must be subtracted from those of the L cone.

Each opponent mechanism can be thought of as one axis in a three-dimensional space that

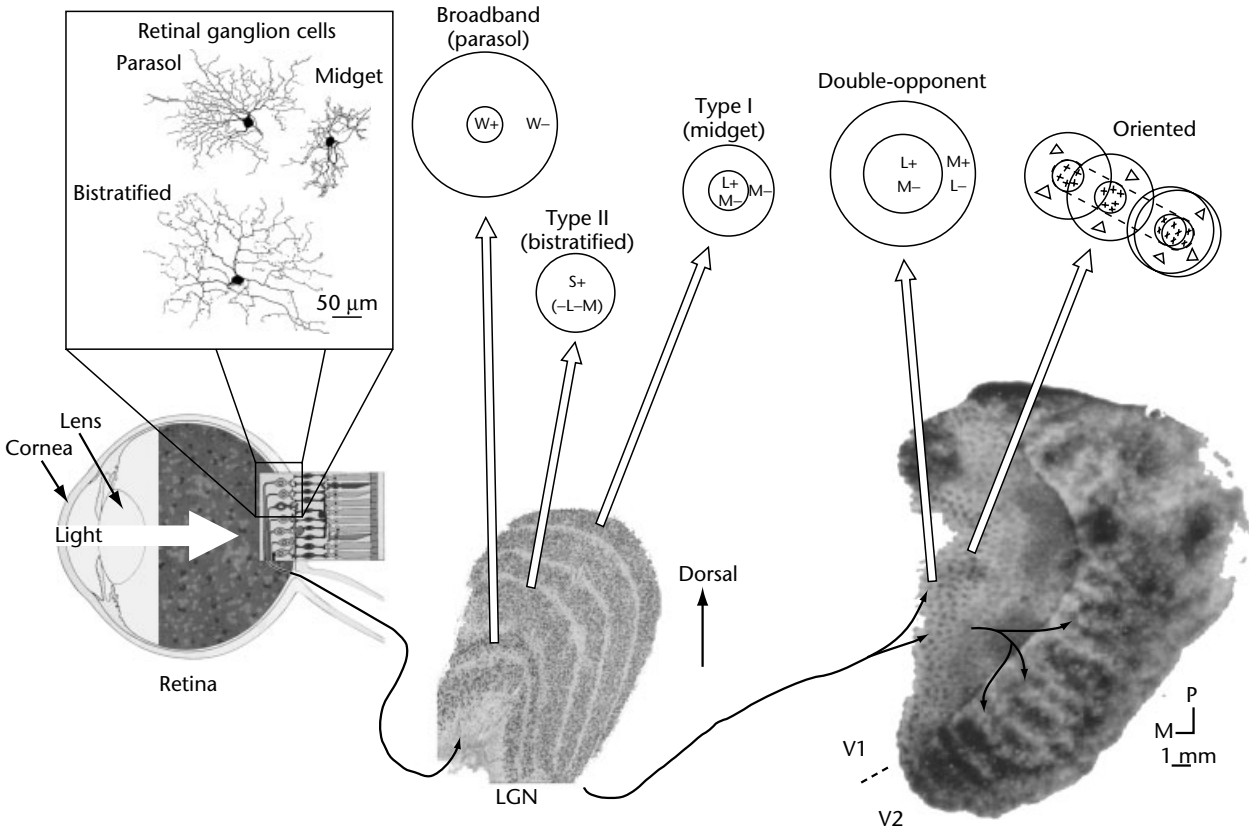

Figure 3. [*Figure is also reproduced in color section.*] A summary of color processing in the visual system. Light enters the eye and is focused on the retina by the cornea and lens. The three classes of cones respond to the light. Different retinal ganglion cells (inset; adapted from Dacey and Lee, 1994) sample the cone mosaic and provide input to the lateral geniculate nucleus (LGN). The retinal ganglion cell names 'midget' and 'parasol' reflect the relative sizes of their dendritic fields, which in turn reflect the relative sizes of their receptive fields. The cells of the LGN, here stained with Nissl substance, comprise six well-defined layers: four dorsal (or parvocellular) layers and two more darkly staining ventral (or magnocellular) layers. Each purple dot is a single cell, about 10 µm in diameter. The parvocellular layers contain type I cells; the receptive field of an L-ON center/M-OFF surround type I cell is given. The magnocellular layers contain the broadband cells. Between the darkly staining parvocellular and magnocellular layers are the koniocellular layers. Type II cells reside in these layers. Broadband cells, type II cells and type I cells are the LGN targets of parasol, bistratified and midget ganglion cells, respectively.

Neurons in the LGN send their axons to the primary visual cortex (V1). In this figure, V1 is represented by a tangential section of one hemisphere of unfolded and flattened squirrel monkey cortex that has been stained with the metabolic enzyme cytochrome oxidase (M, midline; P, posterior). Cytochrome oxidase (CO) staining clearly demarcates the border between V1 and the second visual area, V2, and reveals CO blobs in V1 and the CO stripes in V2. Color information is processed by the double-opponent cells, which reside in the V1 blobs and send their axons to the thin CO stripes of V2 (arrows). Between the blobs are cells that are sensitive to the orientation of a visual stimulus.

encompasses all colors. So any given color could be uniquely defined by three variables: the activity along the red–green axis, the activity along the blue–yellow axis and the activity along the black–white axis. The scientific dispute between Hering and Helmholtz and their supporters is the source of much animosity in the field of color, even today, although studies have now reconciled them.

The retinal ganglion cells, which receive input from the cones, project to neurons in the lateral geniculate nucleus (LGN). These in turn project to neurons in the primary visual cortex (Figure 3). The most common retinal ganglion cells are the midget cells and the parasol cells. Midget cells project to type I cells in the four parvocellular layers of the LGN. Parasol cells project to broadband cells in the two magnocellular layers. Most type I cells receive antagonistic inputs from M and L cones and therefore respond in opposite ways to different colors (DeValois *et al*., 1958; Wiesel and Hubel, 1966; Reid

and Shapley, 1992). A type I cell may be excited by long-wavelength light and suppressed by middle-wavelength light. These cells represent the sort of building block for Hering's red–green opponent process; the three cone types represent Young and Helmholtz's trichromacy.

A third type of retinal ganglion cell is the bistratified cell (Dacey and Lee, 1994). Bistratified cells are excited by S cones and suppressed by a mixture of L and M cones, making them likely candidates for Hering's blue–yellow mechanism. Bistratified cells project to the (S versus M + L) type II cells in the koniocellular layers of the LGN (Figure 3).

Black–white cells must contribute to our perception of color. For example, the addition of black changes the color of orange to brown. Many parvocellular cells do not show cone opponency, and could therefore represent black–white, but it is unclear whether these or the broadband cells of the magnocellular layers (or an unidentified class of cells) underlie the black–white color axis (Wiesel and Hubel, 1966).

COLOR CONSTANCY

Perhaps the greatest misperception about color is that it is equated to wavelength. This misperception is cultivated early in our education when we are taught (incorrectly!) that long-wavelength light is 'red' and short-wavelength light is 'blue'. Though wavelength is the critical determinant of color, it is not the only determinant. For example, our perception of white depends on responses from all three cone classes, which is normally achieved when we see broadband light. However, after viewing a colored surface, one class of cones may become fatigued, perhaps by bleaching of the photopigment, and a previously 'white' surface will appear as a colored afterimage (Figure 4a).

Chromatic context also affects our perception of color. This is well known by artists, who place red against a green background to make it redder. Another example where wavelengths do not correlate directly with color is the phenomenon of induced colors: a gray spot can be made to appear colored if it is surrounded by a large colored annulus (the larger the annulus and the less sharp the boundaries, the stronger the effect). In fact spatial context even colors afterimages (Figure 4b). The discrepancies between physical cues and our perceptions can leave us confused. However, as Edwin Land pointed out, one should avoid asking the question, 'What color is it really?' as if to imply that our visual systems are deceiving us. Color is a product of our physiology and its interaction with the physical world; visual illusions simply point out what our visual systems are constantly (and usually effectively) doing.

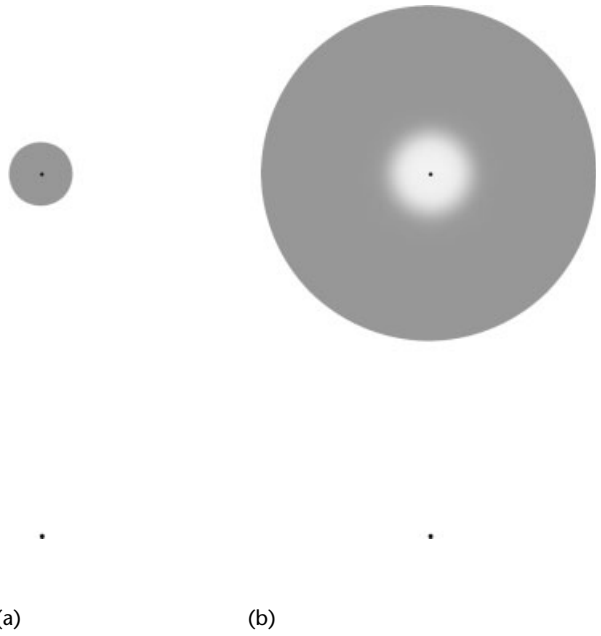

Figure 4. [*Figure is also reproduced in color section.*] There is more to color than meets the eye! Stare at the fixation dot in the middle of the green disk (a), being careful to hold your gaze steady. After 20 s or so, transfer your gaze to the fixation dot below; you should see a reddish afterimage. Now consider the small, fuzzy gray disk in the center of the colored annulus (b). After prolonged viewing the gray seems to adopt a weak reddish tinge. Such induced colors are much more striking when the colored annulus occupies the entire visual field surrounding the central gray spot. Try generating an afterimage to the gray spot. The afterimage to the gray spot is surprisingly green! This shows that the spatial configuration of a scene affects both the color of perceived images and the color of afterimages.

An object will appear colored if it selectively absorbs some wavelengths and reflects others. The spectral distribution of reflected light is a product of the absorptive properties of the object's surface and the spectral properties of the light source (the illuminant). So if the illuminant changes, the reflected light will change too. Illuminants are constantly changing. A bright sunny day, under a blue sky, will contain a large proportion of shorter wavelengths, while a tungsten light bulb will produce longer wavelengths. The paradox of color vision is that despite these different illumination conditions, and the resulting difference in reflected light, the color of objects is fairly constant. A red apple is red, for example. It is not that a red apple is red only when viewed under a certain illumination

condition such as a blue sky. This color constancy is mostly a property of our visual systems and not a function of memory.

It is easy to see why our visual systems have evolved in this way. If we were to assign a color to an object based solely on the light reflected from it then we would assign different colors to the same object depending on the conditions under which the object was viewed. Color constancy means that colors are properties of objects (which are constant) and not viewing conditions (which are continually changing).

Edwin Land, the inventor of instant photography, went to great lengths to reiterate that the color we assign an object is largely independent of the spectral content of the illuminant but is correlated with the absorption properties of the object or surface (Land, 1977). He was prompted by the familiar problem faced by color photographers: a scene photographed under tungsten light comes out with a reddish cast, and one photographed outside on a sunny day with a bluish cast. This is in contrast to our perceptions of the scene under the two illumination conditions – we see neither a reddish cast nor a bluish cast. Land concluded that our visual systems do not simply equate color and reflected wavelengths. In his experiments, Land used different light sources to illuminate different patches of a colored 'Mondrian' display, and varied the spectral content of his illuminants. He was able to show that two differently pigmented patches could be made to reflect the same spectral distribution and yet, remarkably, the patches still appeared as different colors. He also showed that an identical surface could be made to reflect a different spectral distribution and yet appear the same color.

The puzzle remained. How could the visual system achieve different color judgments for two areas if the light from the two areas were the same? Land devised the retinex algorithm, which is capable of determining illuminant-independent colors (Land, 1977). According to this algorithm, the critical determinant of the color of a surface is the chromatic context in which the surface appears. This might sound like a reiteration of what artists already knew empirically, but it went further. It provided a testable hypothesis about the visual system. It claimed that color is determined by abrupt changes in the relative cone activities across a scene. For example, retinex would identify a region as 'red' only when the long wavelength light reflected from it is surrounded by regions reflecting shorter wavelengths. Thus we would not expect to 'see' the reddish cast of a tungsten light because the cast is diffuse.

DOUBLE-OPPONENT COLOR CELLS

The cone-opponent retinal ganglion and LGN cells could subserve wavelength discrimination. However, color is not simply wavelength discrimination (see above). Rather, color is achieved through a spatial comparison of wavelengths across an image. A cell having a receptive field fed by a single cone class in a spatially opponent fashion might be the building block for such a comparison: for example, a cell excited by L cones in one part of visual space but suppressed by L cones in an adjacent part of visual space (an L-ON center/L-OFF surround cell); but despite intensive searches, no retinal ganglion cells or LGN cells like this have been found. The cone-opponent type I cells (see Figure 3) have spatially opponent receptive fields, but the centers and surrounds are fed by different cone classes, and the opponency is in the wrong direction to subserve color constancy. So where in the primate visual system is such a comparison made?

In 1968, Nigel Daw showed that some cells in goldfish retina have receptive fields that are both chromatically and spatially opponent, and therefore capable of computing simultaneous color contrast (Daw, 1968). Computational studies have shown that such 'double-opponent' cells could subserve color constancy in primates: a single double-opponent cell exceeds the requirement of a spatial comparison for one cone class: it is a spatial comparison for two cone classes. A common type of double-opponent cell, for example, is L-ON center/L-OFF surround and M-OFF center/M-ON surround.

The existence of double-opponent cells in the primary visual cortex (V1) of primates has been controversial, but there is now a consensus that they do exist (Conway, 2001; Johnson *et al*., 2001) (Figure 5). Cortical cells that show simple chromatic opponency (such as LGN type II cells) also exist, although they probably do not represent a distinct cell class but rather the end of a continuum of cone-opponent cells that show very weak surrounds.

In addition to mediating spatial color contrast, double-opponent cells may also play an important part in temporal color contrast (a red spot is redder if preceded by a green spot) because they respond to both the onset and cessation of a stimulus (Cottaris and DeValois, 1998) and show stronger responses to sequences of oppositely colored stimuli, e.g. green and then red (Conway *et al*., 2002).

Cortical cone-opponent cells represent about 10% of the total population of cells in V1. Both red–green double-opponent cells – i.e. L versus M

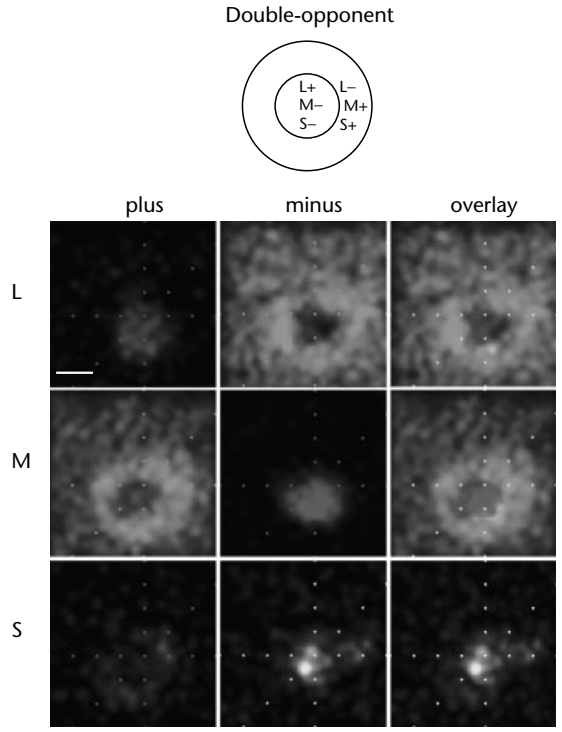

Figure 5. [*Figure is also reproduced in color section.*] The receptive field of a double-opponent cell in monkey V1. The left-hand column shows the spatial extent of the cell's response to increasing activity of the three cone classes (L, top; M, middle; S, bottom); the middle column shows the same cell's response to decreasing the activity of the three cone classes. Comparing the maps (right-hand column) shows that this cell's receptive field is both spatially and chromatically opponent. This double-opponent structure is critical to color constancy – our ability to determine an object's color despite changing illumination conditions. From Conway (2001).

– and blue–yellow double-opponent cells – i.e. S versus (L + M) – are found, and these, with a class of opponent achromatic cells, could be the sole basis for color perception despite their relative scarcity, because color perception is coarse and would require many fewer cells than (say) form perception. Perhaps not by coincidence, color in color televisions requires only about 10% of the bandwidth.

Curiously, some red–green cells appear to receive S cone input. This needs to be studied further. It also remains to be shown how double-opponent cells are constructed from the LGN inputs and why there are more red–green double-opponent cells than blue–yellow ones.

Double-opponent cells reside in the cortex in clusters; moreover, these clusters are coarsely localized in metabolically distinct regions of cortex called 'blobs' (Figure 3, bottom right) (Livingstone and Hubel, 1984). Blobs are easily identified in primate visual cortex by staining with the metabolic enzyme cytochrome oxidase. Why double-opponent cells are localized to the cytochrome oxidase blobs remains a mystery – perhaps these cells require more energy and therefore express higher levels of this metabolic enzyme. Surprisingly, other animals with poor color vision have cytochrome oxidase blobs (although the blobs in some of these mammals, such as cats, are not as prominent). Thus, it may be that the blobs represent regions of cortex dedicated to a more generic function, like parsing surfaces, of which color is only one component.

Nevertheless, the segregation of color cells in the LGN (in the parvocellular and koniocellular layers) and in the primary visual cortex (in the cytochrome oxidase blobs) shows that color is largely processed separately from other visual attributes. This segregation of color processing is evident perceptually (see below) and was used to advantage by Matisse (see Figure 1).

COLOR IS PROCESSED SEPARATELY FROM FORM AND MOTION

Color signals carried by the blobs of V1 are relayed to V2 and then to higher visual areas. Like V1, V2 displays an interesting pattern of staining for the enzyme cytochrome oxidase; unlike V1, the staining consists of alternating thick and thin stripes separated by interstripes (see Figure 3). Cells residing in the blobs of V1 send their axons to the thin stripes of V2 (Livingstone and Hubel, 1984). Not surprisingly, cells in the thin stripes are more likely to be color selective than cells in the thick stripes. The color cells in the V2 thin stripes respond best to colored spots, but they do so over a larger area of visual space. They are not responsive to a large field of color that encompasses the entire region over which small spots are effective. Such 'complex' color cells may be useful in identifying color boundaries present anywhere within a large area.

Color signals carried by cells in V1 and V2 are relayed to subsequent areas where, presumably, color percepts are elaborated. The V2 thin stripes project to V4; the V2 thick stripes, on the other hand, project to the middle temporal area, an area specialized for analyzing motion. Many V4 neurons respond better to some wavelengths than to others (Zeki, 1983), suggesting they are involved in color vision. Their receptive fields are much larger than the receptive fields of V1 cells, suggesting they are involved in elaborating color constancy.

Extrastriate visual areas are better described in the macaque monkey than in the human, but it becomes difficult to compare the areas of humans and monkeys the further the areas are from V1. In humans, for example, an area (V8) situated in the inferotemporal cortex is specialized for computing color (Hadjikhani *et al.*, 1998); it is debated if monkeys have a homolog of this area. Perhaps V4 is the monkey equivalent of human V8. Neurons in V4 are color biased (Zeki, 1980) but they are also selective for other attributes of a stimulus, such as the stimulus orientation (Schein and Desimone, 1990), suggesting that V4 is not simply a color area. To complicate the matter further, unlike lesions of V8 in humans, partial lesions of V4 in monkeys have little effect on tasks requiring color vision. Perhaps V4 is involved in piecing together form and color information; conversely, V4 may actually be a complex of areas, one devoted to form processing and another to color processing. The increasing resolution of functional magnetic resolution imaging may soon make it possible to address these issues.

Certain people who have damage to V8 following a stroke show a profound loss of color perception. Remarkably, this acquired achromatopsia does not interfere with their perception of form and motion – further suggesting that color is processed separately from other visual attributes. Oliver Sacks described one such stroke patient who was an artist (Sacks, 1995). After the patient had lost his color vision, he made peculiar color choices in his paintings; but he was still able to represent luminance and shape, because the areas of his brain dedicated to processing those aspects of the visual world were unaffected by the stroke. Moreover, he had no loss of motion perception.

CONCLUSION

An observer would say that the color and the shape of an object are inextricably linked. If color and form are processed separately by the cortex, how do they then become bound? How would this binding be manifest in the brain? The binding might simply be found in the correlated activity of the two pathways: an orange ball would produce separate sensations of 'round' in the form pathway and 'orange' in the color pathway, but the sensations would be elicited simultaneously. The reliability of the simultaneous activation of the two pathways, possibly reinforced by neural connections joining separate areas, could be enough to bind the 'round' ball with its 'orange' color. But how to test this hypothesis, or any hypothesis for binding for that matter, is challenging.

Parallel processing is an efficient means of computing information because it is fast: multiple aspects of a scene can be processed simultaneously. Although many lines of evidence support a parallel processing model for visual perception (Livingstone and Hubel, 1988), some anatomical and physiological studies show that the visual system does not operate according to such a simple model. There are cells in the superficial layers of V1 (not confined to blobs) that are both selective for stimulus orientation and also more responsive to some wavelengths than others. What contribution do such 'oriented color' cells make to color perception? What are the LGN inputs to red–green double-opponent cells? Do the same LGN cells provide input to sharply orientation-tuned cells? How is the activity of the three chromatic axes in V1 integrated to bring about the perception of specific hues, and how is hue then bound with form? Perhaps most compelling, how do colors bring about emotional responses? These and many more questions will keep the field of color vision research alive for many years to come.

CONTENTS

Computational neuroscience involves the construction of explicit computational models that implement neural mechanisms to simulate cognitive functions such as perception, learning and memory, motor function, and language.

INTRODUCTION

This article describes computer models that simulate the neural networks of the brain, with the goal of understanding how cognitive functions (perception, memory, thinking, language, etc.) arise from their neural basis. Many neural network models have been developed over the years, focused at many different levels of analysis, from engineering, to low-level biology, to cognition. Here, we consider models that try to bridge the gap between biology and cognition. Such models deal with real cognitive data, using mechanisms that are related to the underlying biology.

THE RELATIONSHIP BETWEEN COGNITIVE AND NEURAL THEORIES

Computational models provide an important tool for linking data across multiple levels of analysis. The cognitive implications of cellular and network properties of neurons are often not immediately apparent: there are too many factors at many different levels interacting in complex ways. Trying to develop behavioral predictions that capture the complexity of the neural level can be like trying to predict the weather from a number of satellite measurements. A computational model, of the weather or of the brain, can help by formalizing information and relating it through complex, emergent dynamics. Cognitive properties can thus be understood as the product of a number of lower-level interactions, and neural properties can be understood in terms of their functional role in cognitive processes. Further, the effects of manipulations of lower-level interactions (e.g. through genetic knockouts or lesions) can be simulated and reconciled with the observed behavioral effects. Importantly, these simulations can make sense of much more subtle behavioral effects than the generic impairment of behavior on a cognitive task.

Although models thus have the potential to clarify brain–behavior relations, they do not always do so. Models can be underconstrained by neural and behavioral data, and thus be of questionable value in showing how the brain actually subserves behavior. Moreover, models may be devised merely as demonstrations that a behavior can be simulated, but this is insufficient for understanding why the models behave as they do. Thus, models must be evaluated in a balanced way for whether they advance understanding of specific phenomena, provide general principles, and make useful links between brain and behavior.

This article reviews a number of neuroscience-based computational models of various cognitive phenomena, with an emphasis on the general principles embodied by these models and their implications for understanding the general nature of cognition. Specifically, we examine models of: vision, including topography and receptive fields

in primary visual cortex and spatial attention emerging from interactions between parietal and temporal streams of processing; episodic memory subserved by the hippocampus; conditioning and skill learning subserved by the basal ganglia and cerebellum; working memory and cognitive control subserved by the prefrontal cortex; and language processing guided by neuropsychological cases. For a more comprehensive treatment of many of these models and the ideas behind them, see O'Reilly and Munakata (2000).

COMPUTATIONAL MODELS OF VISION GUIDED BY NEUROSCIENCE

Vision is one of the best-studied domains in cognitive neuroscience, having a long tradition of integrating biological and psychophysical levels of analysis. Computational models of vision have been influential in both the vision and computational research communities. We review two areas of visual modeling here: topography and receptive fields in primary visual cortex; and spatial attention and the effects of parietal lobe damage. Other major areas of visual processing that have been modeled include object recognition, motion processing, and figure–ground segmentation.

Topography and Receptive Fields in Primary Visual Cortex

The primary visual cortex (V1) provides an interesting target for computational models, because it has a complex but relatively well-understood organization of visual feature detectors (a 'representational structure') subject to considerable experience-based developmental plasticity (Hubel and Wiesel, 1962; Gilbert, 1996). Thus, the major question behind many of the V1 models has been: can we reproduce the complex representational structure of V1 through principled learning mechanisms exposed to realistic visual inputs?

First, we summarize the complex representational structure of V1. V1 neurons are generally described as edge detectors, where an edge is simply a roughly linear separation between regions of relative light and dark. These detectors differ in their orientation, size, position, and *polarity* (i.e. whether they detect transitions from light to dark or dark to light, or dark–light–dark or light–dark–light). The different types of edge detectors (together with other neurons that appear to encode visual surface properties) are packed into the two-dimensional sheet of the visual cortex according to a particular topographic organization. The large-scale organization is a 'retinotopic map', which preserves the topography of the retinal image in the cortical sheet. At the smaller scale are 'hypercolumns' (see Figure 1), containing smoothly varying progressions of oriented edge detectors, among other things (Livingstone and Hubel, 1988). The hypercolumn also contains 'ocular dominance columns', in which V1 neurons respond preferentially to input from one eye or the other.

Many computational models have emphasized only one or a few aspects of the many detailed properties of V1 representations; for reviews, see Swindale (1996) and Erwin *et al*. (1995). For example, models have demonstrated how ocular dominance columns can develop based on a Hebbian learning mechanism, with greater local correlations in the neural firing coming from within one eye than from across eyes (Miller *et al*., 1989). Hebbian learning encodes correlational structure by strengthening the weights between neurons that fire together, and decreasing the weights between those that do not. (See Oja (1982) and Linsker (1988) for mathematical analyses of Hebbian correlational learning.)

Several models have demonstrated how a realistic set of oriented edge-detector representations can develop in networks presented with natural visual scenes, preprocessed in a manner consistent with the contrast-enhancement properties of the retina (e.g. Olshausen and Field, 1996; Bell and Sejnowski, 1997; van Hateren and van der Schaaff, 1997; O'Reilly and Munakata, 2000). The Olshausen and Field (1996) model demonstrated that sparse

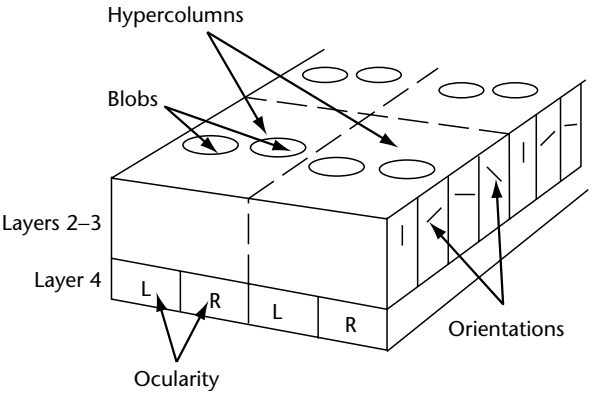

Figure 1. Structure of a cortical hypercolumn, representing a full range of orientations (in layers 2–3), ocular dominance columns (in layer 4, one for each eye), and surface features (in the blobs). Each such hypercolumn is focused within one region of retinal space, and neighboring hypercolumns represent neighboring regions.

representations (with relatively few active neurons) provide a useful basis for encoding real-world (visual) environments, but this model was not based on known biological principles. Subsequent work has shown how biologically-based models can develop oriented receptive fields, through a Hebbian learning mechanism with sparseness constraints in the form of inhibitory competition between neurons (a known property of cortex) (O'Reilly and Munakata, 2000). Furthermore, lateral excitatory connections within this network (another known property of cortex) produced a topographic organization consistent with several aspects of the hypercolumn structure (e.g. gradients of orientation, size, polarity, and phase tuning and pinwheel discontinuities: see Figure 2).

To summarize, these V1 models demonstrate how Hebbian learning mechanisms exposed to naturalistic stimuli, with certain kinds of biological prestructuring (e.g. connectivity patterns and inhibition), can produce aspects of the observed representational structure of V1. However, many complex aspects of early visual processing remain to be addressed, including motion, texture, and color sensitivity of different populations of V1 neurons.

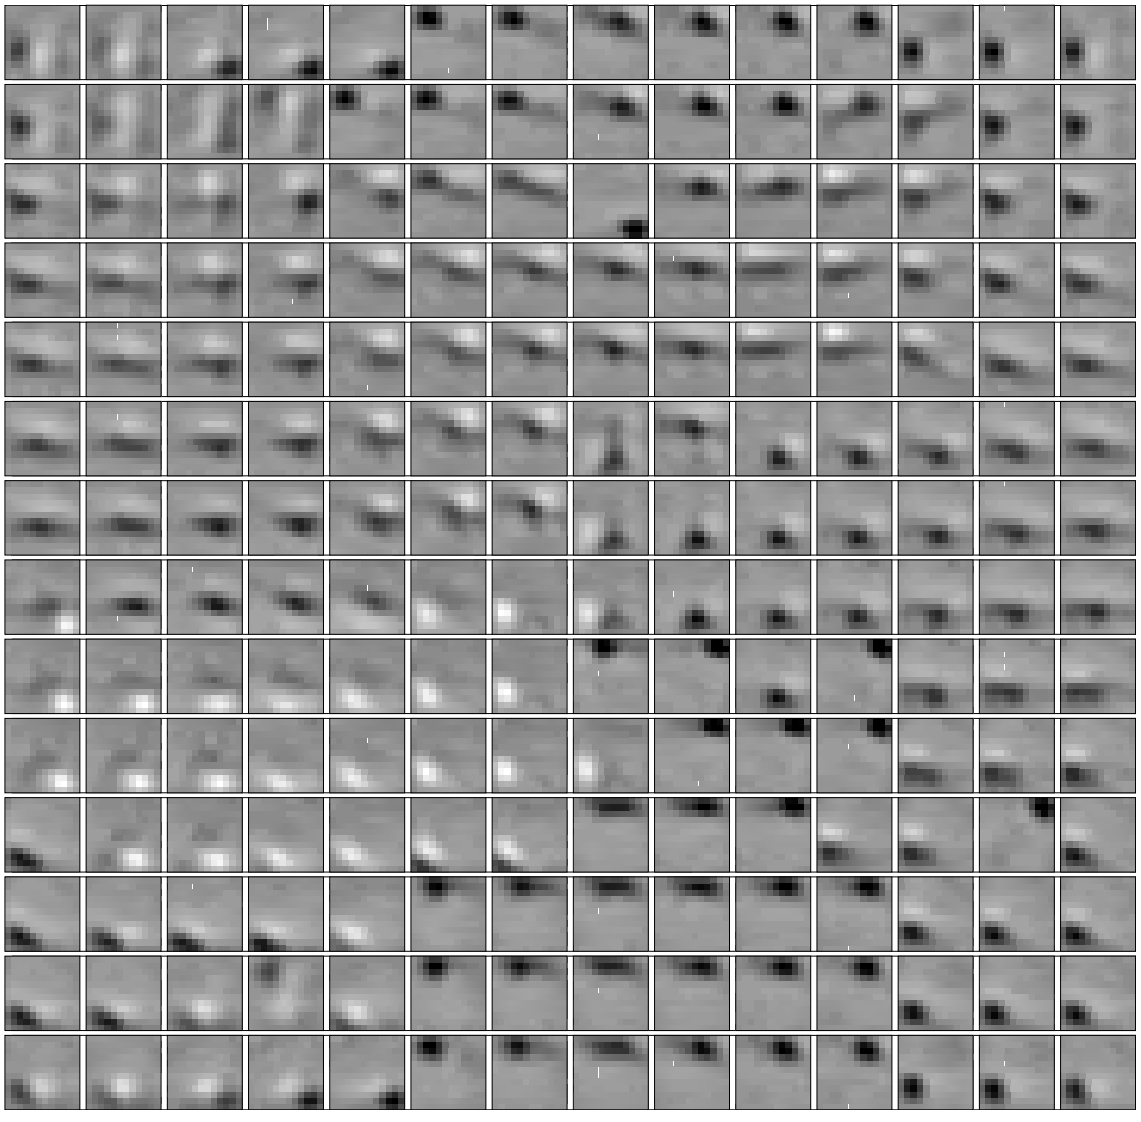

Figure 2. The receptive fields of model V1 neurons (O'Reilly and Munakata, 2000). Lighter shades indicate areas of on-center response, and darker shades indicate areas of off-center response. Individual units are shown by smaller grids (showing weights into those units from different locations in the retinally-organized input). These are organized into a larger grid representing the location of each unit within the simulated V1 hypercolumn.

Spatial Attention and the Effects of Parietal Lobe Damage

Many computational models of higher-level vision have explored object recognition (e.g. Mozer, 1991; Fukushima, 1988; LeCun *et al*., 1989) and spatial processing (e.g. Pouget and Sejnowski, 1997; Mozer and Sitton, 1998; Vecera and O'Reilly, 1998). Here we describe a model of spatial attention (Cohen *et al*., 1994) that demonstrates how biologically-based computational models can provide alternative interpretations of cognitive phenomena. Spatial attention has traditionally been operationalized according to the Posner spatial cuing task (Posner *et al*., 1984: see Figure 3). When attention is drawn, or cued, to one region of space, participants are faster to detect a target in that region (a validly cued trial) than a target elsewhere (an invalidly cued trial). Patients with damage to the parietal lobe have particular difficulty with invalidly cued trials.

According to the standard account of these data, spatial attention involves a 'disengage' module associated with the parietal lobe (Posner *et al*., 1984). This module typically allows one to disengage from an attended location to attend elsewhere. This process of disengaging takes time; hence the slower detection of targets in unattended locations. Further, the disengage module is impaired with parietal damage, so that patients have difficulty disengaging from attention drawn to one side of the space.

Biologically-based computational models, based on recurrent excitatory connections and competitive inhibitory connections, provide an alternative explanation for these phenomena (Cohen *et al*., 1994; O'Reilly and Munakata, 2000). In this framework, the facilitative effects of drawing attention to one region of space result from excitatory connections between spatial and other representations of that region: this excitatory support makes it easier to process information in that region. The slowing observed in the invalid trials results from inhibitory competition between different spatial regions. Under this model, damage to the parietal lobe simply impairs the ability of the corresponding region in space to have sufficient excitatory support to compete effectively with other regions.

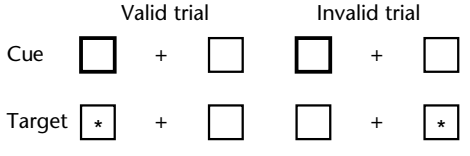

Figure 3. The Posner spatial attention task. The cue is a brightening or highlighting of one of the boxes, which focuses attention on that region of space. Reaction times to detect the target are faster when this cue is valid (the target appears in that region) than when it is invalid (the target appears elsewhere).

The two models make distinct predictions (Cohen *et al*., 1994; O'Reilly and Munakata, 2000). For example, following bilateral parietal damage, the disengage model predicts disengage deficits on both sides of space (Posner *et al*., 1984), but the competitive inhibition model predicts reduced attentional effects (smaller valid and invalid trial effects). Data support the latter model (Coslett and Saffran, 1991; Verfaellie *et al*., 1990), demonstrating the utility of biologically-based computational models for alternative theories of cognitive phenomena.

COMPUTATIONAL MODELS OF EPISODIC MEMORY AND THE HIPPOCAMPUS

Damage to the hippocampus, in the medial temporal lobe, can produce severe memory deficits, while leaving unimpaired certain kinds of learning and memory (Scoville and Milner, 1957; Squire, 1992). Many computational models have been developed to explore the exact contribution of the hippocampus, and these models have had a major influence (e.g., Marr, 1971; Treves and Rolls, 1994; Hasselmo and Wyble, 1997; Moll and Miikkulainen, 1997; Alvarez and Squire, 1994; Levy, 1989; Burgess *et al*., 1994; Samsonovich and McNaughton, 1997).

One framework has combined known biological features of the hippocampal formation with computationally motivated principles about learning and memory to further clarify the unique contributions of the hippocampus in memory (McClelland *et al*., 1995; O'Reilly and Rudy, 2000, 2001; O'Reilly and McClelland, 1994; O'Reilly *et al*., 1998). The central idea is that there are two basic types of learning that an organism must engage in – learning about specifics and learning about generalities – and that because the computational mechanisms for achieving these types of learning are in direct conflict, the brain has evolved two separate brain structures to achieve them. The hippocampus appears to be specialized for learning about specifics, while the neocortex is good at extracting generalities.

Learning about specifics requires keeping representations separated (to avoid interference), whereas learning about generalities requires overlapping representations that encode shared

structure across many different experiences. Furthermore, learning about generalities requires a slow learning rate to gradually integrate new information with existing knowledge, while learning about specifics can occur rapidly. This rapid learning is particularly important for episodic memory, where the goal is to encode the details of specific events as they unfold.

These computational principles provide a satisfying and precise characterization of the division of labor between the hippocampus and the neocortex. The models that implement these principles have been shown to account for a wide range of specific learning and memory findings, including nonlinear discrimination, incidental conjunctive encoding, fear conditioning, and transitive inference in rats (O'Reilly and Rudy, 2001) and human recognition memory (O'Reilly *et al*., 1998). However, these models fail to incorporate important aspects of the hippocampal formation (e.g. the subiculum and the mossy cells in the hilus), and many more complex behaviors that depend on the hippocampus (and its interactions with other brain areas) remain to be addressed.

COMPUTATIONAL MODELS OF CONDITIONING AND SKILL LEARNING IN THE BASAL GANGLIA AND CEREBELLUM

A convergence between biological, behavioral and computational approaches has been achieved in the domain of conditioning (learning to associate stimuli and actions with rewards). In the computational domain, reinforcement learning mechanisms can change the behavior of a simulated animal according to reward contingencies in the environment (Sutton and Barto, 1998). Such learning mechanisms, including the 'temporal differences' algorithm (Sutton, 1988), not only work well mathematically (e.g. Dayan, 1992), but also correspond with aspects of neural recordings made in the reward-processing area of the brain (Montague *et al*., 1996; Schultz *et al*., 1997).

Specifically, a straightforward neural implementation of the temporal differences algorithm involves a systematic transition of reward-related neural firing similar to that observed in dopamine neurons in the midbrain. During a simple conditioning task where a sensory stimulus (e.g. a tone) reliably predicts a subsequent reward (e.g. orange juice), these neurons initially fire in response to the reward, but then after some trials of learning they respond to the sensory stimulus that predicts the reward and no longer to the reward itself (Schultz *et al*., 1993; Schultz *et al*., 1995). This transfer of reward-related firing from the actual reward to predictors of the reward is an essential property of the temporal differences mechanism as implemented by Montague *et al*. (1996), which thus provides a principled, provably effective explanation for why the brain appears to learn in this manner.

Models of motor performance and skill learning have been developed based on the biological properties of the relevant underlying brain areas, including the basal ganglia (which includes the striatum, globus pallidus, substantia nigra, subthalamic nucleus, and nucleus accumbens) and the cerebellum (e.g. Beiser *et al*., 1997; Wickens, 1997; Houk *et al*., 1995; Berns and Sejnowski, 1996; Schweighofer *et al*., 1998a, b; Contreras-Vidal *et al*., 1997). These models accord well with detailed neural properties of these areas, but tend to focus on simpler aspects of motor performance: complex motor skills remain to be addressed.

COMPUTATIONAL MODELS OF WORKING MEMORY, COGNITIVE CONTROL, AND PREFRONTAL CORTEX

The prefrontal cortex is important for a range of cognitive functions, which can be described generally as higher level cognition, in that they go beyond basic perceptual, motor, and memory functions. For example, frontal cortex has been implicated in problem-solving tasks like the Tower of Hanoi (e.g. Shallice, 1982; Baker *et al*., 1996; Goel and Grafman, 1995), which requires executing a sequence of moves to achieve a subsequent goal. Many theoretical perspectives summarize the function of frontal cortex in terms of 'executive control', 'controlled processing', or a 'central executive' (e.g. Baddeley, 1986; Shallice, 1982; Gathercole, 1994; Shiffrin and Schneider, 1977), without explaining at a mechanistic level how such functionality could be achieved. Computational models provide an important tool for exploring specific mechanisms that might achieve 'executive-like' functionality.

Working Memory and Active Maintenance

One proposal is that the fundamental mechanism underlying frontal function is 'active maintenance', which then enables all the other 'executive' functionality ascribed to the frontal cortex (Cohen *et al*., 1996; Goldman-Rakic, 1987; Munakata, 1998;

O'Reilly *et al*., 1999; O'Reilly and Munakata, 2000; Roberts and Pennington, 1996). For example, a flexible, adaptive, active maintenance system can meet information processing challenges by using the strategic activation and deactivation of representations (activation-based processing) instead of weight changes (weight-based processing) (O'Reilly and Munakata, 2000). There are tradeoffs between these types of processing (e.g. activations can be more rapidly switched than weights, but they are also transient); so using both kinds of processing is better than using either alone.

There is considerable direct biological evidence that the frontal cortex subserves the active maintenance of information over time, as encoded in the persistent firing of frontal neurons (e.g. Fuster, 1989; Goldman-Rakic, 1987; Miller *et al*., 1996). Many computational models of this basic active maintenance function have been developed (Braver *et al*., 1995; Dehaene and Changeux, 1989; Zipser *et al*., 1993; Seung, 1998; Durstewitz *et al*., 2000; Camperi and Wang, 1997). Some models have further demonstrated that active maintenance can account for frontal involvement in a range of different tasks that might otherwise appear to have nothing to do with maintaining information over time.

Inhibition, Flexibility, and Perseveration

For example, several models have demonstrated that frontal contributions to 'inhibitory' tasks can be explained in terms of active maintenance instead of an explicit inhibitory function. Actively maintained representations can support (via bidirectional excitatory connectivity) correct choices, which will therefore indirectly inhibit incorrect ones via standard lateral inhibition mechanisms within the cortex. A model of the Stroop task provided an early demonstration of this point (Cohen *et al*., 1990). In this task, color words (e.g. 'red') are presented in different colors, and people are instructed to either read the word or name the color in which the word is written. In the conflict condition, the ink color and the word are different. Because we have so much experience of reading, we naturally tend to read the word, even if instructed to name the color, so that responses are slower and more error-prone in the color-naming conflict condition than in the word-reading one. These color-naming problems are selectively magnified with frontal damage. This frontal deficit has usually been interpreted in terms of the frontal cortex helping to inhibit the dominant word-reading pathway. However, Cohen *et al*. (1990) showed that they could account for both normal and frontal-damage data by assuming that the frontal cortex instead supports the color-naming pathway, which then collaterally inhibits the word-reading pathway. Similar models have demonstrated that, in infants, the ability to inhibit perseverative reaching (searching for a hidden toy at a previous hiding location rather than at its current location) can develop simply through increasing ability to actively maintain a representation of the correct hiding location (Dehaene and Changeux, 1989; Munakata, 1998). Again, such findings challenge the standard interpretation that inhibitory abilities *per se* must develop for improved performance on this task (Diamond, 1991).

The activation-based processing model of frontal function can also explain why frontal cortex facilitates rapid switching between different categorization rules in the Wisconsin card sorting task and related tasks. In these tasks, subjects learn to categorize stimuli according to one rule via feedback from the experimenter, and then the rule is changed. With frontal damage, patients tend to perseverate in using the previous rule. A computational model of a related intradimensional/extradimensional (ID/ED) categorization task demonstrated that the ability to rapidly update active memories in frontal cortex can account for detailed patterns of data in monkeys with frontal damage (O'Reilly *et al*., 2002; O'Reilly and Munakata, 2000).

Computational models of frontal function can provide mechanistic explanations that unify the various roles of the frontal cortex, from working memory to cognitive control and planning and problem-solving. However, it remains to be shown whether complex 'intelligent' behavior can be captured using these basic mechanisms.

COMPUTATIONAL MODELS OF LANGUAGE USE GUIDED BY NEUROPSYCHOLOGICAL CASES

Damage to language-related brain areas causes a wide variety of impairments. One class of such impairments, the dyslexias (also known as alexias), have been the subject of a series of influential computational models of the normal and impaired reading process (Seidenberg and McClelland, 1989; Plaut and Shallice, 1993; Plaut *et al*., 1996). These models simulate the pathways between visual word inputs (orthography), word semantics, and verbal word outputs (phonology), and can account for different kinds of dyslexias in terms of differential patterns of damage to these pathways.

These models have been influential in part because they suggest an alternative, somewhat

counterintuitive, interpretation of how words are represented and how language processing works. Traditional models have assumed that the brain contains a 'lexicon', with distinct representations for different words. Furthermore, these models assume that reading a word aloud (i.e., mapping from orthography to phonology) can occur via two different routes: pronunciation rules (for 'regular' words like 'make'), or a mechanism like a lookup table (for 'exception' words like 'yacht') (Pinker, 1991; Coltheart *et al*., 1993; Coltheart and Rastle, 1994). In contrast to these dual-route models, the neural network models posit a single pathway to process both regular and exception words, and they employ a distributed lexicon without centralized, discrete lexical representations. Lexical processing occurs in pathways that map between different aspects of word representations (see Figure 4).

In general, neural networks can learn all kinds of different mappings: fully regular ones, like the spelling-to-sound mapping of the 'a' in words like 'make' and 'bake', as well as irregular mappings that occur in words like 'yacht'. Nevertheless, networks are sensitive to both the degree of regularity and the frequencies of different mappings. Specifically, neural network models predict frequency-by-regularity interactions that would not be expected in dual-route models, and which are observed in behavioral tests (Plaut *et al*., 1996). Furthermore, these network models can account for patterns of deficit with brain damage that would seem improbable under dual-route models. For example, people with surface dyslexia can read non-words (e.g. 'nust'), but they are impaired at retrieving semantic information from written words, and have difficulty in reading exception words. It would be natural in neural network models to interpret this as damage in the pathway between orthography and semantics. Interestingly, surface dyslexics' difficulty with exception words is generally limited to low-frequency exceptions (e.g. 'yacht'); they do not have difficulty reading high-frequency exceptions (e.g. 'are'). This pattern suggests that the remaining 'direct' pathway between orthography and phonology can handle both regular words and high-frequency exceptions, as in the network models. This pattern of data is not easily explained by the dual-route models: with two pathways, either regular words or exceptions should be affected, but not both, and independently of frequency.

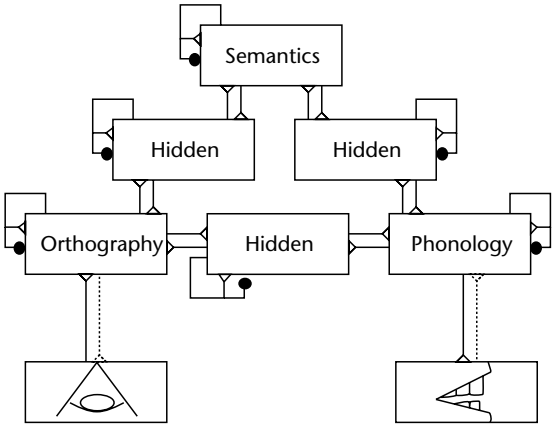

Figure 4. A neural network model of reading aloud. Words are represented in a distributed fashion across orthographic (visual word recognition), phonological (speech output), and semantic areas.

Neural network models of language can provide alternative, counterintuitive ways of explaining some of the complex patterns of deficits that occur with brain damage. Nevertheless, such models remain controversial: neural network accounts are challenged by revised versions of dual-route models, and by the complexity of different neuropsychological profiles associated with damage to different language areas.

CONCLUSION

Computational models based on the neural networks of the brain can provide important insights. Many models have applied a set of basic principles to a range of phenomena, and arrived at explanations completely different from those based on purely verbal cognitive theories. Hence, these models have played an important role in guiding empirical research and theorizing in a number of domains.

Despite these successes, many researchers remain skeptical of models. A common concern is that different models may employ different sets of mechanisms to explain the same data, so that it may not be very significant that a given model can simulate a set of data. Several points have been made in response to this concern.

Firstly, it applies not only to computational models, but to scientific theorizing in general (several theories can account for the same data). Competing theories and models can be evaluated by many other criteria than simply accounting for a set of data, such as the accuracy of their predictions, the coherence of their theoretical framework, and the ease of accounting for new data (Munakata and Stedron, 2002).

Secondly, mechanisms developed independently can turn out to be equivalent (e.g. O'Reilly, 1996), providing converging evidence for their utility, and indicating more coherence to principles than might otherwise be evident.

Thirdly, a common set of mechanisms appears to be emerging as the field continues to mature. For example, over 40 different phenomena (including most of what has been described above) have been modeled using a common set of mechanisms (O'Reilly and Munakata, 2000). This set of mechanisms was developed over many years by many different researchers, and has now been consolidated and integrated into one coherent framework (O'Reilly, 1998).

Therefore, there is a largely consistent set of ideas underlying many neural network models, and this framework provides an important way of understanding the connections between cognition and underlying neural systems.

Consciousness, Disorders of

Introductory article

Fred Plum, Weill Medical College of Cornell University, New York, USA
Nicholas D Schiff, Weill Medical College of Cornell University, New York, USA

CONTENTS

Disorders of consciousness include coma, stupor, confusion and other abnormal states of acute brief or moderately sustained unconsciousness.

INTRODUCTION

The brain generates the mind, and the healthy, wakeful mind formulates consciousness. The American psychologist William James in 1890 stated, 'Consciousness is the [indispensable] fundamental awareness of the self's internal ego.' He then expanded that self-centered focus to identify the self's greater qualities of memory, attention, intention, chronological time, emotion, learned behavior, and several other less general psychological qualities. At that early time, only philosophical thinking interpreted gross anatomic knowledge in trying to understand how the awake brain might lose conscious functions.

Modern neurological medicine has defined several distinct behavioral pathological states that arise from inherited and acquired brain injuries and lead to disorders of consciousness. Brain injuries that reflect global disorders of consciousness include stupor and coma, the vegetative state, akinetic mutism, absence and partial complex seizures, delirium, and severe dementia. These global disorders, described below, totally disable the capacity of the individual for intentional behaviors. Though different in pattern, 'focal' disorders of consciousness can exist in several serious illnesses. A patient suffering a focal disorder of consciousness can be awake and interact with the environment, and yet exhibit severe alterations in awareness. These disorders uniquely illustrate the constructed nature of conscious experience.

THE FORMULATION OF CONSCIOUSNESS

All people with a healthy brain and body can recognize themselves, their thoughts and their intentional conscious activity. Descriptions may vary in detail, but ask people what they think about the quality called their consciousness and the first reply is likely to be, 'I'm awake and I'm here'. Proof often follows with (for example) 'I'm John Smith!'

An educated person recognizes conscious awareness as a continuously unfolding, automatic sense of being awake, alive, and logically thoughtful. Actually, one's mind is being continuously filled with flowing thoughts, normal language, recent memories, learned motor behavior, or novel discoveries. Even the most educated person, however, sometimes wonders about how the brain automatically experiences normal emotions, how it generates logical thinking, and how it induces the smooth flow of relevant or original thoughts and coordinated deeds.

'Now, how did I come to think about that?' is an often-expressed question, but usually not one that is part of everyday conversation. Nor do we wonder what preceding activities our brain generates when we automatically take our daily walk down the same lane. Even when we 'instinctively' jump out of the way of an unseen, oncoming vehicle, we often fail to realize that our awake, preconscious frontal lobe thought and acted first. Only after we have jumped away from the danger do we become aware of our act and experience an emotional feeling of fright. This example illustrates how we often act or even speak before we consciously think.

The normal brain's cognitive processing systems organize intentional behaviors drawing on a rapidly accessed, vast store of relevant memories. It preconsciously formulates either incoming or spontaneous information in less than a quarter of a second. It is astonishing to realize that the functions of memory, intention, and perception may largely occur before any act or expressed thoughts enter immediate conscious awareness. We may

think it strange that when we hold a conversation, our mind has preconsciously formulated what we are going to say a half-second or more before we actually say it. The Nobel laureate in medicine, Gerald Edelman, recognized this normal, instinctive preconscious formulation of thoughts, words and athletic acts in the ingenious title of his book, *The Remembered Present, A Biological Theory of Consciousness*.

Neuropsychological Dimensions of Consciousness

Consciousness is a time-ordered, egocentric process that interweaves inner and outer perceptions, stored memories, and immediately innovative thoughts. Emotional feelings imbue conscious awareness and sharpen intentional actions. Memory provides not only the ultimate storehouse of explicit conscious knowledge; it also develops the preconscious, implicit brain learning of motor skills and physical practice. Memory qualities and quantities depend on the combination of our innate cognitive talents, our subsequent schooling, our continuously thoughtful appraisal of new objects, and our interpersonal learning from and about people. The goal can be athletic, intellectual, or both. All evidence indicates that the earlier the young begin to learn and continue lifelong studies, the greater will be their future mental and behavioral capacities. Indeed, the longer a person's education and thought-requiring occupation last, the greater the brain's and body's functional longevity.

How this serially time-ordered, organized process of consciousness incorporates outer information with inner attention and immediate evaluation is the subject of intense neuroscientific investigation. Several distinct neuropsychological qualities can be ascribed to distributed networks of brain regions that selectively contribute to organized, wakeful human consciousness. These networks include the brainstem and allied arousal systems which control the sleep–wake cycles of the entire forebrain; prefrontal cortical regions (e.g. anterior cingulate cortex, frontal eye fields) which support continuous attention to self and environment and immediate intention; and posterior cortical regions of the temporal lobes (superior temporal gyrus) and parietal lobes (inferior parietal cortex) which support self-sensory perceptions and instinctive, and automatic awareness of inner and outer spatial relationships. Memory systems of the brain are widely distributed and depend on the integrity of the medial temporal lobe (hippocampus, entorhinal cortex) for initial storage, and on multiple cortical association areas (frontal, parietal, temporal, and occipital) and parts of the thalamus for functions of both storage and retrieval.

Additional neuropsychological qualities include the mind's chronological ordering of events (of unknown localization but disordered by injuries to the thalamus), moods and emotions (contributed by distributed regions of the 'limbic' brain). Learnt symbolic abstractions of verbal (left hemisphere), musical (right hemisphere), and geometric languages (left posterior parietal regions) contribute to humans' singular qualities of normal awareness.

SPECIFIC DISORDERS OF CONSCIOUSNESS

Coma

Coma is a totally unconscious and unarousable brain state resembling sleep, in which the eyes are closed and which lasts 24 h or more, due to any of several major causes. One is the use of sustained therapeutic anesthesia. More frequent causes are direct brain injury or diseases affecting the brain's cerebral hemispheres and arousal systems. Table 1 compares the loss of neuropsychologic

Table 1. Global disorders of consciousness

	Coma	*PVS*	*ASZ*	*AKM*	*HKM*	*CPS*	*DEL*
Arousal	−	+	+	+	+	+	+
Attention	−	−	−	+	+/−	+/−	+/−
Intention	−	−	−	−	+	+/−	+/−
Memory	−	−	−	−	−	−	+/−
Awareness	−	−	−	−/?	+/−	+/−	+/−

AKM, akinetic mutism; ASZ, absence seizures; CPS, complex partial seizures; DEL, delirium; HKM, hyperkinetic mutism; PVS, persistent vegetative state; −, absent; + present (in crude form for attention, AKM, and intention, HKM), +/− incompletely expressed; −/? apparently absent.

components incurred in coma with those of other disorders of consciousness.

Stupor

Stupor is a condition of deep sleep or behaviorally similar unresponsiveness from which the person cannot be aroused except by vigorous and repeated exogenous stimulation. As soon as such stimulation ceases, the person relapses into the unresponsive state. Light stupor is typical in cases of overdoses of soporific drugs or alcohol. Deep stupor more frequently reflects severe pharmacological, metabolic, or traumatic injury to the brain. The term 'semi-coma' is occasionally used in nonmedical writing to describe patients in stupor or persistent vegetative state but is not considered a diagnostic category.

Persistent Vegetative State

The vegetative state is a condition in which physiologically active, systemic organs continue to sustain the life of a body that has become at least temporarily devoid of a conscious brain. In most cases of coma, wakefulness will return spontaneously in a matter of days or weeks; but in some people, despite a wakeful appearance, the mind may be absent for many weeks, months or forever. This tragedy has been named the *persistent vegetative state* (PVS). Such patients express irregularly timed sleep–wake patterns, but all feeding and bodily care must be provided by external sources. The term 'arbitrarily' identifies patients who remain psychologically unconscious for at least a month. They are alive, but totally unaware of self or their environment. The vegetative state presents the fundamental clinical dissociation of arousal from all other components of consciousness (Table 1).

The clinical judgment of unconsciousness in PVS has been supported by the results of positron emission tomography (PET) scan studies that reveal overall cerebral metabolism to be reduced by 50% or more below the normal rate. The observed metabolic levels are equivalent to those found in persons undergoing deep surgical anesthesia. In a study of behavioral and physiological variations in a few patients in the vegetative state, one woman randomly expressed occasional single, understandable words. Her PET studies revealed isolated islands of left frontotemporal cerebral structures that operated at an abnormally low metabolic rate but at nearly twice the rates of the remaining brain. Similar isolated expressions have been encountered in several other vegetative patients. Typically, the patients express easily identifiable, stereotypical, emotional-limbic responses. These emotional expressions probably reflect distinct and isolated limbic mechanisms; their preservation is likely to depend on integrative brainstem structures that lie outside the corticothalamic systems that typically undergo overwhelming injury in PVS patients.

Syncope

Syncope (fainting) consists of brief unconsciousness caused by reduction of systolic arterial blood flow through the brain. Most syncope is benign and occurs in persons younger than 50 years. Termed 'vasogenic', it reflects sudden dilation of the body's cholinergic and sympathetic neurovascular systems, reduces systemic blood pressure and deprives the erect brain's critical oxygen supply. A second type is less frequent and affects older people suffering from postural orthostatic hypotension. A third type affects elderly people with severe cardiac, cardiopulmonary, or systemic atheromatous illness. Such patients rarely regain normal brain function if they fail to gain accurate awareness in more than 4–5 minutes.

Concussion

Concussion is an unconscious state that immediately follows a severe traumatic head injury. Since its ultimate duration cannot be predicted accurately, some surgeons call post-traumatic lack of consciousness 'concussion' for 24 h; after that, the term is changed to 'coma'.

At its least, concussion interrupts the brain's organized thoughts and impairs or blocks its recent memory. Acute severe concussions may suddenly and briefly suppress vegetative brainstem functions, thereby invoking transient breathlessness, slowed heart rate, low blood pressure, and widening of the pupils. Boxing knockouts for 10 s or more vividly exemplify moderate to severe concussion, as the bewildered athlete staggers from the ring and sometimes falls. A few knocked-out boxers will remain unconscious after the count, and a very few may die from acute brain hemorrhage. A measurable group may gradually develop dementia during their early sixth decade. Many drivers or passengers in serious road traffic accidents can suffer brief knockouts of a few seconds, followed by several hours of confused memory and, frequently, light coma or unsteady behavior. Lack of arousal during this time is sometimes regarded as short-term concussion, but brief coma

is a more accurate label to apply until the person awakens.

Confusion

Confusion can be either temporary or permanent. Temporary confusion refers to disturbed memory and an inexact orientation of time, place, or person. Awakening from deep sleep after moderate sedation, suffering the effects of using excessive alcohol or street drugs, or awakening in a strange room, are typical examples. Chronic, waking confusion relates to sustained difficulties in identifying time, date, the environment and the failure to recognize long-known persons. It is also a gentle term for dementia.

Absence and Complex Partial Seizures

Seizures reflect severe impairments of self-aware consciousness, accompanied by unique forms of behavior. Absence seizures typically occur in children and are often noted as 'staring spells'. During the event the eyes typically fix in a forward stare, motion ceases, and movements of the lips or eyelids may be noted. People who undergo frequent absence attacks (once called *petit mal*) may lose extended self-awareness for a matter of hours and sometimes longer. During these states they remain awake and usually continue vaguely purposeful behavior.

Absence seizures originate from the cerebral cortex but involve brainstem and thalamic neuronal networks. People suffering severe complex partial seizures, a different neurological disorder often emanating from the temporal lobes (see below), lose their cognitive memories, but may also express a variety of learned behaviors. Both types of event exhibit attentional and intentional failure, loss of working memory, and perceptual dissociation. In their classic form, absence seizures may be interpreted to represent momentary vegetative states (see Table 1).

Akinetic Mutism

The term 'akinetic mutism' covers different behavioral expressions that relate to damage of several cerebral and subcortical structures. While sometimes confused with the vegetative state, akinetic mutism may resemble a state of constant hypervigilance. Such patients appear attentive and vigilant but remain motionless. The preservation of visual tracking in the form of following persons or moving objects with smooth, roving eye movements can differentiate this condition from the vegetative state. Classic akinetic mutism as listed in Table 1 reflects the recovery of a crude wakeful attentiveness without the apparent recovery of any other neuropsychologic function.

A similar picture, but excluding absence of eye movements, can rarely be a feature of untreated, rigid Parkinson disease. A strong clinical resemblance to this syndrome has been identified in some forms of variant Creutzfeldt–Jakob disease. The hyperattentive form of this disorder is typically seen in patients with large bilateral injuries to the medial and ventral frontal lobes (see below).

Hyperkinetic Mutism

Hyperkinetic mutism is a wakeful, continuous movement disorder accompanied by at least partial loss of global self-awareness. Patients with hyperkinetic mutism exhibit totally unrestrained but coordinated motor activity in the absence of external evidence of awareness of the environment. The patients also demonstrate an inability to develop conditioned responses, and produce no apparent memory of self.

Hyperkinetic mutism is the converse of akinetic mutism, with preserved unconscious expression of frontal intentional mechanisms, loss of sustained directed attention presumably requiring posterior attentional components of the inferior parietal lobe or posterior temporal lobe (see below), and a state of behavioral unawareness despite a whirlwind of activity. In contrast to the akinetic mute state, these people demonstrate minimally expressed intention and attention. The fragment of intention expressed in the meaningless motor activity of the hyperkinetic mute person is a reciprocal of the crude form of attention seen in akinetic mutism. Both examples reveal the fundamentally unconscious nature of such fragmentary neuronal activity.

Similar examples of such unconscious motor activity include the repetitive, uncontrollable production of words in the neurological disorder known as Tourette syndrome.

Delirium

Delirium is generally perceived as an acute or semiacute temporary deficit of attention and working memory. A salient component is temporal disorientation. Delirium may follow acute, moderately severe head injuries, encephalitis, bacterial meningitis, exceptionally high fever, heat stroke, or withdrawal from chronic alcoholism or drug misuse. Delirium in patients less than 45 years old usually

subsides without serious reduction in intelligence, but in alcoholism the person must abandon alcohol completely after the first or second delirious bout or begin to lose intellectual capacities permanently. Elderly people suffering mild dementia often become delirious during acute systemic illness or frequently changed surroundings. Visual hallucinations or impaired perceptions often occur in systemic delirium, whereas auditory hallucinations appear more often, but not solely, in people with schizophrenia.

Dementia

Dementia is characterized by two different conditions. One is a permanent, sometimes fluctuating loss of short-term or long-term memory. It can follow severe brain trauma, a sudden, sustained loss of oxygen to the brain, or surgical removal of the anterior areas of both temporal lobes. The other consists of an insidious, gradual loss of (first) short-term and (later) long-term memory. This process results from degeneration and death of nerve cells in the cerebral cortex.

Focal Unconsciousness: Agnosia, Anosognosia, and Neglect

Agnosia is a term specifically applied to different types of focal losses of awareness. Examples include an inability to see or feel objects as a whole greater than the sum of several parts, and a loss of specific capacities to hear aspects of sounds. A rare bilateral injury to the ventral temporal occipital lobe may produce the loss of perception of motion, leading to an experience of life as if seen constantly through a stroboscope, never in continuous motion.

Anosognosia is a term specifically applied to a loss of awareness and an inability to consciously perceive. Examples of anosognosia include denying that one's hand is one's own and unable to move intentionally. This form of focal unconsciousness is also labeled 'neglect' and is typically applied to a syndrome arising from damage to the right parietal lobe. This normally provides automatic knowledge of the contralateral body as well as the immediate outer space that surrounds it. Neglect increasingly appears to be a disorder of entry of primary sensory information into the appropriate internal context to be integrated into the construction of consciousness. Neglect can be seen following damage to either frontal or posterior (inferior parietal or superior temporal) cortices (see below).

RELEVANCE TO UNDERSTANDING HUMAN CONSCIOUSNESS

Anatomic Relationships

Disorders of consciousness are often generated by selective brain injuries. Specific neuropsychological deficits accompanying these disorders reflect the relatively segregated cerebral neuronal networks that generate human consciousness and complex behavior. Autopsies over almost two centuries and the increasing knowledge of functional anatomy provided by modern brain imaging have greatly added to neuropsychological understanding of conscious or unconscious behavior. Several brain regions are implicated in these disorders, including the two cerebral hemispheres, each of which possesses approximately half of the cerebral cortex, the thalamus, and the basal ganglia. Near the mid-brainstem, they connect with the large cerebellum and the arousal systems that lie within the brainstem. To discover just how this network generates consciousness has become a major scientific effort. (*See* **Cerebellum**; **Basal Ganglia**)

Nonspecific arousal is generated largely in the brainstem and is indispensable to supporting sleep–wake cycling and the wakeful states of consciousness. Cholinergic (pedunculopontine, later dorsal tegmental nuclei), noradrenergic (locus ceruleus), and other neuronal populations located within the upper brainstem, hypothalamus, and basal forebrain have a key role in organizing this large-scale human behavior. By itself, however, arousal is independent of expressed neuropsychological qualities, as is evident in the vegetative state or in 'absence seizures' (see Table 1). Brain mechanisms that govern sleep and its various dreams and perambulations only partially overlap the circuitry of normal wakeful consciousness. The integrity of both distributed cortical and other subcortical structures as is necessary for the expression of integrated cerebral activity to generate consciousness.

Cognitive capacities expressed in the conscious state depend on the moment-to-moment continuity of short-term memory (disordered in delirium) with other neuropsychological components. Short-term or working memory appears to depend strongly on the integrity of the prefrontal and parietal cortices along with subcortical structures. The richness of mental life contained in the storage of long-term memories is a distributed capacity of the association regions of the cerebral cortex and is severely degraded in dementia.

The cortical regions indispensable for conscious behavior are the frontal lobes: these largely govern and express behavior, both immediate and learnt. Their functions provide the executive generator and dictator of consciousness, organizing mood, behavior, and mind. Within the frontal lobes the basal forebrain area has evolved from ancient mammalian brains and occupies most of the undersurface. It participates in generating emotional feelings and social behavior as well as stimulating the person's intentional purposes. The lateral and medial prefrontal areas (including the dorsolateral prefrontal regions, supplementary motor zones, and anterior cingulate cortices) largely influence physical coordination and participate in volitional and cognitive aspects of attention and working memory.

The most posterior regions of the lateral and medial frontal lobe generate and regulate coordinated expressions of logical manipulations, language, intended eye movements and, ultimately, all coordinated, intentional behavior. Examples include skilled athletics, the expression of well-learnt and practiced instrumental music, and other rapidly expressed activity.

Functional generation of self-directed attention and intention are mapped strongly in the ventral-medial frontal lobes and less frequently the posterior thalamus and rostral mesencephalon.

Akinetic mutism reflects the disabling of the ventral-medial and medial frontal and prefrontal networks (including a large contribution from the deep gray-matter structures of the basal ganglia, which interact with the cortex via long-loop connections with the thalamus and underpin much routine learnt behavior), providing volitional drive and self-directed (executive) attention. The crude aspect of attention remaining in this state of impaired consciousness may originate from automatic orienting systems driven by posterior parietal and subcortical structures (thalamus).

The posterior parts of the cerebrum, including the parietal, occipital and temporal lobes, in conjunction with the thalamus, generate the perceived contents of thoughtful consciousness. They receive their direct signals of attention and intention from the frontal lobes and express their immediate demands. The occipital lobes receive inputs of retinal vision, which are processed further within the adjacent temporal lobe. Auditory stimuli are also processed in the temporal lobe. Abstract cognitive icons represent the verbal, musical, mathematical, geometric, and pictorial languages that make up our intellectually conscious knowledge. Most of these particular cognitive qualities and contents are dominantly expressed by the left cerebral hemisphere:

The right inferior parietal lobe and adjacent superiorlateral temporal lobes, however, normally provide a person's dominant preconscious attentive perception and awareness of both the left side of the body and its surrounding environment. Severe acute damage to the right parietal-temporal areas as described in the paragraph on focal unconsciousness may cause total unawareness of the entire left side of the individual's personal universe. Lost is the memory of being able to see, or to remember normal vision; lost is the accurate perception of any existing left-spatial noises; lost is total awareness or memory of the absent hemiworld to the left and, remarkably, the person's ability to recognize his or her own left arm, leg or ear. This remarkable clinical syndrome demonstrates that our conscious experience is instinctual and can be lost in parts.

Evidence from neurological disorders of consciousness demonstrates that subcortical structures are also essential for normal integrative brain function associated with consciousness. Most causes of the global disorders of consciousness reviewed above appear to arise from either large bilateral injury to frontal (e.g. bilateral medial-basal frontal injuries and akinetic mutism) or posterior association cortices (bilateral temporal-parietal association areas and hyperkinetic mutism). In addition, it is known that selective subcortical injuries (generally damage to medial aspects of the thalamus or upper brainstem) may produce identical or very similar disorders. The subcortical injuries that may produce transient coma, vegetative state, akinetic mutism, or conditions resembling hyperkinetic mutism also implicate brainstem and thalamic structures. These include the brainstem arousal systems important for sleep and wake cycling and related brainstem and thalamic substructures that play a part in the complex, large-scale integration of many cerebral networks. The contribution of these deep brain structures may lie in the selective facilitation of activity patterns that allow widely separated brain regions to briefly communicate

CONTENTS

In many regions of the cortex, neuronal response properties remain relatively constant in a direction perpendicular to the surface of the cortex, while they vary in a direction parallel to the cortex. Such columnar organization is particularly evident in the visual system, in the form of ocular dominance and orientation columns.

INTRODUCTION

The most prominent feature of the architecture of the cortex is its horizontal organization into layers. Each layer contains different cell types, and forms different types of connections with other neurons. However, a strong vertical organization is often also apparent: neurons stacked on top of each other through the depth of the cortex tend to be connected and have similar response properties despite residing in different layers. This type of vertical structure is called a *cortical column*, and has been hypothesized to represent a basic functional unit for sensory processing or motor output. Columnar organization has been most extensively studied in the somatosensory and visual systems.

DISCOVERY OF COLUMNAR ORGANIZATION

Cortical columns were first discovered electrophysiologically by Mountcastle (1957). When he moved an electrode obliquely to the surface of somatosensory cortex, he encountered neurons that responded to different sensory submodalities (e.g. deep versus light touch). However, when the electrode was moved perpendicularly to the cortical surface, all neurons had similar response properties. He summarized his findings as follows:

> These data … support an hypothesis of the functional organization of this cortical area. This is that the neurons which lie in narrow vertical columns, or cylinders, extending from layer II through layer VI make up an elementary unit of organization, for they are activated by stimulation of the same single class of peripheral receptors, from almost identical peripheral receptive fields, at latencies which are not significantly different for the cells of the various layers.

Shortly following this, vertical uniformity was also found in the visual system by Hubel and Wiesel (1977). Here, response properties that vary across the cortical surface but not through the depth of the cortex include the location of the neuron's receptive field in visual space, and the degree to which neurons are dominated by one eye. Columnar organization has also since been found in the auditory cortices of cat and monkey, where alternating bands related to monaural or binaural responses occur. A number of techniques have been employed for the experimental determination of cortical columns since the original use of electrode penetrations. These include methods based on axonal transport of substances such as horseradish peroxidase; on the differential consumption of radioactive 2-deoxyglucose by neurons; on optical imaging techniques, where cortical activity is converted to a visual signal by changes in reflectance or by voltage-sensitive dyes; and most recently on functional magnetic resonance imaging (fMRI).

There are some difficulties with defining exactly what is meant by a column. In some cases it is relatively clear: for instance, 'barrels' in somatosensory cortex and ocular dominance columns in visual cortex have fairly discrete boundaries with neighboring columns. In other cases, for instance orientation columns, there is a smooth variation in response properties moving parallel to the cortical

surface, rather than a series of discrete jumps. Another problem is that the term 'column' has been used to refer to structures at several different scales. At one extreme, from an anatomical point of view, are narrow vertical chains of neurons seen in Nissl-stained sections, barely more than one cell diameter wide, sometimes called *minicolumns*. At the other extreme, largely from a theoretical point of view, are complete functional units up to 1 mm in size, sometimes called *hypercolumns*. In between, Szentágothai (1978) specifies a generic column to be 200–300 μm wide. This article avoids such definitional issues by focusing on well-characterized examples of columnar organization. (*See* **Neuroimaging**)

COLUMNS IN THE VISUAL SYSTEM

Ocular Dominance Columns

Moving parallel to the surface of the primary visual cortex (V1) of several mammalian species, notably ferrets, cats, monkeys, and humans, there is a regular alternation between groups of neurons that respond best to input in the left eye and neurons that respond best to input in the right eye. The anatomical basis of this physiological pattern is the segregation of the thalamic input fibers – lateral geniculate nucleus (LGN) afferents – representing the left and right eyes to the visual cortex (Figure 1(a)). Although these fibers terminate primarily in layer 4 of the cortex, and this is where ocular preference is most sharply defined, a similar bias is also seen in higher and lower layers. This vertical structure of monocular preference is called an 'ocular dominance column' (reviewed by Hubel and Wiesel, 1977). When the entire pattern of eye preference is visualized in V1, for instance by injection of a radioactive tracer into one retina and its subsequent transport to the cortex, an alternating pattern of stripes is observed (Figure 1(b)). The periodicity of this pattern varies depending on the species and location in the cortex, and also varies substantially between individuals (Horton and Hocking, 1996):

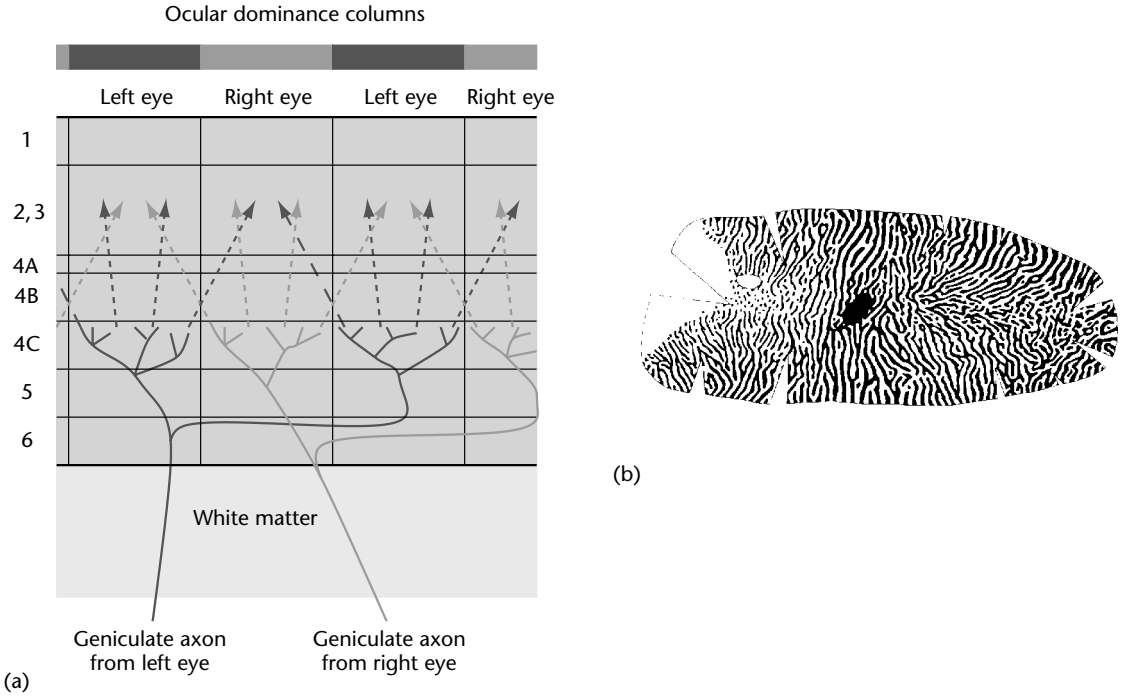

Figure 1. Ocular dominance columns in a monkey. (a) Anatomical basis. Each afferent axon from the lateral geniculate nucleus ascends through the deep layers of V1 (layers 5, 6) subdividing repeatedly and terminating in layer 4C in a couple of 0.5 mm-wide clusters separated by 0.5 mm gaps (approximately). Axons from the two eyes alternate, giving ocular dominance columns in 4C. The presence of horizontal connections and the arborization between different layers brings about overlapping and blurring of ocular dominance columns beyond layer 4: the ocular dominance of a given cell varies then between pure monocularity and pure binocularity. Adapted from Hubel (1995). (b) The pattern of ocular dominance columns from the primary visual cortex of a macaque monkey. White represents regions of cortex dominated by input from one eye, black the other eye. The width of individual columns is 0.5–1 mm. Source: LeVay *et al*. (1985) *Journal of Neuroscience* **5**: 486–501, © 1985 by the Society for Neuroscience.

in fact, each ocular dominance pattern is apparently as unique as a fingerprint. It can be seen from Figure 1 that these columns are in fact more like slabs, being long and relatively narrow rather than short and round.

Orientation Columns

Another type of columnar organization observed in the visual cortex is the orientation column. Many neurons in V1 respond best to an edge or bar of light at a specific orientation. This preferred orientation remains roughly constant through the depth of the cortex but varies mostly smoothly across the surface of the cortex. The overall pattern of orientation columns can be visualized by optical imaging methods. Cortical tissue changes its reflectance properties very slightly when neurons are active, and so by examining changes in reflected light from the cortical surface as visual stimuli of varying orientations are presented one can build up a picture of the complete map. An example is shown in Figure 2. A notable feature is the presence of pinwheels, point singularities around which all orientations are represented in a radial pattern. Superimposing the ocular dominance and orientation maps from the same animal, one observes regular geometric relationships between the two columnar systems. For instance, ocular dominance and orientation columns tend to meet at right angles, and orientation pinwheels tend to lie at the center rather than at the borders of ocular dominance columns.

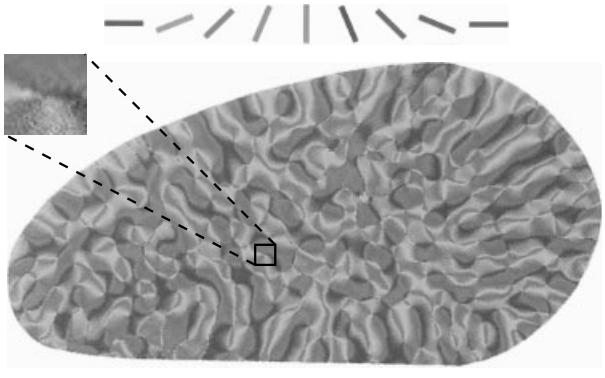

Figure 2. The orientation map in primary visual cortex of a tree shrew. The different degrees of shading represent patches that have different orientation preferences. The detail shows a pinwheel, where the orientation preference changes by 180° along a closed path around the center. Adapted from Bosking *et al*. (1997) *Journal of Neuroscience* **17**: 2112–2127, © 1997 by the Society for Neuroscience.

Other Types of Columns

Besides ocular dominance and orientation columns, several other types of columns are also present in the visual cortex. The most fundamental of these are what might be called position columns. Neurons in V1 have small receptive fields localized at specific positions in visual space. Moving vertically through the cortex, neurons have receptive fields at similar positions, while moving horizontally there is a smooth progression of visual field position versus cortical position, forming a topographic map of visual space in the cortex. This locality of information processing in visual cortex can also be seen from the fact that a small injury (e.g. a tumor or stroke) in part of V1 can cause blindness in a localized area in the visual field (a scotoma) with normal vision elsewhere, rather than an overall worsening of vision. Other receptive field properties that are organized into columns include preference for the spatial frequency of a stimulus across the receptive field, preference for the direction of movement of a stimulus, and disparity of inputs from the two eyes. All these columnar systems occupy the same cortical territory as the ocular dominance and orientation columns, and show complex geometric relationships that have yet to be fully characterized. Color-sensitive cells in layers 2–3 of monkey visual cortex (although not in other layers) are grouped in blobs, in which neurons respond to the color of a stimulus, but are mostly insensitive to orientation – unlike cells outside the blobs (the interblobs) which show marked orientation selectivity. (*See* **Color Vision, Neural Basis of**; **Depth Perception**)

Factors Driving the Formation of Columns

A number of different experiments on visual deprivation, where the visual experience that an animal receives is distorted, have shown that it is possible to produce physiological and structural changes in the columnar organization of visual cortex. For example, if one eye is sutured closed or strabismus is induced then most cells become monocular; if animals are presented with only bands at a specific orientation angle, then the proportion of cells that respond to that angle increases; if movement in a particular direction is excluded, the cells that would have responded to that movement direction no longer do so. Recovery to normal structure is also possible. However, both deprivation and recovery are effective only in an early period of the life when the connections are

developing. These experiments suggest that the development of ocular dominance columns is the result of two competing processes: segregation is promoted when neural activity is equal in each eye but not correlated between both eyes; and binocular innervation of neurons and merging of the two sets of columns is promoted by the correlation in activity between corresponding retinal areas of the two eyes that results from normal binocular vision.

However, the relative importance of intrinsic, or genetically programmed, factors versus extrinsic, or activity-driven, factors is still not clear. On the one hand, Crowley and Katz (1999) found that total removal of retinal influence early in visual development did not prevent segregation of geniculocortical axons into ocular dominance columns of normal periodicity. They thus propose that ocular dominance column formation relies on molecular cues present on thalamic axons, cortical cells, or both. On the other hand, Sur and colleagues (e.g. Sharma *et al*., 2000) have surgically rewired the optic nerve of newborn ferrets to feed into auditory thalamus (itself deprived of auditory inputs), which in turn projects to primary auditory cortex (A1) – rather than the normal pathway, optic nerve to LGN to V1. Such rewired ferrets develop in A1 a pattern of orientation columns with some similarities to that normally present in V1, though with a less regular periodicity. Such new cortical structure perceptually acts as visual; that is, the animals use the rewired A1 to see, rather than hear – although the resulting visual acuity is lower than normal. This suggests that retinal inputs can drive the formation of columns.

COLUMNS IN THE SOMATOSENSORY SYSTEM

The first physiological indication of cortical columns came from experiments by Mountcastle (1957) in the somatosensory cortex of cats. He found three types of neurons: those activated by light pressure on the skin, those activated by movement of hairs, and those activated by deformation of deep tissues (as occurs during for instance joint movement). As summarized by Mountcastle:

> Cells belonging to each subgroup were found in all the cellular layers. In 84 per cent of penetrations across the cellular layers which were directed perpendicularly, all the neurons encountered belonged to either cutaneous or deep subgroups. These modality-specific vertical columns of cells are intermingled for any given topographical region.

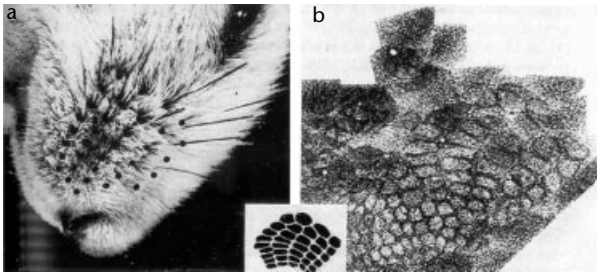

Figure 3. Posteromedial barrel subfield from a mouse's muzzle. Reprinted from Woolsey TA and van der Loos H (1970) The structural organization of layer IV in the somatosensory region (SI) of mouse cerebral cortex. *Brain Research* **17**: 205–242, © 1970, with permission from Elsevier Science.

More recent results have amplified this. For instance, Favorov and Diamond (1990) found discrete jumps in receptive field location between neighboring columns in cat primary somatosensory cortex, with no significant receptive field shifts within a column. However, the most striking example of columns in somatosensory cortex are the 'barrels' discovered by Woolsey and van der Loos (1970). In animals such as mice and rats, the long whiskers of the face are present in a stereotyped spatial pattern of rows. This is reflected in the posterior-medial barrel subfield of primary somatosensory cortex by a similar spatial pattern of columns, one column for each whisker (Figure 3). These are best defined in layer 4 where the thalamic afferents terminate. However, specialization to a single whisker is also apparent in higher and lower layers, and owing to their three-dimensional shape these columns were dubbed 'barrels'. The number and layout of these barrels can be altered by manipulations of the sensory periphery, such as removing a whisker.

COLUMNS IN OTHER SYSTEMS

The primary auditory cortex (A1) of animals such as cats and bats shows a systematic, spatially distributed representation of several independent auditory stimuli (reviewed in Schreiner, 1995). However, these auditory maps appear somewhat disordered because the local scatter of receptive field properties can vary over a wide range. The most regular map is that of preferred frequency, organized along a tonotopic axis without gradient reversals that mimics the tonotopic organization of the cochlea. Orthogonal to this axis, no systematic change of the preferred frequency is observed, with neurons being arranged along isofrequency contours. Other response parameters vary along the

isofrequency contours in a systematic way, such as the bandwidth and shape of tuning curves. Further maps also appear to be represented in a columnar fashion, such as the coding of intensity and sound localization, but the details of their organization are still unclear. (*See* **Audition, Neural Basis of**)

Inferotemporal (IT) cortex is a visual area essential for object perception and recognition. Using intrinsic signal imaging and extracellular recording in macaque monkeys, Tsunoda *et al*. (2001) showed that the neural activity evoked in IT by complex objects is laid out spatially as distributed patches. This result suggests that an object is represented by a combination of cortical columns, each of which represents a visual feature. However, not all the columns related to a particular feature were necessarily activated by the original objects. Thus, objects would be represented by using a variety of combinations of active and inactive columns for individual features, rather than simply by the addition of feature columns. It is unclear, though, whether an object is represented by a combination of modules, each specific to a visual feature or a part of the object (feature-based or part-based representation), or whether modules are specific to the object (object-based representation). (*See* **Temporal Cortex**; **Object Perception, Neural Basis of**; **Vision: Object Recognition**)

Columnar maps also exist outside the cortical areas, such as in the brainstem (maps of interaural delay, of interaural intensity difference, and of auditory space) and the superior colliculus (map of motor space, or gaze direction). (*See* **Motor Areas of the Cerebral Cortex**)

INTRACOLUMNAR AND INTERCOLUMNAR CIRCUITRY

Cortical columns are also distinguished from each other by their patterns of circuitry. The majority of intracortical circuits are local, connecting neurons within the same columns, with only a minority of connections being between columns. Again, this organization has been most extensively studied in the visual system.

Callaway (1998) proposed a generic model of vertical connectivity linking layers within a column in primary visual cortex of cats and monkeys (Figure 4). The model is based on three simplifying assumptions: only excitatory synapses are considered; each cortical layer provides its primary output to only one layer; and only two types of connections are considered (feedforward and feedback). A direct path from inputs (coming from the LGN) to outputs (going mainly to other areas in the cortex) passes through cortical layers 4C and 2–4B, with layers 6 and 5 providing feedback (modulatory) connections, respectively. Since these dense connections are mostly confined within a column, this provides a great deal of purely intracolumnar – and therefore local – information processing. Long-range connections (generally up to a few millimeters long) between columns mostly project within layer 2/3. They are generally sparse and patchy, and tend to connect spatially separated columns with the same feature preference, such as the same orientation or ocular dominance preference (although some recent experiments do not fully agree with this cluster-like connection pattern). It is easy to imagine how such specific patterns could arise as a result of Hebbian learning, since columns with similar feature preferences would be expected to have highly correlated activity. Likewise, it has been suggested that color blobs are preferentially linked to color blobs of the same ocular dominance, and interblobs to interblobs.

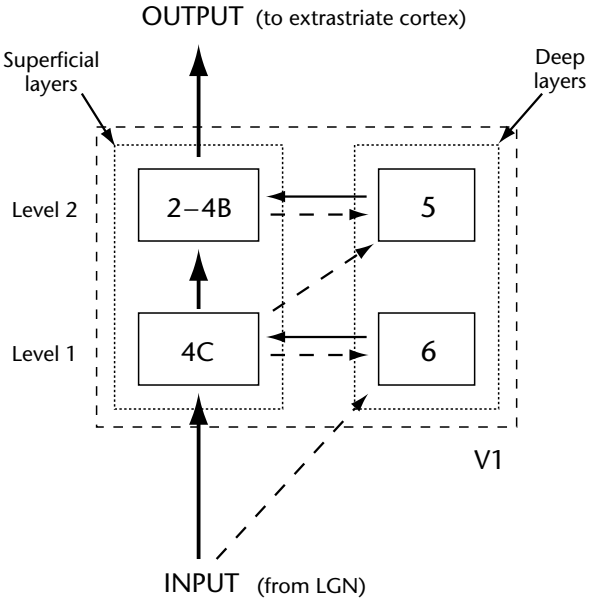

Figure 4. Two-level model of local cortical circuitry in V1. A direct path from input (from the lateral geniculate nucleus, LGN) to output (to extrastriate cortex) is provided by the two feedforward superficial layers 2–4B and 4C; feedback deep layers 5 and 6 modulate the activity of each level. Adapted from Callaway (1998).

COLUMNAR DEVELOPMENT AND COMPUTATIONAL MODELS

The high degree of order displayed by columnar structures and the large amount of data acquired,

especially regarding the development of ocular dominance columns in primary visual cortex, has inspired several computational models of columnar development. Such models are useful to explain the processes at work as well as to produce predictions that can guide future experiments. They should also be able to account for interspecies variations and be generalizable to models for other areas of the cortex, assuming that the underlying mechanisms of cortical development are reasonably universal. An excellent review of such developmental models can be found in Swindale (1996). (*See* **Neural Development**; **Neural Development, Models of**)

Most models of visual cortical development are based on the following assumptions (which are partially supported by experimental data): patterned retinal activity in the afferents to cortical neurons; Hebb synapses; radially symmetric, short-range excitatory and long-range inhibitory lateral cortical connections; and normalization of synapse strength. Thus, most of these models largely disregard genetic factors and assume that the columns in the primary visual cortex appear during development from an apparently uniform cortical sheet by a process of activity-dependent self-organization that modifies synaptic strengths in response to patterns of visual stimulation. These patterns can be produced both externally by the world, and generated internally by spontaneous activity in the retina (Meister *et al*., 1991). The rule by which synaptic strengths appear to change is roughly the one proposed by Hebb (1949): 'neurons that fire together wire together'. The models often represent the cortex as a two-dimensional array of neural units (each representing a collection of real neurons) and thus directly embody the definition of column. The visual stimulus is represented either in an abstract, low-dimensional way, as a vector of independent components representing ocular dominance, orientation preference, retinotopic position or direction preference; or in a concrete, high-dimensional way, as a vector containing the connection strengths between a cortical cell and a set of receptor cells in the retina. (*See* **Hebb Synapses: Modeling of Neuronal Selectivity**; **Hebb, Donald Olding**)

A common characteristic of these models is that they try to maximize coverage as well as continuity, as originally suggested by Hubel and Wiesel. Coverage refers to the fact that all combinations of eye and orientation preference occur at least once within any region (of a certain, small size) in stimulus space – otherwise, the animal might be blind to the unrepresented stimulus (although it has been suggested that higher cortical areas could interpolate between incomplete representations in lower cortical areas). Continuity refers to the fact that the preferences of neighboring neurons in cortex tend to be similar. Representing a high-dimensional stimulus space in a two-dimensional cortex results in coverage and continuity competing at the expense of each other, with the striped organization observed being perhaps a locally optimal solution to their trade-off. (*See* **Vision: Occlusion, Illusory Contours and 'Filling-in'**)

Two particularly important types of models are correlational (e.g. Miller *et al*., 1989) and competitive (e.g. Goodhill, 1993). In correlational models the input–output function of neurons is linear, and receptive field development is driven by the eigenvectors of an operator dependent on the correlation of the input patterns, the intracortical connections, and the LGN arborization. In competitive models the input–output function of neurons is highly nonlinear, and such models implement something more akin to cluster analysis. Generally speaking, these models account for much of the observed phenomenology of cortical maps, including the striped structure of ocular dominance and orientation columns with the appropriate periodicity and interrelations, and the location of pinwheels and fractures. However, no model so far can account for all observed features for both ocular dominance and orientation maps at the same time, or for some of the more elusive data. (*See* **Pattern Recognition, Statistical**; **Receptive Fields**)

WHY A COLUMNAR ORGANIZATION?

The presence of a columnar organization in various regions of the cortex of many mammalian species has suggested that columns form the basic information processing elements of the cortex, with each column being responsible for analyzing a small range of stimuli, and the same modular unit being repeated multiple times to span the entire range of stimuli (e.g. Szentágothai, 1978). As such, columns have been considered to be a fundamental functional feature important for perception, cognition, memory, and even consciousness (Szentágothai, 1978; Eccles, 1981). However, there is no general agreement about the reason for the existence of such groupings. Such columnar structure has not been found in some mammalian species closely related to other species that do have columns (Purves *et al*., 1992). Thus, it has been argued that the columnar organization of the cortex may not imply a functionally modular organization (Swindale, 1990; Purves *et al*., 1992). In particular,

Purves *et al*. suggested that the production of iterated patterns of circuitry might be an incidental consequence of the activity-dependent elaboration of synaptic connections and be of little significance to cortical function. In other words, a given cortical system might work just as well if columns did not form. Purves *et al*. suggest several factors that could drive such origin. (*See* **Modularity in Neural Systems and Localization of Function**; **Synaptic Plasticity, Mechanisms of**)

CONCLUSION

Many areas of the cortex, particularly in the visual and somatosensory system, can be divided into repeating modules characterized by discrete patterns in both function and anatomy. The best-studied examples are 'barrels' and touch-modality columns in primary somatosensory cortex, and orientation and ocular dominance columns in primary visual cortex. There are many vertical connections linking neurons within a column, and a few horizontal connections linking different columns. Columnar development may be driven by activity-dependent self-organization, and can often be modeled using Hebbian learning rules – although the relative importance of genetic factors and patterned activity is not clear. As yet no compelling justification has emerged for why columnar structure exists. (*See* **Vision, Early**; **Pattern Vision, Neural Basis of**; **Cortical Map Formation**)

Cortical Map Formation

Intermediate article

Jon H Kaas, Vanderbilt University, Nashville, Tennessee, USA

CONTENTS

Cortical maps are orderly representations of sensory receptors or body movements that form during the development of the brain. Proper development depends on genetic information, molecular signals based on relative position in the brain, and information in spontaneous and evoked neural activity patterns.

INTRODUCTION

The functional machinery of the brain includes cortical areas and subcortical nuclei that are interconnected to form systems. Many of these nuclei and cortical areas systematically represent a sensory surface or the motor control of muscles. In the visual system, the inputs from the retina terminate in topographic patterns in thalamus and midbrain nuclei to form maps of the retina or visual space. The map in the laminated lateral geniculate nucleus in the thalamus projects to primary visual cortex, V1, to form a map of the hemiretinas of the two eyes that see the contralateral half of the visual world. Area V1 projects in turn to several additional visual areas to activate further maps of the contralateral visual hemifield. Monkeys and humans have over 25 visual areas, most of which can be described as containing maps of the contralateral visual hemifield (Kaas, 1989). The interconnected maps form a processing hierarchy for visual information in which the early maps, especially the one in V1, most precisely map the visual hemifield, while higher-order representations progressively become less retinotopic. However, these maps may represent other aspects of visual information in systematic ways, as they start to reflect more of the visual outcomes of cortical computations. The collections of interconnected cortical and subcortical maps constitute the visual system, and the auditory and somatosensory systems are constructed similarly.

The motor system is defined somewhat differently. Motor cortex includes a primary area and other areas where neural activity at any specific location in the map elicits a specific movement or set of movements. The movements can be elicited by natural neural activity or by neural activity evoked by focal electrical stimulation within these areas. By electrically stimulating a large number of sites across a motor area, the representation of movements can be experimentally revealed. For example, primary motor cortex, a mediolateral strip of cortex in the caudal portion of the frontal lobe, represents foot movements medially near the brain midline, trunk movements more laterally, forearm and hand movements next, and face movements most laterally (Penfield and Boldry, 1937). As motor areas also receive rather indirect sensory inputs, they can be said to represent somatosensory or other sensory inputs, but these sensory maps are seldom discussed. Likewise, movements can be evoked from somatosensory areas of cortex, at higher levels of stimulating current, and these somatosensory areas can also be said to contain motor maps. Monkeys and humans have as many as ten areas in each cerebral hemisphere that map movements of the muscles of the contralateral half of the body, as well as two main areas for moving the eyes and directing gaze into the contralateral visual hemifield. Because the internal representational organizations of the sensory and motor areas can be revealed by successively recording from neurons or stimulating neurons in many locations in each representation with microelectrodes, the recording or stimulating procedures are sometimes referred to as 'mapping' the brain.

In addition to recording or stimulating with microelectrodes, there are other ways of recording or imaging brain activity in response to sensory stimuli or repeated movements that also allow the organizations of brain maps to be revealed. The use of 'noninvasive' imaging procedures has revealed the locations and internal organizations of visual, auditory, somatosensory, and motor maps in humans. The existence of orderly maps in the

cortex has been implied for some time by the nature of perceptual and movement deficits that follow focal lesions of regions of cortex in human patients. Motor maps were directly revealed in the 1870s when investigators exposed the surface of the brains of dogs and monkeys and described regions where body and eye movements could be evoked by electrical stimulation. Comparable evidence for sensory maps came later in the 1930s and 1940s when the invention of the oscilloscope and amplifiers made it possible to record the weak electrical activities of cortical neurons as they responded to sensory stimuli. These recording and stimulation methods have long been applied to humans when their brains were exposed during surgery. With the existence of such maps now well established, the interesting and challenging question of how they emerge in the developing brain can be addressed.

THE DEVELOPMENT OF CORTICAL MAPS

The primary sensory and motor maps occupy the same relative positions in the neocortex of most mammalian species. Thus, the visual cortex is at the back, auditory cortex is lateral, somatosensory cortex is toward the front, and motor cortex is just ahead of somatosensory cortex. There are several theories as to how this happens.

One theory is that the subdivision of the cortex into areas begins early in brain development, well before the neocortex has even been generated by the migration of cells from a generative zone along the cerebral ventricles. According to this theory, cellular interactions occur in the pool of dividing cells along the ventricle so that the cells become committed to certain fates and collectively form an early plan of the overall organization of neocortex. When the cells migrate in a point-to-point fashion to cortex, they carry with them the basic organization of where emerging cortical maps are relative to each other and even the internal organizations of maps. Thus, the basic organization of cortex is determined by interactions between progenitor cells before they even generate the cells that form cortex. This theory has been called the *protomap hypothesis* (Rakic, 1988), and it suggests that there is something inherent within each emerging cortical region that directs the region to become a specific cortical area.

A second view is that neocortex is generated as a *uniform sheet* and that patterns of inputs from the thalamus and later the emerging cortical connections subdivide the cortex into areas. Thus, each region of cortex starts out with no particular identity, but it acquires an identity when axons from another part of the brain arrive and tell it how to differentiate. The problem with the view that regions of cortex have no particular identity is that this does not explain by itself why visual cortex is always located toward the back and motor cortex toward the front of the neocortex. One possibility would be to utilize well-known differences in the front to back and lateral to medial neurogenic gradients in the emerging neocortex and thalamus to form patterns or connections. Axons could grow out in maturational order to arrive at cortical targets in maturation order, providing an overall organization in cortex. If axons maintained neighborhood relations with each other as they grew to cortex, as they largely seem to do, considerable order in cortex could result. Thalamic axons, according to this possibility, only need to be attracted to cortex, and the sorting mechanism would be a consequence of positional differences in developmental order, which in turn would be dependent on position effects on gene expression and the consequent molecules. Refinement of the initial order and the addition of local circuits in cortex could then follow.

Alternatively, and most likely, some sort of *positional signaling* is used. An early hypothesis of how growing axons reach and recognize an appropriate target was the chemoaffinity theory proposed by Roger Sperry in the 1960s (Sperry, 1963). According to this proposal, both the guidance of axons to the target region and the recognition of the appropriate target neurons are achieved by the operation of highly specific chemical affinities between substances in the growing axons and in the neurons of the target structure. Such a proposal nicely accounts for the formation of highly specific patterns of connections, but it fails to explain all observations. Most notably, lesions of neocortex very early in development (before the thalamic axons arrive) do not completely abolish some divisions of cortex and leave others intact; instead, smaller than normal areas form on the smaller sheet of neocortex. This type of observation is more compatible with a modified form of Sperry's chemoaffinity theory.

One proposal is that molecular gradients across developing neocortex indicate a general front to back and medial to lateral direction for patterns of thalamic connections, but not specific locations for connections (Fukuchi-Shimogori and Grove, 2001). Thus, axons from the visual thalamus would seek a high (or low) region of expression in the gradient and always would grow to the back of the neocortex (Huffman *et al*., 1999). If the back part of

neocortex had been removed, these axons would still grow to the back of the portion of neocortex that remained. Local competition between axons guided to positions along a molecular gradient would then lead to winners and losers in the reduced cortical sheet, but not all of the visual axons would be losers. In contrast, if appropriate target neurons were completely prespecified either in a map in the generative cells along the ventricle or in a similar protomap formed in the early cortical sheet, then removal of the target cells would completely abolish a cortical area. In principle, chemical gradients in cortex could provide the signals, given adjustable thresholding mechanisms and competition for synaptic space, for both cortical areas emerging in the correct places with the correct thalamic inputs, and at least approximately correct topographic patterns within cortical areas. Thus, molecular patterns intrinsic to cortex guide the development of cortex while allowing several outcomes. A pluripotential cortical sheet is differentiated by molecular gradients.

All cortical areas may not be specified in the same way. Possibly a few cortical areas, especially the primary areas, are specified very early in development and can only become those areas, although this does not seem to be the case for the visual cortex of opossums or somatosensory cortex of rats, where the outcomes have been experimentally altered. However, an argument has been made for primary visual cortex of monkeys and humans, as this cortex has more neurons across the thickness of cortex than other cortical areas, and the posterior ventricular zone that generates neurons for primary visual cortex generates more neurons. These observations suggest that the protomap of primary visual cortex already exists in the ventricular generative zone. Yet a major role in the specification of visual cortex by thalamic inputs is clearly indicated. In humans in whom the eyes fail to develop and in monkeys with eye removal early in fetal life, many of the neurons in the developing lateral geniculate nucleus of the thalamus degenerate without visual input, and the number of thalamic neurons projecting to visual cortex is greatly reduced. As a result the primary visual cortex is only a fraction of its usual size (Rakic, 1988). Some of the cortex that would normally become primary visual cortex develops features of nonprimary visual cortex. Thus, it appears that the region of primary visual cortex becomes primary visual cortex only if it receives an adequate input of visual axons from the thalamus.

The internal organization of cortical maps probably depends on a balance of intrinsic factors leading to regional differences in gene expression and gene products, and extrinsic factors including regional and local differences in neural activity patterns evoked by sensory stimuli, self-movement, or by correlated spontaneous activity. A combination of such molecular and activity-dependent mechanisms would best account for the basic features of cortical map development listed below.

- At least the crude topographic features of cortical maps appear to develop independently of any information from sensory receptors and afferents. In other words, the basic features of cortical maps develop without instruction from the receptor sheet. Activity patterns relayed from the periphery are not necessary. The most compelling evidence for this comes from studies of thalamocortical connections in genetically eyeless (anophthalmic) mice where the connections between the lateral geniculate nucleus of the visual thalamus and primary visual cortex are at least approximately normal in topography. Similar results have been reported in other mammals reared after the removal of retinal afferents early in development. Also, the basic pattern of connections between the ventroposterior nucleus of the somatosensory thalamus and primary somatosensory cortex of rats appears to form before the thalamus is activated by somatosensory inputs. The topographic order of the thalamocortical pattern is said to develop independently of a 'template' of the periphery.
- Detailed cortical maps of the receptor sheets often develop prenatally, and thus they develop without postnatal experience. Newborn mammals of many species have orderly normal maps of the body surface in primary somatosensory cortex at birth, and in newborn lambs and monkeys the retinotopic organization of primary visual cortex appears to be normal at or soon after birth.
- The internal organizations of sensory maps closely reflect the features of the sensory sheet. The maps reflect the densities of receptors across the skin or retina so that the maps are proportional to receptor densities rather than skin or retinal territories, although a behaviorally important receptor surface may achieve extra space in cortical maps. Even errors in the arrangement of receptors or the projections of afferents are reflected in the order of cortical maps. For example, the number and arrangement of the vibrissae on the face of rats and mice is highly consistent across individuals, and the maps in primary somatosensory cortex (S1) separately and precisely represent each whisker. When rare individuals with an extra whisker or two are examined, an extra anatomical module in S1 is found for each of the extra whiskers. Likewise, S1 of star-nosed moles with an array of 11 ray-like sensory appendages protruding from each side of the nose has 11 modules or bands in the face portion of S1, one for each ray. However, rare individuals who develop with 10 or 12 rays have 10 or 12 bands in S1 (Catania and

Kaas, 1997). Similarly, Siamese cats have a mutant gene that alters skin and eye pigment and also changes the projection pattern from the retina somehow so that the segment of the retina that projects to the contralateral lateral geniculate nucleus in the thalamus is extended by some 20° of visual angle. This extra input is often incorporated into the order of cortex maps so that primary visual cortex (V1) represents an extra 20° of visual space in a single retinotopic pattern (Kaas and Guillery, 1973).

- There is evidence from the study of rats that the segregation of afferents from the two eyes, or from different whiskers on the face, in sensory cortex depends on having intact inputs from the eyes or face in early development. In rats reared after section of sensory nerves at birth, the cortical arbors of thalamocortical neurons are unusually large and overlapping, with less focused distributions of synapses. In visual cortex, inputs relayed from the two eyes normally divide the space in visual cortex into alternating ocular dominance bands. If one eye is removed early in development, thalamocortical axons related to the remaining eye occupy nearly all of cortex. Similarly, if the activity of retinal neurons in one eye is simply reduced by rearing a cat or monkey with one eye sutured shut, the thalamocortical axons related to the normal eye acquire most of the cortical space (Hubel *et al*., 1977).
- The development of cortical maps is altered if they are abnormally innervated. Several investigators have induced the sensory projections from one sensory system to innervate a thalamic nucleus for another sensory system early in development, thereby causing the sensory map in cortex to receive the wrong sensory input. When visual inputs from the retina were induced to innervate the medial geniculate nucleus of the auditory thalamus, the medial geniculate neurons thereby relayed visual rather than auditory information to primary auditory cortex (A1). This cortex then developed a map of the retina that had some, but not all, of the features of visual cortex. The researchers concluded that the nature of the sensory input, visual or auditory, influenced, but did not totally determine, cortical map development (Roe *et al*., 1990).

MOLECULAR MECHANISMS OF CORTICAL MAP FORMATION

Regional differences in the expression of molecules in the developing cortex appear to have major consequences for the course of cortical development. Many molecular correlates of developmental stages and features have been described, including the expression of nerve growth factors and receptors for those factors, growth-associated proteins, structural proteins associated with synapses, membrane-associated glycoproteins, and axon guidance molecules. The underlying question concerns the factors that relate to differences in gene expression allowing various signaling and neuron construction molecules to be expressed at the proper time and place in the developing neocortex.

According to the early views of chemospecificity postulated by Roger Sperry, molecular signals – either regionally expressed or expressed as gradients across developing cortex – would at least set up the basic organization of cortex by guiding incoming connections to appropriate locations and maintaining synaptic contacts at those locations. Other local features of cortical organization might then emerge as a result of gene expression related to the neural activity patterns induced by the initial connections. The key assumption here is that the early regional differences in the expression of molecular signals depend on factors intrinsic to developing cortex.

Important evidence on intrinsic differences in the expression of molecular signals comes from studies of mutant mice in which thalamocortical afferents failed to develop. Despite a total lack of thalamic inputs, the emerging neocortex demonstrated both graded and sharp patterns of gene expression, including genes thought to be important in axon adhesion and in neuronal differentiation. Thus, developing neocortex has intrinsic signals that seem to be capable of directing regional differentiation. Further evidence comes from studies of abnormal thalamic connections in mutant mice lacking certain regulating genes. In these mice, the early expression of specific molecular markers are shifted toward the back in the developing cortex. As a result, thalamic connections are also shifted toward the back. For example, the somatosensory inputs that normally go to the middle of neocortex terminate instead in the back where visual inputs normally terminate. The visual inputs in turn are displaced to the very margin of the posterior neocortex. Thus, these experiments provide compelling evidence for the existence of intrinsic molecular positional cues for incoming thalamic axons.

In summary, it appears that differences in gene expression in cortical neurons based on their position in the cortex or their previous history as precursor cells in the ventricular generative zone provide the molecular guidance necessary for at least the gross pattern of thalamocortical connections to develop. This pattern includes a basic set of cortical sensory and motor areas, and at least the crude topographic order of the sensory and motor maps within those areas. However, refinements of crude patterns within maps appear to depend on information carried from the receptor sheet to the thalamus and then to cortex.

ROLE OF EXPERIENCE AND NEURAL ACTIVITY

The prevailing view is that cortical maps emerge in development as a result of a combination of mechanisms that require neural activity and those that do not. The activity-independent mechanisms are thought to be important in forming cortical areas and the crude topography of cortical areas, while activity-dependent mechanisms are thought to be essential in achieving precision in the connection patterns that make up cortical maps.

The early evidence of a role for activity in the formation of cortical maps came from the landmark experiments of David Hubel and Torsten Wiesel. In the early 1960s these investigators experimentally sutured together the lids of one eye in kittens whose eyes had not yet opened, thus depriving that eye of pattern vision. When the visual system of these cats was examined after they matured, few neurons in primary visual cortex were responsive to the previously closed eye and the anatomical relay of connections from the deprived eye to visual cortex were sparse. The interpretation of these results was that axons from neurons in the lateral geniculate nucleus of the thalamus that were activated by the deprived eye were less active than those related to the normal eye, and the two types of axons were in competition with each other for synaptic space on cortical neurons. The more active axons for the normal eye grew and took over most of the cortical neurons, while the axons for the deprived eye lost contacts with cortical neurons and failed to grow with the expanding brain and innervated little of visual cortex.

Subsequently there have been many deprivation studies that demonstrate that it is possible to alter the development of the visual system. Such results provide further evidence for activity-dependent mechanisms. Nevertheless, the roles of activity and especially experience continue to be questioned. For example, the separate alternating territories in primary visual cortex with inputs from one or the other eye, the ocular dominance columns, develop before birth in many mammals. Thus, they do not depend on pattern vision. However, the development of these columns has been attributed to spontaneous or nonvisual activity in the neurons of the two eyes before they are exposed to light. Neurons close together in any structure, including the eye, tend to be interconnected and spontaneously active at the same time. Thus the patterns of activity relayed to the thalamus from each developing eye would differ, and this difference would be relayed to cortex as a basis for segregating axons related to each eye in ocular dominance columns. Evidence suggests that such segregations of thalamocortical terminations develop even without eyes. However, this observation, if valid, does not eliminate the possibility of spontaneous activity being essential, as differences in spontaneous activity patterns could occur in the layers of the lateral geniculate nucleus normally related to each eye.

CONCLUSION

Over years of active investigation, a general theory of cortical map development has emerged. In brief, a few major factors appear to be highly important for the formation of map topology, modular organization within maps, and neuron response properties.

First, molecular mechanisms that are independent of external influences seem to be responsible for guiding axons to their approximate locations in cortex. Which molecules govern this guidance and establishment of a crude topographic order for connections remains largely uncertain, but a number of promising candidate substances are under investigation. Another uncertainty is how these molecules come to be expressed in regionally specific patterns. When and how are position cues recognized? Spatiotemporal gradients in neuron generation and maturation, and substrate cues for gene expression, are likely to be important. Several guidance and chemoaffinity factors have been demonstrated.

Neural activity patterns provide another important source of information, and this information is used to select some synaptic contacts over others. Neurons are induced by activity patterns to locally grow and form more connections, or to retract and lose connections. Much research supports the premise that, in both the mature and developing nervous system, synapses on a neuron that are active while the neuron itself is active are strengthened, while those that are inactive during such discharges are weakened. The physiological consequences of such changes in synaptic effectiveness, which are rapidly induced, have been called *long-term potentiation* (LTP) and *long-term depression* (LTD). The changes are often referred to as 'Hebbian' plasticity after the early proposal of cellular mechanisms for learning by Donald Hebb.

The key variable is whether overlapping inputs on cortical neurons are active at the same time. Activities that are correlated in time across receptors in the receptor sheet are based on proximity and receptor transducing factors. The same stimuli

are likely to activate nearby receptors, but classes of receptors in the same location are differentially responsive to the same stimulus. In the central nervous system, proximity is additionally important because of local interconnections, and local computations add to response diversity by producing neurons that have new selectivities for features of sensory stimuli. Selections of synapses based on correlated and discorrelated activities fine-tune the internal representational order of sensory maps so they more closely reflect the proximities and disjunctions on the receptor sheets. Such selection also distributes and segregates inputs differing in correlated spontaneous activity based on proximity levels. Neurons projecting from one structure to the next would be more densely interconnected if adjacent than widely separate, and the local interconnections would induce correlations in activity. Thus, activity patterns could promote the formation of topographically matched connections between cortical areas. Neurons driven by different receptor classes would be separately activated and their overlapping projections would segregate. Similarly, neurons that became selective for different stimulus attributes, as a result of the computations of central neurons, would develop segregated projections. Thus, activity patterns would induce sharply defined modules such as ocular dominance columns, stimulus orientation modules, and light-on or light-off layers in cortical maps.

Early-maturing maps, largely the primary cortical areas, would be most influenced by prenatal activity patterns, especially correlated spontaneous activity but also sensory responses evoked by self-generated movements, while later-maturing maps would have the opportunity to use information from a more complex external environment and the processing outcomes of early maturing cortical areas and thalamic nuclei.

Finally, the susceptibility of neurons to both local substrate cues in the molecular environment and to the effects of neural activity patterns changes over the course of maturation, leading to the concept of critical or susceptible periods for developmental change.

Decoding Neural Population Activity

Introductory article

Peter Foldiak, University of St Andrews, St Andrews, UK

CONTENTS

The brain uses the activity patterns of a large number of neurons to represent information about the world. Decoding methods allow us to read out this neural code and interpret the neural activity pattern.

INTRODUCTION

Brain activity can be observed using a variety of technical methods. Functional imaging techniques such as positron emission tomography and functional magnetic resonance imaging allow us to observe which brain areas show increased activity during the performance of various tasks. However, these methods have relatively poor resolution in space and time, which means that we can only observe average brain activity over many thousands of neurons and over many consecutive brain states. This prevents us from seeing functionally important details in brain activity. Yet we need to understand more than just which areas are involved in certain tasks; we are interested in the computations within these areas. As much of the interesting difference between brain states is visible on the level of much smaller groups of neurons and on a faster time scale, we need more detailed indicators of brain activity. In fact, the detailed response properties of individual neurons even within a small area of the brain seem to be substantially different from each other, which means that if we want to understand information processing in the brain, we need to observe the activity of single cells. Single cell recording is the only technique that gives us the precise times of each action potential (a 'spike train') from an isolated neuron.

In the sensory system, we try to make sense of these spike trains in terms of the sensory input stimuli, while in the motor system we try to understand the relationship between neural spikes and the resulting movements. One view of this relationship is captured by the concept of neural 'tuning curves'. It assumes that most of the information in the spike train can be summarized by a single number, the neural response. This number is often thought to be the firing rate, which is the number of action potentials generated by a neuron during a time interval, divided by the length of that interval. Other aspects of the spike train, such as the more precise timing of the spikes in relation to each other or to the onset of a stimulus, may also be carriers of information. A tuning curve is the (average) response of the neuron as a function of certain properties or parameters of the stimulus input or motor output. An example would be the orientation tuning curve of neurons in primary visual cortex, where the stimulus is a grating of equally spaced parallel dark and bright bars (or two-dimensional sine wave grating), and the neuron responds differently to gratings of different orientations. The orientation tuning curve plots the response as a function of the grating orientation, showing a peak at the 'preferred' orientation of the neuron and lower values elsewhere. A more complete description of the neural code also includes a measure of the response variability, as the neuron's response can be different on each stimulus repetition depending on unpredictable external and internal factors (e.g. stimulus and transduction noise, physiological state, attention, neural interactions).

The other, complementary way of asking questions about the relationship between the spike train and the stimulus (or movement) is by trying to identify the stimulus or movement based on the observed response from a neuron or responses from several neurons. This is the problem of decoding.

POPULATION VECTOR METHOD

A simple method of decoding the response of a neural population is based on the peaks of tuning

curves. It was originally developed for predicting arm movements based on the responses of a population of neurons in motor cortex but it can also be applied to populations of sensory neurons to decode a sensory stimulus. Essentially it is a response-weighted sum of the preferred values of the encoding neurons. Each neuron has a vector associated with it that points in the direction that corresponds to the peak of its tuning curve. In the case of arm movements, the direction of this vector is the direction of the arm movement in physical space that maximized the neuron's response. The direction of this vector stays fixed but the length of this vector for each neuron is scaled at each moment to the size of the neuron's response. The population vector at any moment is the sum of the vector contributions of the individual neurons in the population (Figure 1). Under some assumptions about the shapes of the tuning curves and the distributions of their peaks, the population vector will be a reasonable prediction of the stimulus or movement parameters (e.g. the direction of arm movement). To understand this procedure, imagine that each neuron represents a single 'preferred' direction and the strength of each neuron's response indicates how close the actual direction is to the neuron's preferred direction. As the most active neurons will contribute the longest vectors to the vectorial sum, the neurons with the preferred directions closest to the actual direction will have the greatest weight in determining the resulting population vector. This weighted sum is then an estimate of the actual direction, and the estimate should get better as the number of neurons in the population increases. While the population vector method is relatively simple to apply, there are several problems with it:

- Neurons in a population do not generally fulfill the condition that the peaks of the tuning curves of the neurons in the population have to be uniformly distributed in all directions (i.e. roughly the same number of neurons have to have peaks in each direction). If there is an excess of peaks in a certain direction, the population vector will be biased in that direction.
- It assumes a specific form of the tuning curve (falling off as a cosine function from the peak). In many cases, these assumptions are not good approximations of the actual tuning curves and their distribution in the population. The only information it uses about the actual tuning curve is the location of its peak, and we have no way of incorporating any additional information (e.g. breadth of tuning, or multiple peaks) we might have about the true tuning curves.
- Even if all conditions necessary for the population vector method are met, there are other methods that give better estimates.
- It has no way to take neural variability into account.
- It generates a single estimate, with no indication of confidence in the estimate or distribution of alternatives.
- In some cases the stimulus parameters do not naturally fall in a space where vectors make sense (e.g. discrete or nominal variables), and the population vectors cannot be calculated.
- Implementing the population vector method in neural machinery is not particularly easy or plausible. Alternative methods that take weighted sums of the neural responses are not equivalent to it, and are biologically much simpler and fit better with what is known about neural response properties.

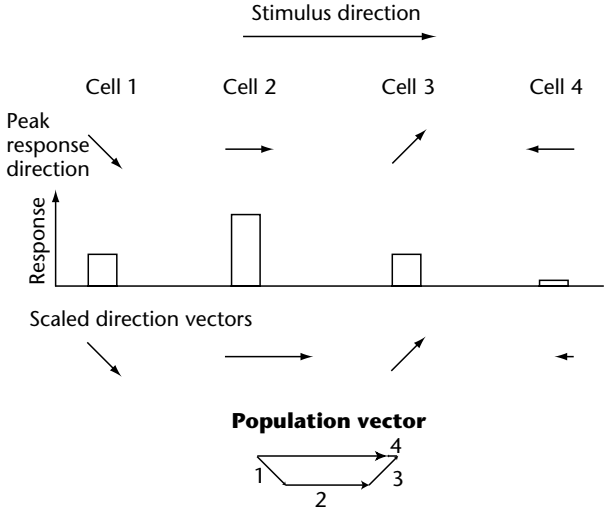

Figure 1. Calculation of the population vector for a horizontal stimulus (or movement) direction from the responses of four neurons.

BAYESIAN METHODS

Most of the above problems (except for the last) can be solved by thinking of both tuning curves and estimates as probability distributions. A description of a neuron's response properties is then given by a conditional probability distribution: $P(r|s)$. This distribution describes the probabilities of observing any response value (r) given that a particular stimulus (s) is presented. The conditional probability is also related to the joint probabilities $P(r,s)$ of the response and the stimulus:

$$P(r|s) = P(r,s)/P(s) \quad (1)$$

where $P(s)$ is the prior probability of seeing stimulus s, without any knowledge of the response. If these conditional distributions can be estimated for all stimuli, we have a full description of the neuron's tuning and variability. Decoding then

becomes easy by applying Bayes' theorem, which allows us to calculate the probabilities of each of the possible stimuli given the observed responses: $P(s|r)$. Bayes' theorem follows from the definition of conditional probabilities

$$P(s,r) = P(r|s)\ P(s) = P(s|r)\ P(r) \tag{2}$$

and it states that

$$P(s|r) = P(r|s)\ P(s)/P(r) \tag{3}$$

where $P(r)$ is the probability of a given response, which is summed across all stimuli as

$$P(r) = \Sigma P(r|s)\ P(s) \tag{4}$$

and it is used to normalize the $P(s|r)$ distribution to sum to 1. An example of two discrete stimuli and two discrete responses from a single neuron is given in Figure 2. The formulas given above are applicable to discrete sets of stimuli and responses, but can also be expressed for continuous variables in terms of continuous probability distributions. When the responses of several neurons are available, the response can be considered to be a vector variable, and the distributions need to be estimated over such a vector space. The problem of estimating the density of a multidimensional probability distribution is usually a difficult one for several reasons. One is that the volume of response space increases exponentially with the number of neurons, and therefore the number of data points needed for estimation increases quickly. The other problem is experimental and is related to whether the responses can be recorded simultaneously from the neurons (e.g. using multiple electrodes). If simultaneous recording is not available then the trial-by-trial relationship between the responses is not observable. Estimates of this dependence and of the prior distribution can influence the results substantially. These apparent disadvantages of the Bayesian method are not avoided, only ignored by the alternative methods. The Bayesian method has a far greater flexibility and power than the population vector method. Not only is it free of assumptions about the shape and distribution of the tuning curves but it is also applicable in cases where vectors could not be defined at all (e.g. in some unknown shape space).

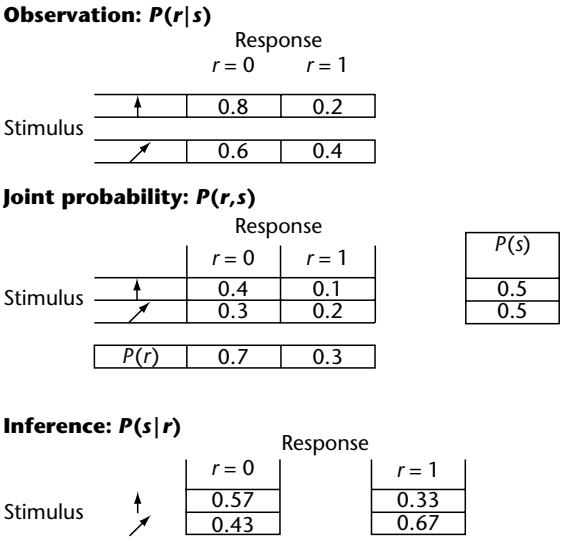

Figure 2. Bayesian decoding of a binary neural response (0 or 1) of a single neuron to a set of two possible stimuli (vertical or diagonal). Such binary responses could be observed if measured in a short time window. The conditional probability $P(r|s)$ is measured separately for the two stimuli, and these are the relative frequencies of the responses. The two stimuli are assumed to occur with equal (0.5) probability. Bayes' theorem (Eqn 3) gives the decoding separately for the two possible responses.

STIMULUS DISCRIMINATION USING POPULATION RESPONSES

The result of applying Bayes' theorem is $P(s|r)$. You can think of this distribution as the answer to the question of what the population response means. The Bayesian method is optimal in the sense that if you have the correct $P(r|s)$ values it gives you the true $P(s|r)$ values, and optimal decisions or discriminations can be made based on this. If the goal, for instance, is to make the smallest number of errors in guessing the stimulus, the most probable stimulus – the one corresponding to the peak of the $P(s|r)$ – should be chosen. Other values of this distribution provide possible alternatives with lower probabilities. A highly peaked probability distribution across the stimuli indicates a high degree of certainty, while a broad, flat distribution is a sign of uncertainty in the decoding due to the variability in the response and the overlap between the conditional distributions. Other optimality criteria can be expressed as a loss function $L(s,s')$, where s is the actual and s' is the chosen stimulus. It can be expected that confusing some pairs of stimuli (e.g. similar stimuli, or where both are members of the same category) will be much less costly than confusing other pairs (e.g. members of different categories, or dissimilar stimuli). The loss function can capture the relevant structure, and Bayesian inference gives the decision that minimizes expected cost.

APPLICATIONS

Decoding methods are not usually considered to be models of physiological processes, as it is not likely that explicit stimulus (or movement) decoding takes place in the brain. Information in inputs, outputs, as well as internal representations are distributed to some extent. There is no clear evidence that any component of such a representation could be considered a decoding of a stimulus. Decoding is still interesting from a theoretical perspective, as it tells us the amount and nature of information available for processing in a certain population, and sets upper limits on performance for a mechanism operating on inputs from this population, just as an 'ideal observer' is a useful theoretical concept in studying human psychophysical performance. It allows the calculation of the efficiency of an actual neural mechanism by providing the best possible level of performance for comparison and the calculation of the amount of information available. Such an ideal observer of the neural activity allows an investigation and interpretation of neural representations in real experimental situations. It does not, however, in itself tell us how the brain actually uses the information in a neural population.

Decoding Single Neuron Activity

Introductory article

James J Knierim, University of Texas–Houston Medical School, Houston, Texas, USA

CONTENTS

Neurons communicate with each other by firing trains of action potentials (spikes). Understanding what information is represented by this activity, and how to decipher the code in which the neural messages are encrypted, are the central issues of single neuron physiology.

INTRODUCTION

One of the most powerful techniques for deciphering the brain mechanisms that underlie cognition is the recording *in vivo* of single neuron activity with the use of microelectrodes. From low-level brain areas (such as primary sensory and motor cortex) to high-level areas (such as prefrontal cortex and hippocampus), single neuron recordings have provided a wealth of data about how information is processed and stored in the brain. One of the great challenges of neuroscience, however, is how to interpret the firing patterns of single neurons. Is information encoded in the average firing rate of neurons, in the precise temporal dynamics of a train of action potentials ('spikes'), or in some other parameter (or set of parameters)? Does the code differ depending on the brain area under study, the experimental task or stimulus at hand, or the amount of experience that the organism has? These questions are at the forefront of neurophysiological research.

REPRESENTING SPIKE TRAINS

Spike trains are usually represented in a few standard formats. Figure 1a shows an oscilloscope trace from an extracellular neuronal recording, with time on the x axis and spike amplitude (voltage) on the y axis. The line underneath the trace denotes the presentation time of the stimulus used to evoke a response from the cell. There are a number of discrete spikes of different amplitudes that rise above the baseline level of activity; each amplitude level presumably corresponds to the firing of a different neuron. Let us concentrate on the cell that fires the largest spikes in the example (denoted by asterisks). The neuron fired few spikes in the periods before and after the stimulus presentation; the rate of firing in the absence of stimulation is referred to as the background level or spontaneous activity level. When the stimulus was presented, the neuron fired a rapid series of spikes. There was a burst of activity shortly after the onset of the stimulus, and the activity decreased over time (although in some neurons the response might stay strong throughout the duration of the stimulus). These raw recordings are usually converted to a number of formats to represent the spike trains. Figure 1b is a spike raster plot from five repetitions of the same stimulus. The first line of the raster is a representation of the oscilloscope trace in Figure 1a. Each mark corresponds to the firing of a spike at that particular time. The neural responses to further repetitions of the stimulus are shown in the subsequent lines. As all responses are aligned to the onset of the stimulus, notice that the first spike of each response can occur after a variable delay period (see below). (*See* **Single Neuron Recording**)

Such spike rasters can be converted into a peristimulus time histogram (PSTH), representing the cumulative firing of the neuron over many trials (Figure 1c). The trial is divided into a series of time bins aligned to the onset of the stimulus, and all of the spikes that occurred within a time bin are summed to create the PSTH. Figure 1c illustrates two superimposed histograms (one black and one shaded), each corresponding to a different stimulus, making it clear that the neural response to one stimulus was greater than the response to the other. Finally, the PSTHs of many neurons can be averaged together, as in Figure 1d. Although the single

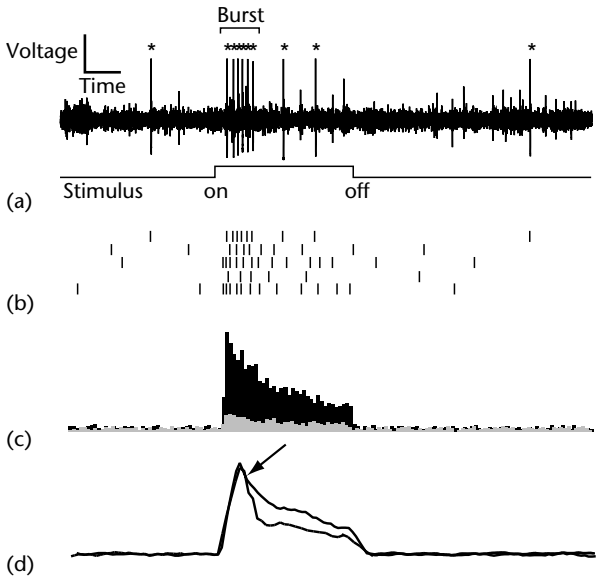

Figure 1. Representations of spike trains. (a) Oscilloscope trace of spikes. (b) Spike raster diagram. (c) Peristimulus time histogram. (d) Peristimulus time histogram averaged over a population of neurons.

neuron in Figure 1c had very different responses to the two stimuli, Figure 1d demonstrates that the average response of a population of many neurons did not distinguish the two stimuli as strongly; moreover, the average response was equal during the initial part of the response, and the difference in response became apparent only after a delay period (arrow). Such population averages provide a 'snapshot' of the overall neural population response to a stimulus or to a behavioral event, which sometimes may prove more informative than the response of any single neuron. (*See* **Decoding Neural Population Activity**)

As understanding of neural firing properties increases and theoretical advances occur, more sophisticated mathematical techniques are being employed to represent spike trains and to decipher the information they encode. Such approaches include the use of information theory to quantify rigorously the amount of information encoded in a spike train, and computational modeling to simulate how neurons or networks of neurons represent and store information. A growing legion of physicists, mathematicians, computer scientists and engineers are joining traditional neuroscientists to develop the analytical tools that will be necessary to understand fully the firing patterns of neurons. (*See* **Information Theory**)

SOURCES OF NEURONAL VARIABILITY

It is obvious from Figure 1b that there is a large degree of variability in the spike trains elicited on each of the five trials, both in the number of spikes fired on each trial and in the temporal pattern of spikes. Such variability is ubiquitous in the brain and derives from two broad sources. The first source is the set of uncontrolled variables that are present in a particular experiment. These uncontrolled variables may be behavioral variables in an alert animal preparation (e.g. changes in the animal's attentional state, changes in gaze direction, and changes in arousal or motivation); stimulus parameters that may change slightly from trial to trial; or other factors, such as changes in anesthesia level in an anesthetized preparation. The second source derives from properties that are intrinsic to the neuron or neural network. For example, the stochastic nature of the opening and closing of individual ion channels may contribute to whether a neuron that is near firing threshold actually generates a spike at a particular time. As a second example, repeated presentations of a stimulus can cause an adaptation of the response, in which the response strength decreases over time as the result of changes in biochemical cascades within a neuron or in the strengths of synaptic connections in the network. Of these intrinsic sources, it is useful to distinguish random sources (e.g. the stochastic properties of single ion channels) from deterministic sources (e.g. response habituation).

MOST EFFECTIVE STIMULI

The spike trains illustrated in Figure 1 are often reduced to a single number, the firing rate, by dividing the number of spikes in a certain period by the length of that period (e.g. the amount of time that the stimulus was presented). Neurons are often characterized by the type of stimulation that produces their greatest rate of firing. For example, the responses of a neuron in the visual cortex to different colors of light can be plotted as a tuning curve that illustrates the overall response selectivity of the cell. Figure 2 illustrates a hypothetical cell that fired strongly to a green light, with little or no response to light of other wavelengths. Such a cell is said to be tuned to, or selective for, a particular stimulus. In contrast, a second cell responded very similarly to wavelengths of all colors. This cell is said to be nonselective for color, although it might

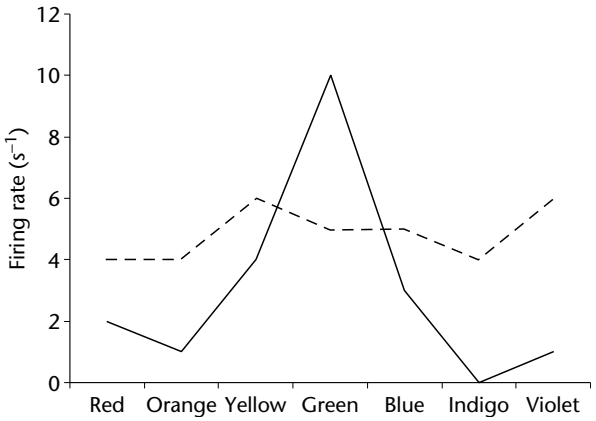

Figure 2. Hypothetical tuning curves for visual neurons. The solid line represents a neuron that is selective for the color green; the dashed line represents a neuron that is not selective for color.

be selective for some other parameter (for example, the size of a stimulus). The characterization of the most effective stimulus for a particular neuron is one of the most prevalent and important analyses of single-unit data. Neurons have been identified in the visual cortex that are selective for color, size, depth, speed of motion, direction of motion, spatial frequency, and other, more complex, properties of visual stimuli. Neurons in the auditory system can be selective for sound frequency, loudness, or the spatial location of a sound source. Neurons in the thalamus and limbic cortex can be selective for the direction in which the animal is facing. These are a few examples of the many different types of selective responses displayed by neurons in different parts of the brain.

Although this type of research is important, a few caveats are necessary. First, finding a cell that is selective for color, for example, does not necessarily mean that the function of the cell is color perception *per se*. The neuron may be part of a network that is actually involved in extracting information about boundaries between objects based on differences in color between the two objects. Second, finding the most effective stimulus that drives a neuron is limited to the set of stimuli that are tested in a given experiment. Thus, a cell may respond best to a red spot of light when tested against other spots of light, but its true function may be related more closely to the perception of complex three-dimensional shapes. If the neuron's response to such shapes is never tested, however, the investigator may incorrectly attribute color selectivity as the primary correlate of that neuron. This point leads to the third caveat, which is that neurons often are tuned along multiple stimulus dimensions. Thus, a cell may be sharply tuned to red on the color dimension, horizontal on the orientation dimension, and far away on the depth dimension. Is such a cell specifically tuned for a horizontally oriented, red bar that is located far away from the observer? Or does this cell act as a filter for many different stimulus parameters in a multiplexed, population code? Most current thought favors the latter interpretation, but how the cell performs this task and how the brain interprets the code is not well understood.

REVERSE CORRELATION METHODS

The analyses described above are based on the methods of presenting a set of discrete stimuli to the animal and measuring the response to each member of the set. Another powerful method of finding the most effective stimulus for a cell is to record the activity of a neuron continuously, during behavior or during the presentation of a continuous stream of stimuli, and to use the method of reverse correlation to determine what aspect of the behavior or stimulus drove the cell to fire. For example, a neuron in visual cortex might be recorded while an animal views a succession of scenes on film. Whenever a spike occurs, the frame displayed at that moment is tagged. After the presentation of the whole film sequence, each tagged frame is analyzed to find the common element (or elements). One way to do this would be to create a prototypical tagged frame by averaging each pixel from all of the tagged frames. If the averaged frame showed a vertically oriented edge, one might infer that the cell was acting as a filter for vertical orientation. As another example, cells in the hippocampus of rats can be recorded as the animal freely explores an environment. For each spike, the spatial location of the animal is recorded, and by reverse correlation of the spikes of the cell with the position of the rat, it can be shown that the cell fires whenever the rat enters a particular part of that environment. Each pyramidal cell in the rat hippocampus fires in different selected regions of different environments, and this finding was one of the principal lines of evidence for the cognitive map hypothesis of hippocampal function. (*See* **Place Cells**)

ENCODING VERSUS DECODING

It is important to distinguish the encoding of neural activity from its decoding. This discussion has so far been concerned mainly with the former operation; that is, how does the brain take information

(either from the external world via sensory receptors or from other brain areas) and transform it into a representation made of spiking neurons. The other side of the problem is understanding how the brain later on decodes this representation. To understand encoding, we want to know how a neuron will respond to a particular stimulus:

$$\text{stimulus} \rightarrow \text{neural response}$$

To understand decoding, we want to know how a downstream neuron interprets this neural response in order to determine what stimulus produced the response:

$$\text{neural response} \rightarrow \text{stimulus}$$

These two processes can be thought of in terms of probabilities, and they can be related by an equation known as Bayes' rule:

$$P(\text{stimulus}|\text{response}) = P(\text{response}|\text{stimulus}) \times P(\text{stimulus})/P(\text{response}) \quad (1)$$

where $P(\text{stimulus}|\text{response})$ is the probability that a particular stimulus was presented given that the neuron produced a particular response (decoding); $P(\text{response}|\text{stimulus})$ is the probability that the neuron produced that response given that the particular stimulus was presented (encoding); $P(\text{stimulus})$ is the general probability of the animal being presented with that particular stimulus out of all possible stimuli; and $P(\text{response})$ is the general probability of the neuron producing that response regardless of what stimulus is presented. (*See* **Neurons, Representation in**)

Understanding encoding is a prerequisite for understanding decoding, and much research focuses on exactly what coding schemes are used by neurons. For example, one of the great debates of neurophysiology is the degree to which the firing of neurons constitutes a rate code or a temporal code: is the information encoded by neurons contained in the firing rate of the neuron, averaged over a certain time interval, or is the information contained in the precise temporal pattern of spikes emitted by the neuron? How neurons perform the decoding operation is also a subject of much research. Although the complexity of the brain and the complexity of cognitive behavior combine to make these tasks daunting, they are necessary for a complete understanding of the brain mechanisms that underlie cognition. Descending Motor Tracts

Introductory article

Michael Peters, University of Guelph, Guelph, Ontario, Canada

CONTENTS

The human ability to 'compose' new kinds of movement allows us to speak and to generate technology. Evolutionary changes in the descending motor tracts and especially the corticospinal tracts lie at the core of this ability.

INTRODUCTION

Action implies movement, and movement is implemented by nerve tracts that descend from the brain to the spinal cord, where they activate motor neurons. The activation can take place by direct contact of the terminals of the tracts on motor neurons, or indirectly, by termination on 'interneurons' in the spinal cord which then activate the motor neurons. Motor neurons are cells that directly activate muscle contraction. Movement ranges from simple reflexive responses to highly complex voluntary movement, and to serve this range of movement, a number of descending tracts are needed.

THE CORTICOSPINAL TRACTS

Of all descending motor pathways, the corticospinal pathways are by far the most massive. In humans there are about a million corticospinal fibers on each side, although there is considerable variability, with values as low as 750 000 and as high as 1 400 000. The vast majority of these fibers cross over from one side to the other, in the pyramidal decussation. The fibers in the corticospinal tract that cross over to the contralateral side form the dorsolateral corticospinal tracts (or funiculi) in the spinal cord (Figure 1). These tracts are thought to be primarily involved in the control of muscles in the distal parts of the limbs (especially the muscles that operate the hand). A minority of fibers originating from the left hemispheres of the brain descend in the left half of the spinal cord. These fibers are largely found in the ventral and medial portion of the spinal cord (Figure 1) and form the ventromedial or anterior corticospinal tracts. The proportion of fibers that remain uncrossed is variable from individual to individual, ranging from individuals in whom the normally crossed portion descends ipsilaterally, to individuals who lack an ipsilateral portion of that tract. The ventromedial corticospinal tracts are largely concerned with the central parts of the body, such as the torso.

Source of Corticospinal Tract Fibers

Where do the corticospinal tract fibers come from and where do they go to? The majority of the fibers come from the cortex that lies anterior to the central fissure. Immediately anterior to the central fissure is the primary motor cortex (usually referred to as M1). Primary motor cortex means the area of the anterior cortex that was first recognized as being specialized for motor function because stimulation in this area would produce movement in the limbs. This is the area from which the densest fiber projections are sent towards the spinal cord. Anterior to the M1 lie several other motor areas. Current work with primates suggests that there are at least seven of these areas. One of these, the supplementary motor area (SMA) also contains a rough topographical map of the body musculature, like the M1 area, and the SMA also sends fibers directly to the spinal cord. Other motor areas are collectively called premotor cortex. Some of these send fibers directly to the spinal cord and others connect to each other and the M1, without any direct output to the spinal cord. In humans, the corticospinal tract fibers that come from anterior of the central fissure amount to some 80% of the tract, with some 20% originating posterior to the central fissure. In monkeys the ratio is closer to 60:40, indicating a relatively greater weight on motor cortex origin in humans.

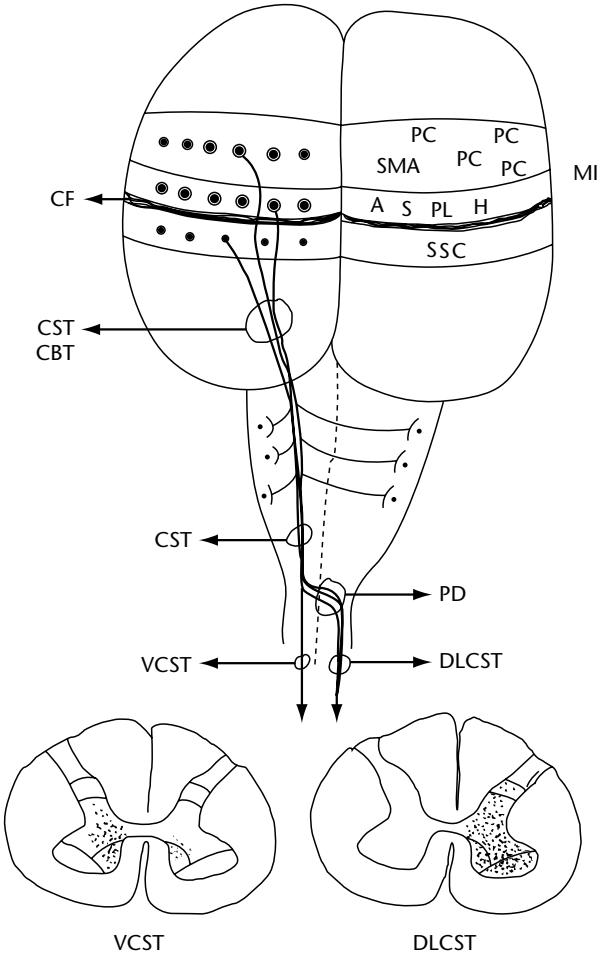

Figure 1. Origin and path of corticospinal and corticobulbar fibers. The bulk of fibers (80%) run from the cortex anterior to the central fissure and 20% from the somatosensory cortex. The bulk of corticobulbar fibers contact the motor nuclei of the nerves that control movements of the head and neck, eyes, facial musculature, jaws and tongue. Some corticospinal fibers do not cross the midline and descend on the ipsilateral (same) side, cross over to the contralateral side to descend the spinal cord as the ventral (anterior) corticospinal tract (VCST). The bulk of corticospinal fibers cross to the opposite side in the pyramidal decussation and descend as the dorsolateral corticospinal tract (DLCST). In the primary motor cortex (M1) there is a topographical relation to body parts, where 'A' denotes axial – the midline parts of the body, 'S' denotes the shoulders, 'PL' denotes the proximal limbs and 'H' denotes the hand. The two spinal cord sections (see Figure 2) show the terminations of the two corticospinal tracts. VCST ends mostly in the ipsilateral intermediate region, on premotor neurons concerned with the axial and proximal parts of the body. DLCST terminates throughout the grey matter, on sensory interneurons, premotor neurons in the intermediate region and on the motor neurons for proximal and distal body parts. Dots in the spinal cord section show predominant terminations of corticospinal fibers. The size of dots in the originating cortical areas indicates the relative contribution of those areas to the descending tracts. Abbreviations: CBT, corticobulbar tract: CF, central fissure; CST, corticospinal tract; MI, primary motor cortex; PC, premotor cortex; PD, pyramidal decussation; SMA, supplementary motor area; SSC, somatosensory cortex.

Destination of Corticospinal Tract Fibers

The termination of corticospinal fibers in the spinal cord reflects their region of origin (Figure 2). Fibers that terminate in the dorsal horn, where the sensory relay cells are located, come mostly from the sensory cortex, posterior to the central fissure. Fibers that terminate on the premotor neurons in the intermediate zone come mostly from the premotor cortex anterior to the primary motor cortex. Finally, fibers that terminate on the motor neurons in the spinal cord come mostly from the primary motor cortex. That fewer components of the corticospinal tract in humans originate from the sensory cortex is supported by the observation that fewer corticospinal tract fibers terminate in the dorsal horn of the spinal cord than is the case for monkeys. While humans share with other primates direct terminations of the corticospinal tract fibers on motor neurons that innervate finger muscles, humans are unique in also having direct terminations on the motor neurons that operate the thoracic musculature. This is needed because of the precise use of the thorax as a 'bellows' in speech.

Finally, descending corticospinal tract fibers end in the gray matter of the spinal cord in an orderly fashion, such that the termination on motor neurons that activate distal muscles, such as hand muscles, is located laterally (that is, near the left or right outer edges of the ventral part) in the gray matter. In contrast, fibers that activate muscles that operate the center of the body, such as the torso, terminate medially (that is, in the gray matter close to the center of the spinal cord).

Loss of the Corticospinal Tracts

Thorough observations about what happens after the corticospinal tracts are severed are only available for monkeys, because in humans accidental damage to the corticospinal tracts is rarely restricted to these tracts. In monkeys with destruction of the pyramids – and therefore of the cortical spinal tracts – there are extremely severe deficits immediately after the damage. However, recovery does take place. Researchers observed a striking

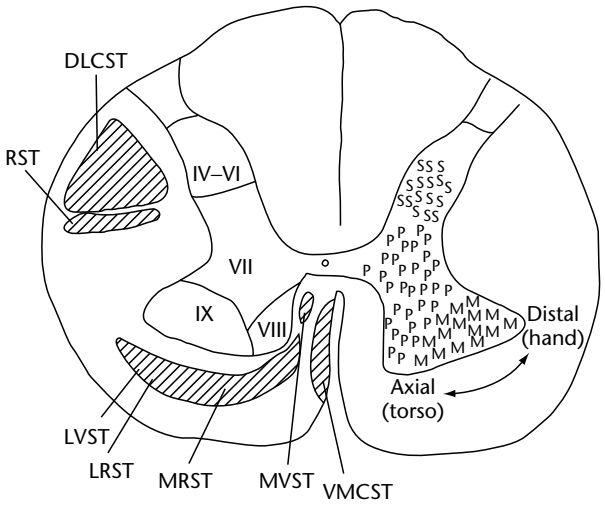

Figure 2. Cross-section of the spinal cord. The central butterfly-shaped region contains mostly cell bodies, and is know as the 'gray matter'. Around it lie the regions through which fiber tracts descend and ascend in the spinal cord, known as 'white matter'. The left half of the section shows the regions or Lamina of Rexed, and the right half shows the major contents of these regions. Cross-sections vary in appearance depending on the level at which the cord is cut. This level is roughly in the region of the shoulders. Motor neurons are arranged in a rough topographical order. The terms 'distal' and 'axial' denote the location of motor neurons that innervate distal portions of the body, such as the hand, and axial portions, such as the torso. Abbreviations: S, sensory neurons in the dorsal horn; P, intermediate region of the gray matter that contains mostly premotor neurons; M, motor neurons that connect directly to muscles. DLCST, dorsolateral corticospinal tract; LRST, lateral reticulospinal tract; LVST, lateral vestibular tract; MRST, medial reticulospinal tract; MVST, ventral vestibulospinal tract; RST, rubrospinal tract (very small in humans); VMCST, ventral or anterior corticospinal tract.

difference in recovery between movements that involved walking and climbing, and movements of the individual fingers. Ultimately the animals were able to walk and climb relatively well, even though the movements remained slow and there were signs of fatigue. In addition, independent movements of the arms recovered so that the animals could reach for food quite quickly and accurately. What did not recover, however, was the ability to use manipulative individual finger movements in, for instance, winkling a morsel of food out of a hole with a single finger. Interestingly, there were also difficulties with releasing an item of food once it was grasped with the whole hand even though the animals had no trouble grasping and releasing a bar of the cage during climbing. All of this suggests a prominent role of the corticospinal tracts in the voluntary execution of precise and independent finger movements.

A final observation concerns the capacity for recovery in animals with sparing of some corticospinal tract fibers. Individual finger movement seems to recover regardless of the precise location of the spared fibers in the tract. This suggests a remarkable plasticity in the role of descending corticospinal fibers, allowing considerable room for reorganization in the relation between corticospinal tract fibers and their target neurons.

THE CORTICORUBROSPINAL TRACT

While it is true that the corticorubrospinal connections show much less prominence in nonhuman primates and humans than in subprimate species, it is also true that the red nucleus itself remains undiminished in relative size. The answer to this puzzle lies in the nature of the red nucleus. It has a magnocellular (large-celled) part that is associated with the contralaterally descending corticorubrospinal tract, and appears to be involved in the direct control of limbs. It also has a parvocellular (small-celled) part that does not seem to be involved in projections to the spinal cord and also seems to play no part in the direct control of the muscles. Instead, this part is richly interconnected with the cerebellum. It is this part that has grown at the expense of the magnocellular part in primates, especially in humans (Figure 3).

Loss of the Corticorubrospinal Tract

In monkeys, selective lesions of the rubrospinal tract lead to slowing of movement as well as limpness and weakness in the hands. However, these problems show recovery to the point where no deficits are noted. If the rubrospinal tract is damaged on one side after loss of the corticospinal tracts, there are permanent problems with the ability to perform those hand and arm movements that showed recovery after corticospinal tract loss. Thus, the animals were no longer able to close the affected hand around a morsel of food, and reaching movements were poor. For instance, if animals were held close to the bars of the cage, they would try to move the affected arm into position by moving the shoulder rather than making use of the arm itself. In contrast, the animals could use the hand for climbing and clinging onto a bar even though there was weakness in the affected hand. In addition, animals showed the ability to right themselves and body posture was relatively normal.

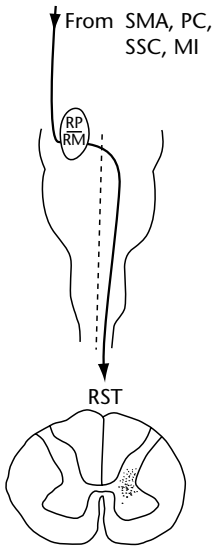

Figure 3. The cortical input from the supplementary motor area. The fibers from the RM cross the midline and descend as the rubrospinal tract (RST) in the spinal cord. They are shown to terminate mostly on premotor neurons in the intermediate region of the gray matter. PC, premotor cortex; SSC, somato-sensory cortex; MI, primary motor cortex to the large-celled portion of the red nucleus; RM, magnocellular portion of red nucleus; RP, parvocellular portion of red nucleus.

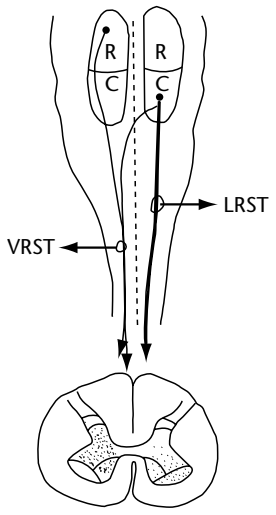

Figure 4. Two of the reticulospinal tracts are shown, in a much simplified form. VRST, ventral reticulospinal tract; LRST, lateral reticulospinal tract; R, rostral (toward the top of the brain) portion of the reticular formation; C, caudal (toward the spinal cord portion of the reticular formation).

However, the arm on the side affected by the lesion was not held in a normal position but hung loosely from the shoulder.

It is clear that postural control of the body is managed by a system other than the corticorubral or the corticospinal system, because such control survives loss of both of these systems.

THE VENTROMEDIAL BRAINSTEM–SPINAL SYSTEM

Several tracts originate in the brainstem, notably from the reticular formation in the region of the medulla oblongata and the region of the pons (Figure 4). Another important component of this system comes from the vestibular nuclei. There are two separate paths within the reticulospinal system; one originates more dorsally and rostrally in the reticular formation and descends ipsilaterally in the medial reticulospinal tract, while a more caudal and ventral portion descends bilaterally in the lateral reticulospinal paths. One hint as to the possible roles of these tracts comes from the observation that axons from neurons in the reticulospinal tract may make contact with target neurons in the region of the spinal cord where information flows out to the forelimbs (cervical level) and then continue to regions concerned with the hind limbs (lumbar levels). In addition, axons may also send collateral branches across the midline. It is likely that these pathways not only manage basic locomotion and postural adjustments but are also involved in the integration of these more basic motor behaviors with voluntary movement.

Loss of Function in the Reticulospinal System

Damage to the descending paths from the reticulospinal tracts and parts of the vestibulospinal tracts in monkeys leads to lasting impairment in body posture and movements. The animals walk unsteadily, and limbs and the trunk are flexed. The shoulders are raised; the head is not held upright in the normal position and falls forward. When the animals jump toward the bars of their cage, they often miss and when they reach for a morsel of food, they cannot move the hand smoothly toward the target. This is due to an ataxia (problem with muscular coordination) in the portions of the arm close to the body. In contrast, once the hands are near a target, the animals can perform delicate individual movements of the fingers; this would be expected because the corticospinal tracts are intact.

The description of the behavior of these animals provides the clearest illustration of the principle that in order to function properly, the corticospinal tracts need the support of the reticulospinal system.

Thus, the increased specialization of the corticospinal system in the guidance of voluntary and skilled movements in human as opposed to nonhuman primates does not render this 'older' system obsolete in humans. If anything, because the requirements of 'composing' and learning new movements demand strong support by the postural and integrative contributions of the brainstem–spinal systems, these systems are as important as ever.

CONTENTS

Neuronal interspike intervals can be characterized in terms of the first-passage time probability density of stochastic diffusion processes under steady state and periodic stimulation. The Wiener and Ornstein–Uhlenbeck models, and models with multiplicative noise, can be used to elucidate neuronal activity.

INTRODUCTION

One of the basic modes of signaling in the nervous system is by the frequency of action potentials. This is true even if the input signal is time-varying, in which case the firing rate is expected to be modulated in time to reflect the time course of the input. The rate coding that is introduced via the stochastic description of single neurons is the focus of this article. A common way to introduce stochasticity is by the assumption that the incoming signal includes a random component, generally denoted as 'noise'. Another source of stochasticity can originate in the neuron itself, where a random component is added to the signal. Taking these circumstances into account, one is led to the conclusion that the deterministic differential equations usually describing the membrane response should be completed by insertion of a noise term, thus becoming stochastic differential equations. The solutions of such equations, under certain regularity conditions on their coefficients, can be viewed as 'sample paths' or 'realizations' of stochastic processes belonging to the class of 'diffusion' processes. This is the rationale for the rise of diffusion models for the description of neuronal activity. Here, the center of interest is single-point models of interspike intervals generation. Such a one-point representation implies severe restrictions, discussed below. This type of simplification neglects the spike's duration and its detailed shape, so that the entire neuronal activity is schematized in the form of identical point-size signals occurring in time according to a stochastic point process. On the other hand, it permits us to quantify not only the mean of the spiking activity, but also its variability – even its probability distribution.

DETERMINISTIC LEAKY INTEGRATE-AND-FIRE NEURONAL MODEL

The electrical circuit model of a neuronal membrane is composed of a resistor and a capacitor in parallel charged by a battery (RC circuit). It can be described by the first-order differential equation

$$\frac{\mathrm{d}v(t)}{\mathrm{d}t} = -\frac{v(t)}{\tau} + i(t), \quad v(t_0) = v_0 \qquad (1)$$

where $v(t)$ denotes the difference between the membrane potential at time t and the membrane potential in resting conditions (i.e. the membrane depolarization), τ is the membrane time constant, $i(t)$ is the input to the neuron and v_0 is the initial voltage after spike generation that for simplicity – and without loss of generality – is sometimes set to zero ($v_0 = 0$). This is also known as the Lapicque model, or the RC circuit model. In this model, under a constant input, $i(t) = i$, as time grows to infinity the depolarization tends to the asymptotic level $i\tau$, and if the input is removed at some instant, say $i(t) = 0$, the depolarization tends exponentially to zero (i.e. to the resting level), the speed of approach to zero depending on time constant τ. The extreme simplicity of eqn (1) witnesses that the action potential generation mechanism is not an inherent part of the model, so that a firing threshold S, with $S > v_0$, has to be postulated. Within this model the neuron is assumed to fire whenever the threshold voltage is reached, and the membrane depolarization $v(t)$ is assumed to be instantly reset to v_0 after each firing. The interspike intervals (ISIs)

are identified with the first-passage time of $v(t)$ through S, namely with the variable

$$T = \inf\{t \geq t_0 : v(t) > S\}, \quad v(t_0) = v_0 < S \qquad (2)$$

In the case of a constant input, the condition for evoking a spike is $i\tau > S$, which defines suprathreshold stimulation. Otherwise the input is unable to produce a spike and the neuron remains silent. For a standard treatment of model described by eqn (1) see Keener *et al*. (1981) and Knight (1972).

STOCHASTIC LEAKY INTEGRATE-AND-FIRE NEURONAL MODEL

One of the stochastic versions of eqn (1), of interest in the present context, is formally obtained by adding to the right-hand side a term to account for the random components that are present as a part of the global signal acting on the neuron. This random component is usually identified, as a useful approximation, with the 'white noise' $\xi(t)$:

$$\frac{dv(t)}{dt} = -\frac{v(t)}{\tau} + i(t) + \sigma\xi(t), \quad v(t_0) = v_0 \qquad (3)$$

By definition, the white noise is a stationary Gaussian process characterized by zero mean and delta-type correlation function. In eqn (3) σ is a positive parameter representing the amplitude of the random fluctuations of the noise, a sort of measure of the degree of unpredictability of the deviations of the noise sample paths from its mean trajectory. Although the mathematical definition of the process $\xi(t)$ is a rather complicated and subtle issue, by analogy with white light as the superposition of all colors, the white noise may be intuitively envisaged as a random process in which spectral components of all frequencies are present and equally represented. For constant $i(t)$ the process defined in eqn (3) is called the Ornstein–Uhlenbeck model of the membrane potential. Its properties in the absence of the firing threshold are as follows: (1) at each time the probability density function of the membrane depolarization is Gaussian; (2) an equilibrium regime exists since in the limit, as $t \to +\infty$, the probability density function that describes the membrane depolarization attains mean $i\tau$, and variance $\tau\sigma^2/2$. Note that the asymptotic variance is independent of the input signal.

Generation of an action potential in the model defined in eqn (3) is again described by the first-passage time of the trajectories of the process across the firing threshold S, i.e. by the random variable (eqn (2)). However, since now the trajectories are different realizations of the stochastic diffusion process modeled by eqn (3), the ISIs are of different length even for constant input. Thus T is a nondegenerate random variable. For this model under constant input $i(t) = i$, as well as for others, the neuronal output is a renewal process, namely intervals between successive firings are independent and identically distributed random variables. Note that now, in contrast with model (1), spikes can be generated due to the presence of noise even for subthreshold stimulations.

Figure 1 depicts the spike generation process. It indicates the effects of a constant stimulation of magnitude i. In the absence of noise (Lapicque model), the depolarization grows exponentially towards the asymptotic value $i\tau$. However, as soon as the neuron's threshold S ($S < i\tau$) is reached, a spike is generated and the depolarization is instantly reset at its initial value. The process then starts afresh. Within such a model, a rigorously periodic sequence of spikes (arrows, Figure 1) at time T, $2T$,… is generated. In the case of the leaky integrate-and-fire model (cf. eqn (3)) the presence of noise alters dramatically the picture, in that the trajectories of the neuron's depolarization now exhibit an erratic time course. In Figure 1 three such trajectories are plotted and the instants t_1, t_2, t_3 of attainment of threshold S are indicated together with the corresponding generated spikes. The first-passage time of the process modeling the neuron's depolarization is now a random variable whose probability density function mimics the probability density of the ISIs. Figure 2 shows an ISI histogram for a finite number of trajectories, and the ISI probability density obtained when all possible trajectories are taken into account.

The properties of this model, including the moments of the random variable T, are complicated (Ricciardi, 1977; Ricciardi and Sacerdote, 1979). Inoue *et al*. (1995) have attempted to compare systematically this model with experimental data, and Lánský (1983) describes a method to estimate parameters based on intracellular recording of the trajectories of $v(t)$.

Until recently the models encountered in applications of stochastic diffusion processes to neuroscience have been predominantly time-homogeneous, reflected by the circumstance that i and σ in eqn (3) do not depend on time. An interest in stochastic resonance (a cooperative effect that arises out of the coupling between deterministic and random dynamics in nonlinear systems) evoked studies on diffusion neuronal models with time-dependent parameters. Analogous to the model in eqn (1), the Ornstein–Uhlenbeck model operates in two distinct regimes – the deterministic

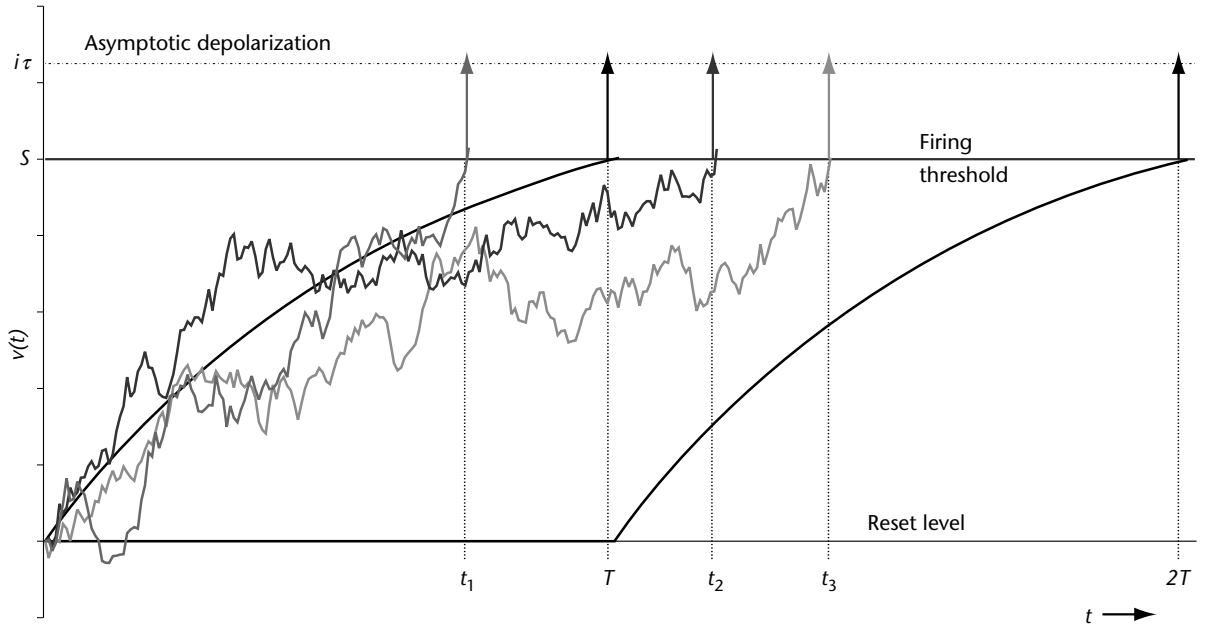

Figure 1. Spike generation mechanism for Lapicque and stochastic leaky integrate-and-fire models.

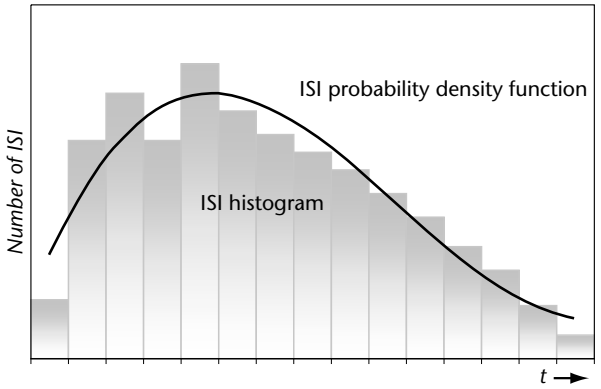

Figure 2. An interspike interval (ISI) histogram and the corresponding first-passage time probability density.

one (suprathreshold stimulation) and the stochastic one (subthreshold stimulation). In the first regime the signal $i(t)$ is large enough, and thus the firing events occur even in the absence of noise, the effect of which is merely to distort the output. In the second (noise-activated) regime the signal alone is insufficient to cause a firing, but the noise itself contributes to activating the neuron. The methods of stochastic resonance extend this view mainly for subthreshold periodic signals. Two sources of periodicity can be expected in the signal: either an endogenous periodicity, or a periodicity of external input, the exogenous periodicity (Lánský, 1997). In both cases, an optimum level σ of noise exists, for which the input frequency is best reflected in the output signal (Bulsara *et al*., 1996; Shimokawa *et al*., 1999). Another type of nonhomogeneity in model (3) is achieved if the natural assumption is made that the amplitude of the noise depends on the signal (Lánský and Sacerdote, 2001). All generalizations mentioned in this section can be applied to any stochastic neuronal diffusion model.

WIENER PROCESS AS A NEURONAL MODEL

If the time constant τ is very large ($\tau \to +\infty$), then eqn (3) takes the form

$$\frac{\mathrm{d}v(t)}{\mathrm{d}t} = i(t) + \sigma\xi(t), \quad v(t_0) = v_0 \tag{4}$$

This is called the Wiener neuronal model. Although eqn (4) can be taken as a definition of this model, it can also be obtained from first principles using the formalism of diffusion equations. To this purpose, let us initially assume that the neuron is subjected to a sequence of excitatory and inhibitory postsynaptic potentials of constant magnitudes $a > 0$ and $b < 0$ occurring in time in accordance with two independent Poisson processes. The membrane potential is thus viewed as a stochastic process $X(t)$ in continuous time with a discrete space consisting of the lattice $x_0 + ka + hb (h, k = \ldots, -1, 0, 1, \ldots)$ with the points of discontinuity randomly occurring in time. Ricciardi (1977) shows that if the input rates are taken larger and larger while simultaneously taking smaller and smaller postsynaptic potentials with

suitable constraints, the membrane potential 'converges' to the diffusion process generated by eqn (4). This was the method initially used in the well-known paper by Gerstein and Mandelbrot (1964), in which the diffusion approach to neuronal modeling was first considered. By including the spontaneous decay of the membrane potential, which is reflected by a finite value of the time constant τ, in this model with discrete jumps, model (3) can be derived as well.

The basic properties of the Wiener model with constant input, $i(t) = i$, are the following: the distribution of the membrane potential at any instant is normal, with mean $it + v_0$ and variance $\sigma^2 t$. Hence, there is no steady state distribution of the membrane potential, in contrast to the Ornstein–Uhlenbeck model. By means of the methods outlined for instance in Ricciardi (1977), one can prove that the first-passage time density function of the Wiener model is given by

$$g(t|v_0, S) \equiv \frac{\partial}{\partial t} Prob\{T < t\} = \frac{S - v_0}{\sigma\sqrt{2\pi t^3}} \exp\left\{ -\frac{(S - v_0 - it)^2}{2\sigma^2 t} \right\} \qquad (5)$$

which is known in statistical literature as the inverse Gaussian distribution. In this model, for $i \geq 0$, neuronal firing is a sure event. If one takes $i < 0$, density (5) can be interpreted as the firing density conditional upon the event 'firing occurs'. The form of the density (5) permits evaluation of the moments of the ISI and the firing rate, as well as estimation of the parameters of the model. The assumptions of model (4) are oversimplified and many important electrophysiological properties of neuronal membrane are not taken into account. Therefore, the Wiener process is more suitable as a statistical descriptor of the data than as a realistic biological model.

GENERAL DIFFUSION MODELS

Consider a general deterministic model characterized by the dynamic equation

$$\frac{\mathrm{d}v(t)}{\mathrm{d}t} = h(v, t) + e(v, t)i(t), \quad v(t_0) = v_0 \qquad (6)$$

where $i(t)$ is an input, $e(v, t)$ describes the effect of this input on the depolarization and $h(v, t)$ is the function describing the rate of change of the depolarization in the absence of input. Both e and h are assumed to be sufficiently smooth functions. Then if $i(t)$ can be written as the sum of signal and white noise, more general models than those previously considered arise (Hanson and Tuckwell, 1983). It is indeed a well-known fact, also reflected in the Hodgkin–Huxley model, that the change of the membrane depolarization by a synaptic input depends on its actual value. Basically, the depolarization of the membrane caused by an excitatory postsynaptic potential decreases linearly with decreasing distance of the membrane potential from the excitatory 'reversal potential', say V_E. In the same manner, the hyperpolarization caused by inhibitory postsynaptic potential is smaller if the membrane potential is closer to the inhibitory reversal potential, V_I. In this way, unlike previous models, depolarizations are confined to finite interval (V_I, V_E). Natural conditions relating the reversal potentials, the initial depolarization and the firing threshold is $V_I < 0 < S < V_E$. The diffusion models, which take into account the existence of the reversal potentials result always in the multiplicative noise effect as in eqn (6). This is in agreement with the general notion that an additive noise is generated by external events that transmit messages, whereas the multiplicative noise is generated inside the processing unit, namely inside the neuron.

FEEDBACK, SPATIAL PROPERTIES AND REFRACTORINESS

The analogy of the process describing the time course of the neuron's membrane potential with the laws describing the diffusion of a substance in a liquid provides an intuitive justification for the use of the term 'diffusion model'. It must be stressed that the neuronal behavior described by diffusion models ultimately assumes that for time-constant input, the output is a renewal process. However, one can conceive models aimed, for instance, at simulating clustering effects in spike generation. Serial dependence among ISIs can be modeled in various ways, for instance by adjusting the reset value after each spike (afterhyperpolarization). Another possibility consists of inclusion into the model of some kind of feedback, usually self-inhibition, often experimentally observed. A further generalization is achieved by taking into account the spatial properties of a neuron. In the simplest way, it can be done by assuming that the model neuron is composed of two compartments: the dendritic compartment, described by a standard diffusion model, and the trigger zone compartment, including the spontaneous decay of depolarization and the firing mechanism. Also, the phenomenon of refractoriness can be included in stochastic diffusion models, usually by postulating the existence of time-varying thresholds,

instead of constant thresholds as assumed in the foregoing.

Disorders of Body Image

Introductory article

Giovanni Berlucchi, University of Verona, Verona, Italy
Salvatore M Aglioti, University of Rome, Rome, Italy

CONTENTS

Body image (or schema) is the complex of perceptions, beliefs, and representations about one's own body that is included in the notion of self. Amputations, cerebral lesions, and psychiatric disorders may induce dramatic alterations of this image.

INTRODUCTION

The ability to distinguish self from nonself is a hallmark of all living organisms. In its most elementary expression, in unicellular animals, the distinction is based on simple physicochemical reactions which serve nutritional and self-defence purposes. Multicellular organisms retain such simple reactions for the same purposes, but if they possess a complex brain (particularly a human brain), the self–nonself distinction takes up an entirely different meaning, insofar as it provides the basis for self-perception and personal identity.

Our brain is housed in a body that is at the same time the instrument of all brain-generated patterns of behavior, and the container of all sensory receptors that inform the brain about the external world and about the body. How can our brain distinguish sensory reports about the external world from those about our own body?

A seemingly logical hypothesis is that we know the external world through visual, auditory, and olfactory receptors, all of which respond to stimuli from objects remote from the body, while we know our body through the somatosensory receptors for touch, thermoception, nociception, and proprioception, all of which are acted upon by stimulants directly applied to the body itself. Accordingly, the physiologist Sherrington distinguished between exteroception, which informs the brain about the external world, particularly through the distance receptors, and interoception and proprioception, which inform the brain about states and changes of states in the body.

However, awareness of one's own body can be gained not only through interoception and proprioception, but also through distance receptors that monitor body postures and movements. Vision, for example, is a major source of information not only about the external world, but also about one's body parts that can be seen directly or through mirrors or other reflecting surfaces. Similarly, somatosensory receptors can supply the brain with direct information about the body, but can also be used to explore one's surroundings and to recognize objects by contact.

In short, all kinds of receptors and all sense organs can make their own special contributions to the separate representations of the body and the external world that the brain concurrently entertains.

SELF-CONSCIOUSNESS

Self-consciousness as awareness of one's own being refers to knowledge of one's own mind as well as to knowledge of one's own body. In contrast to purely mental views of self-consciousness, many current psychological and physiological approaches to the concept of self-consciousness emphasize the importance of the awareness of one's own body.

In the nineteenth century the psychologist William James stated that the nucleus of the self is always the bodily existence felt to be present at the time, and that the entire feeling of one's own mental activities is really a feeling of bodily activities, mainly in the head (motor adjustments of eyeballs, eyelids and eyebrows) and the throat (changes of breathing due to movements of the soft palate, posterior nares, glottis, and so on).

Modern analyses suggest that from earliest infancy, simultaneously perceived flows of multisensory information enable us to gain a realistic and accurate perception of the relations between our

own body and our physical environment. This perception, which is perhaps the earliest form of self-knowledge, is complemented – again at an early age – by the perception of reciprocated relations between our own behavior and that of other people: that is, by the sense of the self as an agent and target of social interactions. Babies a few weeks old engage in elaborated social exchanges, loaded with affective meanings, with their mothers and other individuals, and vocalize in response to heard language. Between one and two years of age, interactions with adults lead children to start to build up organized beliefs and memories, and to think that they have traits, attributes, and values. It is around this age that children not only develop language, but also begin to recognize themselves in a mirror – an ability that may be regarded as an objective index of self-consciousness (Figure 1). Among mammals, only humans, chimpanzees, and orangutans are thought to be endowed with the ability of mirror self-recognition.

BODY SCHEMA, BODY IMAGE, AND CORPOREAL AWARENESS

In classical neurology, notions about the functional representation of the body in the brain were first inspired by observations about postural regulation and perception. Even a minor movement of a single body part entails a widespread adjustment of the postural tone affecting most other body parts, suggesting that the brain keeps a moment-to-moment record of the postural state through the entire musculature. This usually unconscious record surfaces to consciousness when a person is asked to report a postural change imposed on the whole body or a part of it by an examiner.

The term 'body schema' was originally coined to denote this current internal model of one's own postural state, serving as the basis for the appreciation of subsequent postural changes. The term has later been extended to refer to a variety of normal performances which are indicative of a general awareness of the body, whether conscious or unconscious. In addition to the ability to appreciate active and passive postural changes and movements, such performances include the abilities to localize tactile stimuli, to move, name and point to specified body parts, and in general to map sensory inputs and motor outputs onto an orderly topographical model of the external anatomy of the human body.

All these abilities suggest the existence of a mental construct, termed 'corporeal or body awareness', which comprises the sense-impressions, perceptions, memories, and ideas about the dynamic organization of one's own body and its relation to other bodies. In current terminology sensory-perceptual components of corporeal awareness are preferentially named 'body schema', while conceptual and imaginative components are preferentially named 'body image'. This distinction, however, is not easy to make in practice, and the two terms are often used as synonyms. The term 'body image' is also employed to refer to the evaluative and emotional judgment, either self-appreciative or

Figure 1. Children begin to recognize themselves in a mirror at between one and two years of age. Before that, as shown by the behavior of this 7-month-old girl in front of the mirror, children tend to interact with their image as if it were another child.

self-critical, that one has of one's own body. Severe distortions of the body image are now thought to underlie psychogenic eating disorders, particularly the syndrome of anorexia nervosa in which people feel grossly fat even if they are extremely underweight.

The Extended Body Schema: Enlargement of the Body's Boundaries

Noncorporeal objects bearing some functional relation of contiguity to the body, such as clothes, ornaments and tools, may come to be felt as parts of the body itself. When one drives a nail into a wall with a hammer, the perceived end of the arm wielding the hammer is not the hand but the head of the hammer itself. This enlargement of the body's boundaries can be accounted for by the same mechanisms that are involved in the representation of the body *per se*. The execution of a voluntary movement of a limb under direct view activates a coherent multimodal representation of that limb in the body schema, based on the congruence between the internal knowledge of the moving command and the visual and proprioceptive feedbacks from the moving limb. An object held by the limb and moving jointly with it takes part in generating such feedbacks and is thus incorporated into the body schema.

A putative neuronal mechanism for including a noncorporeal object into awareness of the body has been found in the anterior parietal cortex of the monkey brain, where there exist neurons that respond to somatosensory and visual stimuli arising from the monkey's hands. If the monkey retrieves food with its hand, the visual receptive fields of these neurons are limited to that hand; but if the retrieval is helped by a rake, the visual receptive fields expand to include both hand and tool, as if they were a unified body part.

Vision and the Body Schema

Inanimate objects can be incorporated into the body schema even without visual feedback, as exemplified by the stick used by blind people for assistance in walking; but the importance of vision is evident from the fact that blindness, especially if congenital, can conspicuously distort the mental representation of the body.

Vision is also crucial for detecting the correspondence between a part of one's own body and the matching part of another person's body, as well as for the imitation of gestures and other movements. A strong innate tendency to imitate sounds and motor acts sets apart humans from other primates, and is probably a prerequisite both for social communication and for the self–nonself distinction. Hours or even minutes after delivery, babies can imitate orofacial and head movements performed by adult models in front of them. This deceivingly simple performance indicates that babies are able to identify a movement of a specific bodily part of the adult model, and to produce a similar movement in the corresponding part of their own anatomy.

This early capacity for visual imitation of elementary actions has suggested that humans are born equipped with a rudimentary body schema which during maturation undergoes a gradual refinement as a consequence of orderly interactions between visual, tactile, proprioceptive, and vestibular inputs. The latter inputs provide the sensory data for the appreciation of head position in the gravitational field, and for the detection of head acceleration and deceleration during linear and circular movements. In adults, the persistence of a systematic reciprocal relation between the visual perception of another person's body part and the representation of one's own corresponding body part is suggested by the finding that visual discrimination of postural changes in the arms of another person is facilitated during movements of the observer's arms but not legs, and vice versa.

Brain Regions Related to the Body Schema

The premotor cortex of the monkey contains neurons which become active when the monkey either performs a goal-directed movement or views a corresponding movement made by another monkey or human. These neurons, if present in the human brain, may provide a simple mechanism for the imitation of actions as well as for the detection of a correspondence between one's own body parts and the matching parts of another individual's body.

Analysis of cortical activation in normal observers during imitation of finger movements has suggested that a region of the left frontal lobe, corresponding to Broca's area, encodes the general goal shared by observed and imitated movements, whereas the precise kinesthetic representation of the same movements is encoded by specific regions of the right posterior parietal lobe, which may also distinguish between observed and self-produced movements.

Anatomically and physiologically the body is represented in a topographic fashion in somatosensory maps in the anterior parietal cortex,

corresponding to the sensory homunculus, and in motor maps in the posterior frontal lobe, corresponding to the motor homunculus, but the relations between these cortical homunculi and corporeal awareness is far from simple. According to Melzack, corporeal awareness relies upon a large neural network where the somatosensory cortex, the parietal lobe, and the insular cortex play crucial and different roles, as suggested by studies of functional brain imaging, brain stimulations, and brain lesions.

Functional brain imaging has shown that a posterior parietal system (superior parietal cortex, intraparietal sulcus, and the adjacent, most rostral part of the inferior parietal lobule) is involved in mental transformations of body in space. The insular cortex is also involved in body awareness, particularly in relation to emotional aspects of this. Insular lesions can cause somatic hallucinations, and electrical stimulation near the insula induces illusions of body position changes and feelings of being outside one's body. Lesions of the cortical sensory homunculus, or of the cortical motor homunculus, induce tactile, proprioceptive, and motor deficits, but there is no evidence that the body parts numbed or paralyzed by such lesions are eliminated from the mental representation of the whole body.

Body awareness may be altered in the context of a diffuse cognitive impairment involving general mental functions such as attention, memory or language; but can some kind of brain damage selectively impair body awareness in the absence of major deficits in other cognitive domains? A positive answer to this question is provided by the striking alterations or mutilations of the mental representation of the body that can be observed after lesions of the cerebral hemispheres, especially the right cerebral hemisphere and the posterior parietal lobe.

Cerebral Lesions and Body Awareness

Patients with lesions of the right posterior parietal lobe may show a neglect (failure to attend to stimuli) of the left half of their body or parts of it. In many cases such symptoms occur in the setting of a general neglect of the left hemispace, both personal and extrapersonal, insofar as patients do not respond to (or mislocalize) all kinds of stimuli coming from their left side. In these cases, neglect of the left half of the body is best attributed to an overall impairment of spatial attention or space representation rather than to a selective disruption of the body schema. In other cases, however, at least some disturbances may be so pronounced or selective as to hint at a specific alteration of body awareness in the form of a *hemisomatagnosia* – that is, a defective or absent knowledge of half of the body.

Patients with right posterior parietal lesions may fail to detect tactile stimuli to the left side of the body even in the absence of basic sensory impairments, or may refer such stimuli to a corresponding position on the right side. Such mislocalization is called *allesthesia* or, in the case of stimuli to the hand, *allochiria*. Patients may even fail to groom or dress the left half of the body, or leave the left half of the face unshaved.

A pathologic attitude towards conspicuous motor and sensory deficits caused by a right hemisphere lesion on the left half of the body may manifest itself in various ways. Patients may appear unaware of their severe deficits to the point of vehemently denying any impairment at all, or they may admit the existence of deficits but show a lack of concern regarding them, or, on the contrary, exhibit hatred for the affected limbs.

The most severe manifestation of neglect for the left body is *somatoparaphrenia*, a condition in which otherwise rational and objective patients exhibit feelings that a body part does not belong to them, and express a resolute denial of ownership of such part. The neglected or disowned body parts are expunged from the mental representation of the body, so that in order to account for the material existence of these parts the patients resort to improbable rationalizations and confabulations: for example, they may claim that their disowned arm belongs to the examiner or to the previous occupant of the hospital bed. Noncorporeal objects previously associated with a disowned hand and included in the body schema, such as a ring, are similarly disowned, although ownership of such objects is immediately acknowledged when they are removed from the disowned hand (Figure 2). Somatoparaphrenia following posterior parietal lesions may also manifest as a distinct and irrepressible feeling of the existence of supernumerary limbs on the affected body half, perhaps suggesting that different aspects of body awareness are localized in different components of the parietal cortex.

Neglect of one side of the body is most commonly observed following lesions of the right posterior parietal lobe, but may also occur following frontal, cingulate or insular lesions, as well as following subcortical lesions in thalamus and basal ganglia, again on the right. Reports of similar symptoms on the right side of the body following left hemisphere lesions are extremely rare. There is,

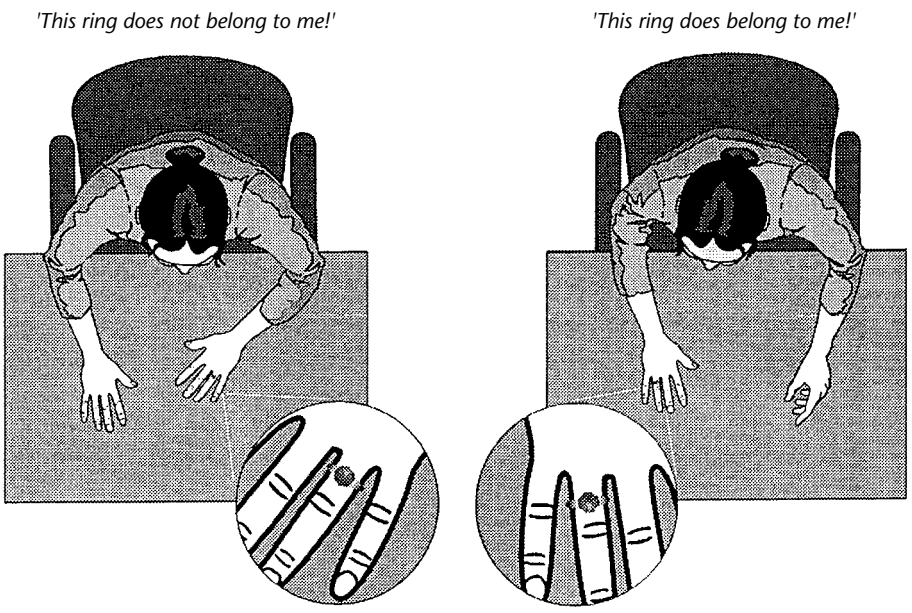

Figure 2. A patient with a right hemisphere lesion exhibited a strong denial of ownership of the left side of the body. She also denied ownership of a ring that she had worn on the left hand as long as the ring was on that hand, but she promptly recognized the ring as her own when it was moved to the right hand. (See Aglioti, Smania, Manfredi and Berlucchi (1996) Disownership of left hand and objects related to it in a right-brain-damaged patient. *NeuroReport* **8**: 293–296).

however, a rare alteration of body awareness, *autotopagnosia*, which seems to depend on a left parietal lesion. Patients with this condition are unable to point to parts of their own or other people's body on verbal command, a disability that cannot be imputed to mental deterioration or language incomprehension because patients can carry out successfully verbal commands unrelated to the body, such as 'touch the pedal of a bicycle'. These patients also have difficulties in describing the spatial relations between body parts: for example, they may say that the mouth is between the nose and the eyes.

Often the difference in efficiency between responses to body-related commands and responses to body-unrelated commands is relative rather than absolute, and it can be argued that at least some cases of autotopagnosia suffer from a general disability to analyze a whole into parts, though such disability is maximally evident in relation to the body.

Autotopagnosia may occur in the setting of the Gerstmann syndrome, also associated with left parietal lesions, which is characterized by dysgraphia (writing disturbances), dyscalculia (calculation difficulties), right–left disorientation, and finger agnosia, the latter being a specific inability to identify and differentiate the fingers of both hands. The relation between autotopagnosia and finger agnosia is a complex one, because patients classified as autotopagnosic may show no finger agnosia, and patients with finger agnosia may perform normally in response to verbal commands targeted to other parts of the body.

The contrast between the symptoms of deranged body awareness associated with left parietal lesions and those associated with right parietal lesions has prompted the following simplistic but effective hypothesis about the relation between the parietal lobes and body awareness: the left parietal lobe houses a conceptual representation of the body, strongly based on a linguistic mediation, whereas the right parietal lobe houses a spatial, nonverbal representation of the body.

Phantom Limb Phenomena

Many people who have undergone amputation report rich and vivid perceptions originating from the amputated body part, which often occur in the form of excruciating pain precisely referred to that part. These 'phantom' perceptions are most common following limb amputation, though they also occur after amputation of other body parts such as the breast in women or the penis in men. Moreover, people with a congenital absence of one or more limbs have been reported to experience phantom perceptions from the limbs that they have never possessed. Even though phantom perceptions are in some sense illusory, they are usually

so distinct and lifelike that patients can, for example, fall down in an attempt to walk with an amputated foot.

The analysis of phantom sensations provides important insights into the mechanisms of corporeal awareness. Peripheral activation of sensory nerves at the amputation scar can contribute to such experience, but there is clear evidence that phantom phenomena have major cerebral causes.

It has been proposed that phantom phenomena are primarily caused by the persisting activity of brain centers that have been deprived of their normal inputs, and by the brain's interpretation of this activity as originating from the lost part. The relevance of cerebral components in determining phantom perceptions is also suggested by their disappearance after lesions to the right posterior parietal lobe. The fact that phantom perceptions are most frequent and vivid following limb amputation is probably due to the functional relevance and the extensive cerebral representation of these body parts. A phantom limb may be perceived as identical in shape to the former real limb, thus suggesting that structures in the central nervous system are committed to the representation of that body part. Furthermore, the persistence of phantom limbs over decades after an amputation attests to a certain degree of stability of somatic representations. This strong tendency of the brain to maintain an intact representation of a lost body part, even a massive one, is perhaps an index of the preservation of the integrity of the self.

Changes in phantom sensations may reflect adjustments or reorganizational changes in the neural substrates representing the lost body part. Phantom limbs, for example, particularly when painful, may shrink in such a way that the hand is perceived as attached directly to the shoulder (the telescoping phenomenon). Complex dynamic aspects of the body schema are also revealed by the recent evidence in limb or breast amputees that vivid phantom sensations can arise as a result of tactile stimulations applied to body regions distant from the amputation line. Sensations in the phantom hand, for example, can be elicited by tactile stimuli delivered to the lower face on the side of the amputation. Like the concurrent veridical facial sensations, the evoked phantom sensations may convey precise information about different features of the facial stimuli. Given the representational contiguity of face and hand, phantom hand sensations from facial stimulation are probably caused by an appropriation of the original cerebral representation of the lost hand by sensory afferents to the adjacent face representation.

NEUROLOGIC OR PSYCHIATRIC DERANGEMENTS OF CORPOREAL AWARENESS

Body dysmorphic disorder, or *dysmorphophobia*, is an enduring excessive concern with a selected bodily flaw which is totally imaginary or grossly exaggerated. Targets for dysmorphophobic concerns may be the shape of the nose, the thickness of the hair, the size of the penis or breast, the appearance of the facial skin, and so forth. Some individuals with dysmorphophobia are aware of the absurdity of their concerns, while many are not; nevertheless, all of them suffer from an intense emotional distress which can disrupt their social and occupational functioning, and indeed their entire life. Patients tend to avoid social contacts in order to conceal their 'ugly' feature from others' view, may obsessively check their appearance in mirrors or, on the contrary, be morbidly afraid of seeing themselves in mirrors or photos. They may seek unnecessary surgical corrections, which invariably fail to eliminate their emotional problem, and may even be driven to such extreme decisions as physically injuring the offensive body part or committing suicide.

Dysmorphophobia differs from anorexia nervosa insofar as people affected by the former condition are concerned with a single feature of their bodily appearance, while in the latter condition it is the overall shape or size of the body that is at the center of the pathologic preoccupation. Moreover, the physical appearance and eating habits of people with dysmorphophobia are normal, whereas those of people with anorexia nervosa are not. Dysmorphophobia usually also differs from obsessive–compulsive disorder, because all patients with the latter typically recognize the absurdity of their disturbing thoughts, which they can at least temporarily hold in check with ritualistic behaviors that are of no help to patients with dysmorphophobia. The modest therapeutic success with serotonin reuptake inhibitors obtained in a few cases of obsessive–compulsive disorder or dysmorphophobia suggests that malfunctions of brain activity regulation by serotonin, a major central neurotransmitter, may underlie both disorders, but no definite notion about these putative pathogenetic mechanisms is yet available.

Body-centered delusions such as underestimation of the size of bodily parts are often observed in major psychiatric illnesses like schizophrenia, where such symptoms are more frequently related to the left body side, and depression, where they are more frequently related to the right body side.

Also, hypochondriac patients tend to refer more frequently to the right side of the body when expressing their complaints (e.g., a pain in an arm). Other deformations of the body image may be experienced during epileptic or migraine attacks, as reported by the British neurologist Macdonald Critchley. For example, a patient with a left parietal meningioma suffered from recurrent attacks of migraine during which the right side would feel bigger and stronger, as if there were a sharp line down the middle. The left side, however, would remain 'calm, cool and collected, while the right side would be tense, anxious, agitated, and highly strung'. These side differences may perhaps be pathologic expressions of the asymmetric functioning of the cerebral hemispheres, but no decisive evidence to support this possibility has been offered.

In heautoscopy (autoscopy) individuals experience a veritable visual hallucination of themselves. A celebrated case is that of the Swedish naturalist Linnaeus who, while examining plants and flowers in his garden, would sometimes see at a little distance his alter ego performing the same actions. A persistent feeling of living outside one's own body characterizes the depersonalization syndrome, while patients with the Cotard syndrome are affected by delusions that their body does not exist, suggesting a specific disorder of corporeal and/or egocentric space awareness.

All the disturbances of the body image described above must have an immediate neural basis, but so far knowledge about the brain activities involved in these conditions is discouragingly small. Even more obscure are the mechanisms by which cultural and social factors act on the brain to produce derangements of the body image. Deep-seated psychological problems related to family and occupational conditions are suspected to be involved in anorexia nervosa, which typically occurs in middle-class young women and shows a high incidence in professional models and ballet dancers. The pathologic attitude toward the body and the related drastic cutdown in eating may be triggered by an exacerbation of a culturally imposed view of thinness as a supreme hallmark of beauty. The endocrine manifestations of anorexia nervosa leave no doubt that the hypothalamus and the adenohypophysis are malfunctioning in this condition, but it is far from clear whether the hypothalamic dysfunction constitutes the primary neural problem or is secondary to starvation and weight loss. Perhaps, in a not too distant future, approaches based on functional brain imaging and other modern neurotechnologies will allow an understanding of the internally generated or externally triggered patterns of cerebral activity which result in this and other distortions of the body image.

CONCLUSION

Studies in nonhuman and human primates indicate that the brain generates separate representations of the body and external world. The term 'body image' (here used as a synonym of body schema) indicates the complex of beliefs, memories, and knowledge about one's own and others' anatomy. This complex mental construct, on which the concept of the self is based, is the product of a continuous interaction between central neural systems dedicated to the representation of the body and peripheral inputs including somatic, vestibular, and visual signals. The ways in which the human body is perceived and represented may change dramatically as a consequence of amputations and cerebral lesions, the effects of which can help localize the neural systems specialized in representing the body. The neural bases of body-related disorders in neurologic and psychiatric diseases are probably due to dysfunctions of these systems as well, but knowledge in this area is still preliminary, though potentially open to improvement thanks to modern approaches to the study of the brain.

Dyslexia

Introductory article

Max Coltheart, Macquarie University, Sydney, New South Wales, Australia

CONTENTS

Dyslexia is a specific impairment in the ability to read; it may be acquired (impaired reading caused by brain damage in a previously literate person) or developmental (failure ever to have learnt to read adequately).

INTRODUCTION

When we learn to read, we build up a system in our mind that is capable of turning the printed word into a pronunciation (that is how we read aloud) or a meaning (that is how we understand text). This is an information processing system: it takes in information in one form (the visual appearance of printed words) and gives out information in a different form (the pronunciation or the meaning of the printed words). In some people, however, this system no longer works, even though it used to; and other people never manage to learn the system properly in the first place. Both kinds of difficulty with reading are referred to as 'dyslexia': the first is acquired dyslexia and the second is developmental dyslexia.

There are many people who learnt to read perfectly but who then, because of brain damage (due to a stroke, for example, or an injury to the head), lost some of their ability to read. Such people may still be able to perform normally other mental activities such as remembering, or recognizing people and objects; sometimes they are also normal at speaking, writing, and spelling – but they can no longer read adequately. The brain damage has specifically impaired the mental information processing system which had been used for the job of reading. This is acquired dyslexia.

Other people never manage to learn to read properly – even people who are normal in intelligence and who had no difficulty as children in learning how to carry out other mental activities such as remembering, recognizing people and objects, and arithmetic calculations. This is developmental dyslexia.

If we are to understand these abnormalities of reading, we first need to understand normal reading. We need to know what the mental information processing system used for reading is like, how it works, and how reading is learnt. Experimental psychologists discovered a great deal about this in the last quarter of the twentieth century.

Suppose normal readers are asked to read aloud some nonsense word such as 'bloof'. All will be able to do so. This fact is simple yet instructive. It tells us that reading aloud does not depend solely on being able to look up, in a kind of mental dictionary, what pronunciation had been learnt for the string of letters. If that were so, no one would be able to read 'bloof' aloud, since no pronunciation could have been previously learned for that particular letter string, because the reader would never have seen it before. How do normal readers read aloud such unfamiliar material? This can be achieved because part of what normal readers have learnt is knowledge about the rules relating letters to sounds; they have learnt how 'b' is pronounced, how 'l' is pronounced, how 'oo' is pronounced, and how 'f' is pronounced. These rules apply even to letter strings never before seen; so they can be used for reading aloud such unfamiliar material.

Could this system of rules be all that is needed for adequate reading aloud? No, because there are many words in English that disobey these rules. The rule for how to pronounce 'oo', used to read 'bloof' aloud, is disobeyed by the real words 'blood' and 'good'. Despite this, normal readers will read 'blood' and 'good' aloud correctly if asked to. How do they do this? It can be achieved because these are words these readers have seen before, and this has allowed them to learn the correct pronunciations (and meanings) of the words and store these in a kind of mental dictionary.

ACQUIRED DYSLEXIA

The mental information processing system used for reading thus contains two different procedures for reading aloud – one a system of rules specifying the relationships of letters to sounds; the other a 'dictionary' procedure that allows the reader to retrieve information previously learnt about familiar words. To read aloud unfamiliar material requires the first procedure. To read aloud words that disobey the rules requires the second procedure.

This mental information processing system must be located somewhere in the brain. If different parts of this system are located in different parts of the brain, theoretically brain damage could harm the rule system without affecting the dictionary look-up system. What would the reading of such a person be like? Any familiar word could still be read aloud correctly, since the dictionary look-up system allows this, but unfamiliar letter strings such as 'bloof' could no longer be read aloud. This kind of acquired dyslexia does occur: it is known as 'phonological' dyslexia, and the first case was reported in 1979; numerous other cases have since been reported.

Suppose instead that brain damage harmed the dictionary look-up system without affecting the rule system. The affected person would still be able to read unfamiliar letter strings such as 'bloof', and real words that obey the rules (such as 'bloom') could still be read aloud. However, words that disobey the rules would be affected; if 'blood' could not be looked up in the dictionary, the rules would have to be used to read it aloud, and that will give an error with the 'oo' part of the word. This kind of acquired dyslexia is known as 'surface' dyslexia; the first case was reported in 1973, and numerous other cases have since been reported.

Several other types of acquired dyslexia have been discovered. For example, if it is true that words disobeying the rules are read aloud by looking them up in a mental dictionary, perhaps this involves reading them via information about the meanings of the words: the route is from print to meaning and then from meaning to speech. If so, anyone in whom brain damage has affected knowledge of word meaning would be impaired at reading words that disobey the rules. This turns out not to be so. In Alzheimer disease and other forms of dementia, knowledge about what words mean will sooner or later be lost. In some unfortunate people to whom this has happened, reading aloud of words, even words that disobey the rules, can still be normal. The person might no longer have any idea what the word 'blood' means, yet would still be able to read it aloud correctly. So here we have a form of acquired dyslexia in which what is impaired is reading *comprehension*, with reading aloud being unaffected.

In yet another well-documented type of acquired dyslexia, known as 'deep' dyslexia, the brain-damaged reader will read a word as some other word similar in meaning; the word 'canary' might be read as 'parrot', or the word 'wrist' as 'watch'. Reading by people with deep dyslexia shows a number of other symptoms too. Words that have a concrete meaning ('leopard', 'cigar') are much more likely to be read aloud correctly than words that are abstract in meaning ('idea', 'character'). The small grammatical words of the language, even though they are generally very short and very common ('the', 'and', 'if', 'but'), are rarely read aloud correctly. Unfamiliar letter strings such as 'bloof' cannot be read aloud at all.

Finally, there is 'letter-by-letter reading', so called because sufferers from this kind of acquired dyslexia typically spell out aloud words they are trying to read, letter by letter, rather than being able to recognize the word immediately as a whole. If they manage to name each letter in the word correctly, then they can generally say the whole word correctly. Despite this severe difficulty in reading, such people can be perfectly normal at writing and spelling.

The discovery of these distinct patterns of acquired dyslexia tells us not only that the mental reading system consists of numerous different components, but also that these different components are located in different parts of the brain; if that were not so, brain damage could not affect one part of the reading system while leaving other parts unaffected.

Only a limited amount is so far known about exactly which parts of the brain are damaged in these different kinds of acquired dyslexia. There is persuasive evidence that the limited reading achievable by people with deep dyslexia depends upon the use of reading mechanisms in the right hemisphere of the brain which may play little or no part in normal reading. Letter-by-letter reading also involves the right hemisphere, since these patients typically have damage to the visual areas of the left hemisphere (so that visual identification of letters cannot occur in the left hemisphere), and also damage to one part of the corpus callosum (which is responsible for transmitting information between the two hemispheres of the brain). The effect of this damage is that after letters are identified in the right hemisphere their transmission to

the reading system in the left hemisphere is abnormally slow and inefficient.

When knowledge about word meanings is affected in Alzheimer disease and other forms of dementia (in patients with impaired text comprehension but intact ability to read aloud) this is due to progressive deterioration of the temporal lobes of the brain, especially the left temporal lobe. Virtually nothing is currently known about which brain regions are specifically impaired in surface dyslexia or phonological dyslexia.

One might assume that, since in acquired dyslexia some part of the brain that is needed for reading is permanently damaged, there could be no effective treatment to improve the reading of such people; but this turns out not to be so. Previously normal readers who no longer recognize the word 'blood', and so can only try to read it using the rules, can learn to recognize it again; that is, surface dyslexia can respond to treatment if this is designed appropriately. Phonological dyslexia, deep dyslexia, and letter-by-letter reading have also been shown to be remediable by appropriate treatment.

DEVELOPMENTAL DYSLEXIA

Turning now to a consideration of difficulties in learning to read – developmental dyslexia – a natural question to ask is the following. If the different components of the reading system can be separately impaired by various forms of brain damage to produce different kinds of acquired dyslexia, is the particular component of the reading system causing the difficulty in learning to read different in different children? If that were so, there would be different kinds of developmental dyslexia, just as there are different kinds of acquired dyslexia. This turns out to be the case.

Some children with developmental dyslexia have a particular problem in learning or using the system of rules specifying the relationships of letters to sounds. This is known as 'developmental phonological dyslexia'. Other children with developmental dyslexia have a particular problem learning or using the dictionary look-up system needed for fluently recognizing words as wholes – this is developmental surface dyslexia.

It is clear that developmental dyslexia is partly a genetic condition involving abnormalities on at least two specific chromosomes, namely chromosome 6 and chromosome 15. It may be the case that the abnormality of chromosome 6 is characteristic of developmental phonological dyslexia and is associated with some general difficulty on processing speech sounds; and it may also be the case that the abnormality on chromosome 15 is characteristic of developmental surface dyslexia.

Since there are genetic influences at work here, one might wonder whether it is possible to remedy these developmental dyslexias. However, it does not follow from the fact that a disorder has a genetic basis that it cannot be treated; and in fact research has shown that both of these kinds of developmental dyslexia respond well to appropriate treatment.

Many children with developmental dyslexia exhibit the symptoms of both of these kinds of developmental dyslexia: they are poor at both learning or using the system of rules specifying the relationships of letters to sounds and also at learning or using the dictionary look-up system needed for fluently recognizing words as wholes. The most plausible explanation for the prevalence of this commonly occurring 'mixed' developmental dyslexia is that each of these reading procedures assists the child in learning the other. A child who is, say, 8 years old will have an auditory vocabulary of perhaps 10 000 words, but a small vocabulary of words that can be recognized in print. Such a child will therefore constantly come across printed words which cannot be recognized in print but which would be recognized if heard. If the child could apply rules relating letters and sounds to such words, sounding out the words would allow them to be recognized. This is a method by which children could teach themselves to recognize whole words; but it is unavailable to the child who is poor at using such rules. So being poor at the rule-based reading route will make it difficult to build up the dictionary look-up reading route.

The reverse is probably also true. How do children learn what these rules are? One way might be by reflecting on the spellings and pronunciations of words they already know, and working out from these what the rules must be. If so, children who have few words in their mental dictionary will have an impoverished database upon which to reflect, and that will limit what these children can learn about letter–sound rules.

CONCLUSION

Great advances have been made in our understanding of developmental and acquired dyslexia. The crucial step was the recognition that the system we use to read is a mental information processing system that contains a number of different processing components, including a letter recognition system, a mental dictionary storing the spellings,

meanings and pronunciations of the words the reader knows, and a system of rules specifying the relationship between letters and sounds. Studies of people with acquired dyslexia have shown that brain damage can impair particular components of the reading system while not affecting others. Studies of people with developmental dyslexia have shown that such people can have difficulty learning particular components of the reading system while being able to learn others well; and such specific difficulties in learning to read are associated with specific genetic abnormalities.

Electroencephalography (EEG)

Introductory article

Terence W Picton, Rotman Research Institute, Toronto, Ontario, Canada
Ali Mazaheri, Rotman Research Institute, Toronto, Ontario, Canada

CONTENTS

Electroencephalography is a measurement of the brain's electrical activity. It provides information about the timing of intracerebral processes which can be used in conjunction with anatomical information derived from hemodynamic studies to learn about events in the human brain.

INTRODUCTION

Electroencephalography (EEG) is the recording of the electrical activity of the brain. When the neurons of the brain process information, they do so by changing the flow of electrical currents across their membranes. These changing currents, particularly those caused by the synaptic excitation and inhibition of cortical neurons, generate electric fields that can be recorded using small electrodes attached to the surface of the scalp. The potentials between different electrodes are amplified and displayed as they fluctuate over time.

The human EEG was first recorded in the 1920s by a German psychiatrist named Hans Berger. Since then, it has been used widely to investigate normal and abnormal brain function.

The EEG is characteristically recorded simultaneously from multiple locations on the scalp. The amplitude of the EEG is very small – usually several tens of microvolts. The recordings use special amplifiers that record the differences in potential between two electrodes. These differential amplifiers cancel out other large electrical activities, such as line noise, and allow us to see the small EEG signals. Two types of recordings are possible: the electrical activity can be recorded from each location relative to a common reference, or the activity can be recorded from each electrode relative to an adjacent electrode. The latter technique effectively records the slope or change of the scalp potentials over space rather than their absolute value relative to a single reference. Figure 1 shows the EEG signals recorded from ten scalp electrodes. The recordings are all relative to a linked-mastoid reference. The signals in Figure 1 are plotted according to the usual EEG convention that negativity at the first electrode relative to the second is shown as an upward deflection.

Electroencephalographic recordings fluctuate in time and are often 'rhythmic' in the sense that they alternate regularly. The most prominent rhythm in the EEG is the alpha (α) rhythm, which has a frequency of 8–13 cycles per second (Hz) and is recorded mainly over the posterior regions of the scalp close to the regions of the brain that process visual information. When the eyes are open the α rhythm is very small and when the eyes are closed it becomes large.

During a rhythm the neurons tend to fire synchronously, and their fields overlap and add to each other to cause the large scalp potentials. Interactions between cortical and thalamic neurons can cause the cortical neurons to fire periodically and thus generate rhythmic scalp potentials. When the visual areas are activated by real or imagined information, the neurons fire independently and their fields tend to cancel each other out. The EEG is then said to be 'desynchronized'. The transition between the α rhythm and the desynchronized EEG occurring with eye opening is shown in Figure 1.

As well as activity generated in the brain, the electrodes also pick up electrical potentials from other sources in the head. The eyes are the most prominent of these sources. Large potentials occur in the anterior regions of the scalp as the eyes or eyelids move. In Figure 1, the anterior regions become more negative as the eyes open, and there is a brief positive deflection during a blink. The scalp muscles also generate activity that is picked up in the EEG. This activity is characteristically faster than the activity arising from within the brain.

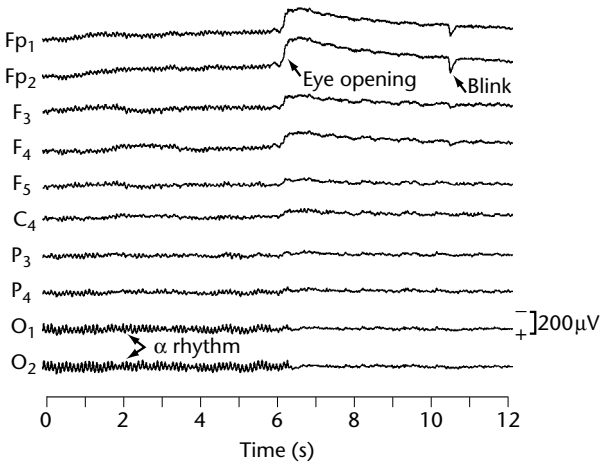

Figure 1. Human electroencephalogram (EEG). This 12 s recording was taken from a normal young woman. The EEG was recorded from ten scalp electrodes, with the activity at each electrode measured relative to a linked-mastoid reference. Negativity at the scalp electrode relative to the reference is plotted upwards. The electrodes are named according to their location on the scalp: Fp, frontopolar (forehead); F, frontal; C, central; P, parietal; O, occipital. Odd-numbered electrodes are on the left and even-numbered electrodes are on the right, and the number varies with the distance from the midline. At the beginning of the recording, the eyes were closed; halfway through the recording the woman opened her eyes. Movements of the eyes and eyelids when the eyes opened were recorded as a large negative wave in the Fp electrodes. While her eyes were open, the woman blinked; this was recorded as a brief positive wave in the Fp electrodes. While the eyes were closed there was a sustained rhythmic oscillation at 10 Hz in the posterior electrodes (O_1 and O_2) – the alpha rhythm.

FREQUENCY ANALYSIS

Electroencephalographic signals are usually plotted as changes in voltage over time, as in Figure 1. Because of the rhythmic nature of the signals, it is often informative to plot the signals according to the frequencies they contain. This change from the time domain to the frequency domain is accomplished using a Fourier transform. The frequency spectrum of the EEG signal then shows various peaks that denote the particular rhythms in the EEG. The frequency representation of the EEG recorded from the right occipital electrode at the back of the head (labeled O_2 in Figure 1) is shown in Figure 2. The α rhythm stands out as a peak in the spectrum recorded when the eyes are closed.

The spectrum of frequencies present in the EEG is broad. As well as the (α) activity recorded at frequencies of 8–13 Hz, the EEG also contains slower activity – theta (θ) activity at 4–7 Hz and delta (δ) activity at 0–3 Hz – and faster activity – beta (β) activity at 14–25 Hz and gamma (γ) activity at 25–50 Hz.

TEMPORAL ANALYSIS OF THE EEG SPECTRUM

The way in which the frequencies of the EEG change over time can show the changing state of the brain. Figure 3 shows the desynchronization of the α rhythm as the eyes open. The upper tracing shows the time-domain EEG recorded from the O_2 region of the scalp. The middle tracing shows the way the spectrum changes over time (EEG spectrograph). Spectra similar to those shown in Figure 2 are plotted with the frequency on the *y* axis and the amplitude of the activity demonstrated using the color scale (*z* axis). Whereas the two spectra in Figure 2 combine activity over several seconds, the multiple spectra plotted in Figure 3 are computed about 40 times a second. The α activity, which is present with the eyes closed and then goes away with eye-opening, shows up as the prominent dark red line at a frequency of 10 Hz. The lower tracing shows the amplitude of activity in the α frequency band over time. This follows the α rhythm over the time course portrayed in Figure 1.

The α rhythm can attenuate even when the eyes are closed. This can occur when the person is using the visual areas of the brain in processes such as problem-solving or imagining visual information. Sometimes the changes in the rhythms following an event (such as a stimulus) are small and can be measured only if the spectral changes are averaged over multiple trials.

SPATIAL ANALYSIS

The EEG signals are characterized by their distribution over the scalp as well as by the way they change in time. The EEG is spatiotemporal in nature. The visually reactive α rhythm is usually distinguished from other EEG activity by its posterior scalp location. Figure 4 shows the scalp topography of the α activity recorded in Figure 1. The α rhythm is typically slightly larger over the right posterior scalp than over the left.

Other rhythmic activities are recorded from different regions of the scalp. The mu rhythm has a similar frequency to the α rhythm but is located over the sensorimotor regions of the cortex and reacts to somatosensory input, motor activity or the thought of motor activity in the contralateral

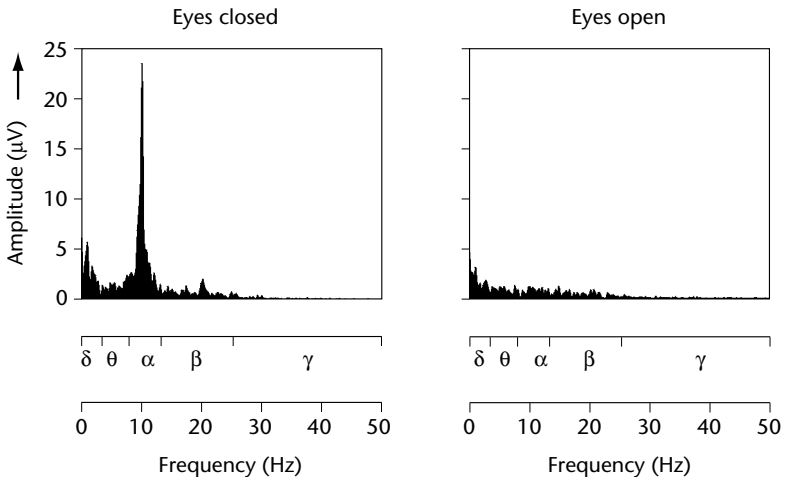

Figure 2. Frequency analysis of the electroencephalogram. The frequency content of the EEG signal at the O_2 electrode (lowest tracing in Figure 1) is shown. The spectrum on the left shows the amplitude of activity at the different frequencies when the eyes are closed (from 1 s to 5 s in Figure 1) and the spectrum on the right shows the pattern when the eyes are open (from 7 s to 11 s). The eyes-closed spectrum shows a prominent peak at 10 Hz.

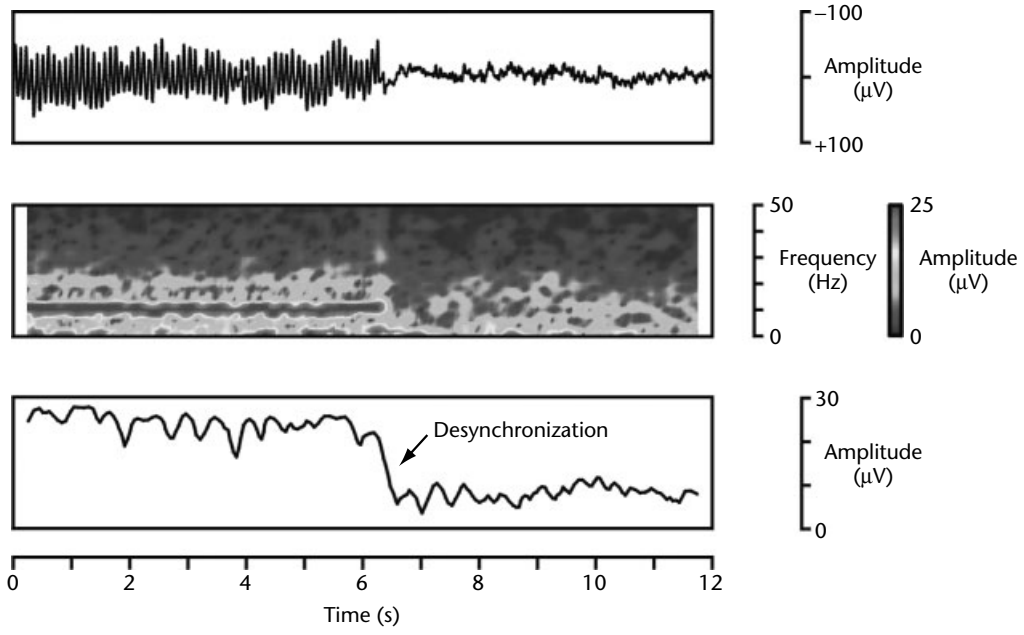

Figure 3. [*Figure is also reproduced in color section*.] Electroencephalographic changes over time. The upper tracing shows the EEG signal recorded from the O_2 electrode in Figure 1. The middle panel shows the spectrogram. This plots the changes in the spectrum over time: the frequency (on the *x* axis in Figure 2) is plotted vertically (*y* axis) and the amplitude of the activity is plotted on the *z* axis as color. A dark red line at 10 Hz represents the α rhythm. This line is clearly recognizable when the eyes are closed and disappears when the eyes are open. The lower tracing represents the amount of activity present in the 8–13 Hz frequency band as it changes over time. When the eyes open, this activity decreases (event-related desynchronization).

hand. Its name comes from the 'm' shape of the waves.

The γ rhythms of the brain have been studied in relation to memory and perception. These rapid rhythms may serve to bind separate aspects of a perceived object by synchronizing relevant neurons from different regions of the brain. The rhythms may also act as a signature for that

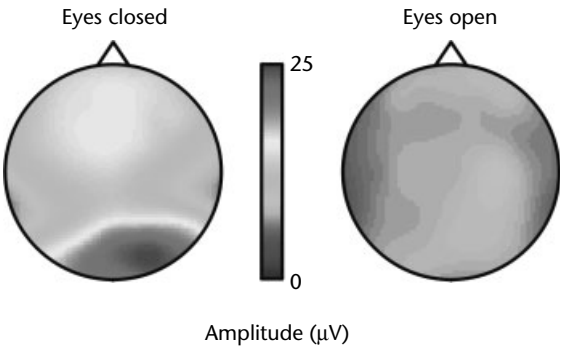

Figure 4. [*Figure is also reproduced in color section.*] Topography of the alpha rhythm. The scalp is viewed from above using an azimuthal equidistant projection centered at the vertex. The outside of the circle reaches the level of the ear canal. The α activity when the eyes are closed is maximally recorded from the posterior regions of the scalp, and is slightly greater on the right than on the left. These maps were based on activity from 65 scalp electrodes (10 of which are shown in Figure 1).

bound information. Bursts of EEG γ activity can occur as a stimulus is perceived or maintained in short-term memory. (*See* **Neural Oscillations**)

CHANGES IN THE STATE OF THE BRAIN

Changes in the EEG as the brain changes its state are most clearly seen during sleep. Many specific patterns of activity define various sleep stages. During a normal night of sleep, the brain will cycle through these various stages once every 90 min or so. In one stage, often associated with vivid visual dreams, there are many rapid eye movements (REM). Another stage of sleep is associated with widespread δ activity – slow-wave sleep. Bursts of activity with frequencies around 14 Hz – sleep spindles – are prominent during the transition between REM sleep and δ sleep. (*See* **Sleep and Dreaming**)

The EEG is used extensively to assess the abnormal brain states that occur with neurological disorders. An abnormal decrease of brain activity is usually associated with slow EEG waves. These can occur in localized regions of the scalp over areas of focal brain damage, or can be more widespread in cases of generalized brain dysfunction. After extensive brain damage there may be no electrical activity recorded from the brain – a state known as 'brain death'. An abnormal excitability of the neurons in the brain, which can occur in epilepsy, is usually associated with high-frequency EEG activity. The most common abnormality is a brief, sharp change in voltage called a spike. Spikes may be generated focally in one region of the brain or may be more widespread in association with a generalized disturbance of consciousness. A common generalized pattern is a combination of spike and wave that recurs at a rate of $3\,s^{-1}$. (*See* **Epilepsy**)

OTHER ANALYSES OF THE EEG

In order to look at the response of the brain to a stimulus or the activity in the brain occurring before a motor act, the process of averaging can be used to distinguish the cerebral activity specifically related to the event from the other activity of the EEG: the stimulus or the act is repeated and the EEG signals related to each occurrence of the event are averaged together. The specific activity – 'event-related potential' – remains the same during averaging, whereas the unrelated EEG activity tends to cancel itself out. The event-related potentials can show what is happening in the brain when a person processes the information in a stimulus and then prepares and executes a behavioral response. Averaging can also be used to assess spectral information (instead of time waveforms) in order to show subtle changes in the frequencies of the EEG in association with stimuli or responses – a process called 'event-related synchronization and desynchronization.' (*See* **Event-related Potentials and Mental Chronometry**; **Auditory Event-related Potentials**; **Visual Evoked Potentials**)

The flow of information from one area of the brain to another can be evaluated by measuring the correlation or coherency between the EEG signals recorded in each area. The amount of correlation can indicate the amount of information transferred, and the time lag can indicate the direction of the transfer. Unfortunately, since the EEG signals recorded from the scalp spread quite widely, much of the correlation between these signals may be caused by current spread in the scalp rather than information spread in the brain. Techniques that calculate the radial currents or extrapolate back from the scalp to the cortical surface can make these studies more precise. It would be even better to determine the actual intracerebral generators for the scalp-recorded activity and to correlate the waveforms generated in these sources. Although there is no unique solution to the problem of calculating the intracerebral sources for electrical signals recorded at the scalp surface, constraints imposed on the solutions from other imaging techniques, which provide anatomy and cortical activation patterns, can lead to sensible solutions.

RELATIONS TO OTHER BRAIN IMAGING METHODS

As well as generating electric fields in the extracellular fluid, the passage of currents through neuronal membranes generates magnetic fields. A magnetoencephalogram (MEG) can therefore be recorded from the surface of the scalp using specialized techniques. These signals are similar to EEG signals since they derive from the same currents in the brain; they differ, however, in terms of which neurons contribute to the scalp-recorded signals and how these signals spread to the recording sensors.

Both the EEG and the MEG are 'functional' tests. They differ from simple structural measurements of brain anatomy by measuring the activity of the brain as it is working. The EEG is therefore related to other tests of brain function that measure cerebral blood flow, such as positron emission tomography or functional magnetic resonance imaging. One difference between these hemodynamic measurements and the electromagnetic measurements is in the timing. The electromagnetic activity changes simultaneously with the neuronal activity, whereas the blood flow changes after a delay. However, blood flow measurements are much more accurate in terms of their anatomical localization. Activation patterns from hemodynamic studies may provide localization for the temporal changes in the EEG – either event-related potentials or event-related desynchronizations. CONTENTS

Emotion is information about the extent to which goals are being met in interaction with the environment.

INTRODUCTION

Emotion is information about the extent to which goals are being met in interaction with the environment. Emotion is a mechanism that emerged in evolution to solve the problem of attributing value to classes of stimuli based on experience, and serves as a means of adapting rapidly to critical stimuli in the environment. It can be viewed as an extension of more rudimentary or reflex-based behavioral systems. For example, mating behavior that is reflexive in reptiles is elaborated and extended in mammals and contributes to the formation of social bonds.

Emotion provides a mechanism for rapidly resetting the organism in response to environmental contingencies. This resetting occurs cognitively (e.g. in attention and memory systems), physiologically (e.g. preparing for exertion, diminishing functions not needed during a crisis, such as digestion), and behaviorally (e.g. shifting the propensity for approach or avoidance behavior). Emotional information can be conveyed internally (experiential) or externally (expressive, for instance gestures or facial expressions), the latter reflecting the inherent social element in emotion, that of signaling to or communicating with other animals.

Thus, emotion involves evaluating the motivational significance of a stimulus and subsequently implementing motivated behavior. The function of emotion is manifold. In response to some change in the environment, emotions (1) interrupt behavior and focus attention on particular elements in one's surroundings, or on one's internal sensations or appraisals; (2) physiologically prepare the organism for alternative action; (3) serve as a means of communication among conspecifics; and (4) help label or 'tag' memories for significance, which can guide approach/avoidance tendencies in related situations in the future, as well as trigger memories of previous experiences that may affect progression of the current behavioral agenda.

WHAT INFLUENCES THE DEVELOPMENT OF EMOTIONS?

There has been spirited discussion about whether emotions are rooted in nature (i.e. genetically hardwired neural circuits) or nurture (learning via experience). Indeed, it has been demonstrated that we possess certain rudimentary emotional functions at birth. However, these basic functions are then subjected to learning and environmental experiences of many kinds. For instance, Rene Spitz's observations of infants raised in hospitals illustrate that social development is disrupted if infants are deprived of appropriate emotional responses from the environment. More than a third of the infants died, and of those who survived, most experienced developmental delays. The effect of the environment is not well understood, but it is likely to be an important source of the heterogeneity observed between people in their emotional behavior. For instance, research shows that offspring of depressed caregivers are at increased risk of maladaptive development and emotional difficulties.

THE STRUCTURE OF EMOTION

Precisely how emotion is organized in the brain remains an unresolved issue. There is debate over whether different emotions should be considered as discrete entities, or viewed from a dimensional

perspective. Proponents of the discrete or basic emotions model contend that there are unique circuits for particular emotions, such as fear, anger, joy, and disgust. Darwin suggested that distinct facial expressions reflected distinct neural circuits for each emotion. This is supported by evidence of the generation and recognition of prototypical facial expressions of emotion in all known cultures. Furthermore, specific neural circuits have been identified in animals by Panksepp for basic emotional states such as rage, fear, joy, and sorrow.

The dimensional approach postulates that emotion is founded on separable motivational systems, such as approach and avoidance (appetitive versus aversive), and can be subdivided into components of valence (unpleasantness–pleasantness) and arousal (unaroused–aroused). Dimensional models of valence are further bifurcated into bivariate and bipolar models; in the former positive and negative emotions are conceptualized as separate dimensions, in the latter they are viewed as opposite ends of the same continuum. Dimensional models can incorporate discrete emotions models, but discrete emotions models cannot encompass dimensional models. For example, discrete emotions can be mapped onto the plane defined by the arousal dimension on the vertical axis and the valence dimension on the horizontal axis.

Substantial evidence from psychometric and psychophysiologic studies in healthy people supports a dimensional perspective. For instance, Watson, Tellegen and colleagues have found that self-report of mood is organized along positive and negative affective dimensions. In addition, Lang and colleagues have demonstrated the validity of the dimensional perspective using emotional stimuli in different modalities (pictures and sounds) to evaluate both subjective emotional and psychophysiological response. Patterns of psychophysiological responses are consistent across positive or negative valence of stimuli, but there are no unique physiological signatures for discrete emotions. Furthermore, a cognitive neuroscientific perspective suggests that the brain mediates various cognitive functions by combining component processes from different brain regions (such as the visual system) rather than dedicating specific neurons or specific regions to one particular function, such as recognition of a particular face. Indeed, attempts to define unique circuitry for discrete emotions in human imaging studies have failed to yield nonoverlapping activation patterns. For instance, Lane and colleagues found that the discrete emotions of happiness, sadness, and disgust were each associated with increases in activity in the thalamus and medial prefrontal cortex. These three emotions were also associated with activation of anterior and posterior temporal structures, particularly when induced by film. Recalled sadness was associated with increased activation in the anterior insula. Happiness was distinguished from sadness by greater activity in the vicinity of ventral mesial frontal cortex. From these findings Lane and colleagues concluded that there are both common and unique components of the neural networks mediating discrete emotions.

A function as complex as emotion is likely to be mediated by the coordinated effort of a variety of subsystems. Much is known about which structures contribute to the cognitive elaboration of emotion. This process requires the conscious awareness of emotions in order to understand the origin and meaning of one's emotions, which can subsequently be incorporated into thought and behavior. However, it is not yet known which brain structures should definitely be included or excluded in this network, and our understanding of how the system works as a whole to mediate the variety of emotions that are observed behaviorally is limited.

HISTORICAL THEORIES OF THE NEURAL BASES OF EMOTION

Study of the neural bases of emotion was neglected throughout most of the nineteenth and twentieth centuries because the experience of emotion was considered too subjective and vague to study scientifically. Furthermore, behaviorist and cognitive approaches predominated in psychology during the second half of the twentieth century.

Visceral feedback theories of emotion are useful from a historical perspective and remain influential in contemporary work on emotion. Their main contribution is the realization that the nature of emotion is a combination of brain and bodily states. Although the brain probably has the more prominent role in the generation of emotions, the experiential aspect of emotions is influenced to a large degree by bodily state and the transmission of this information to the brain.

There are three main visceral feedback theories of emotion. The James–Lange theory of emotion states that the experience of emotion follows bodily feedback: that is, perceiving an emotional stimulus generates visceral sensations or autonomic arousal, which then mediates the experience of particular emotions. Put another way, emotion is simply the perception of visceral sensations, and each discrete emotion has a unique pattern of physiological

arousal. The Cannon–Bard theory focuses on the central nervous system (which includes the brain and the spinal cord), particularly on the thalamus, a structure responsible for gating sensory input. Perceiving an emotional stimulus simultaneously generates an emotional state and induces bodily arousal via the sympathetic nervous system. The pattern of physiological arousal does not correspond with specific emotions. According to the Schachter–Singer theory, the experience of emotion is a combination of generalized physiological arousal and cognitive appraisal. Arousal occurs first in the chain of events, and one's appraisal of this inner state 'labels' the specific emotion being experienced. Thus, the Schachter–Singer theory agrees with the James–Lange theory that physiological arousal is necessary for emotion, but it differs from James–Lange theory in that it argues that each discrete emotion does not have a unique pattern of physiological arousal.

The three models therefore address 'bottom up' and 'top down' mechanisms that determine what the emotion is and how it is experienced. It is difficult to identify clearly a unique autonomic signature for basic emotions. To the extent that autonomic differences are observed between emotions, they are subtle and difficult to detect. (*See* **Autonomic Nervous System**)

Several neuroanatomical theories were proposed in the first half of the twentieth century as the basis for emotional function. They are not generally accepted today in their original forms, but elements of these theories hold some validity and served as the basis for later elaborations. The Papez circuit was the first specific neuroanatomical theory of the subjective experience of emotion. It identified a region of the brain for which the function was not known and attributed to it a function (emotion) that did not have a neural basis at the time. The Papez neural circuit of emotion detailed the flow of information from the sensory nuclei of the thalamus to the sensory cortex and on to the cingulate cortex, and from the thalamus to the mamillary bodies of the hypothalamus. It did not include the amygdala and orbitofrontal cortex, regions that are well supported today as integral to emotional responses, but did include the hippocampus and cingulate cortex; the latter probably participates in emotional experience. MacLean's theory of the triune brain proposed that the generation of emotions occurs in an evolutionarily old region of the brain of mammals ('paleomammalian'), which he deemed the limbic system or the 'visceral' brain. This region is located between the 'reptilian' brain, which controls basic and reflex motor functions, and the 'neomammalian' brain, which mediates higher cognitions. Like visceral feedback theories, the triune brain theory suggested that the subjective experience of emotion stems from the confluence of sensory input from the external world and internal visceral sensations in the limbic system. The concept of the limbic system is a subject of intense debate, as it has not been proved whether all of the structures included in the concept behave as a system in relation to emotional function, and the number of structures to be included is still undecided. The term persists, however, because a better alternative has not yet been found.

EMPIRICAL STUDIES OF EMOTION

The neural substrates of emotion have received considerable attention from researchers such as Damasio, LeDoux, Panksepp, and Rolls. Their work has largely been based on experimental findings in animals and observations in people with brain lesions. More recently functional brain imaging techniques such as positron emission tomography and functional magnetic resonance imaging have been used to study the neural substrates of emotion in healthy volunteers and, to a lesser extent, in clinical populations. Figure 1 illustrates the main brain structures that contribute to emotional function.

Studies of Emotion in Animals

Understanding of the neural bases of emotion has been informed substantially by experimental studies in animals. Lesion studies by Cannon and Bard led to the conclusion that the hypothalamus is essential to organized emotional responses. Since the hypothalamus regulates the autonomic nervous system, the Cannon–Bard theory proposed that bodily responses during emotional states are controlled by higher centers via the function of the hypothalamus. Concurrently, the subjective experience of emotion relies on input from the hypothalamus to the cortex, and thus emotional responses in decorticate animals were labeled as 'sham rage'.

In the 1930s Klüver and Bucy demonstrated that extensive lesions of the anterior temporal lobe of rhesus monkeys produced profound behavioral changes, including psychic blindness (the tendency to approach animate or inanimate objects without hesitation or fear), excessive oral tendencies, hypermetamorphosis (the tendency to react and attend to all visual stimuli), decreased fear and aggression, and hypersexuality. Weiskrantz demonstrated in 1956 that the behavioral abnormalities of the

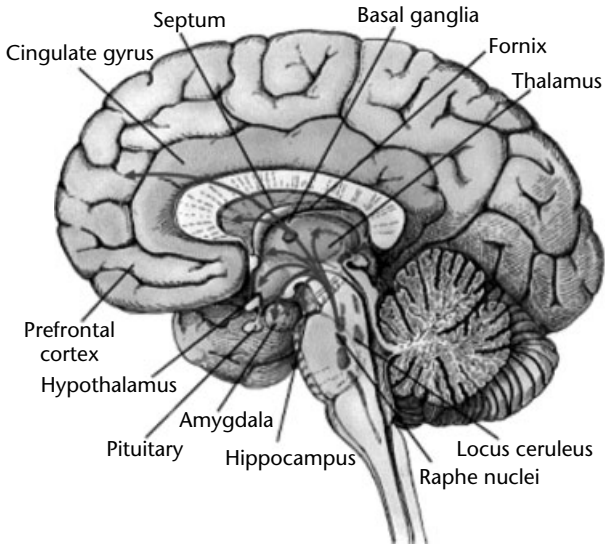

Figure 1. Brain structures that mediate emotion. In the brainstem, the locus ceruleus and raphe nucleus are the source of noradrenergic and serotonergic efferents to widespread regions of the cortex. These diffuse transmitter systems modulate neural activity related to emotion and other functions. The thalamus participates in evaluating the emotional significance of stimuli and organizing emotional behavior. The hypothalamus controls visceral functions. The amygdala and hippocampus mediate emotional conditioning and memory for emotional stimuli and their contextual surrounds, respectively. The basal ganglia facilitate the transition from motivation to action. A paralimbic structure, the cingulate gyrus, regulates attention and may contribute to the conscious experience of emotion. The prefrontal cortex coordinates functions throughout the emotion network, integrates information from the external world, and plays a major part in emotion regulation.

Klüver–Bucy syndrome could be produced by lesions of the amygdala alone.

More recent animal work has delineated neural circuits for specific emotions. From this work, a consensus has developed that the amygdala is essential to emotion. In a programmatic line of research, LeDoux has mapped out the circuitry underlying fear. His work on auditory fear conditioning has demonstrated that there are separate subcortical and cortical pathways that contribute to the fear response. The subcortical pathway, or 'low road', enables quick responses to potentially dangerous stimuli, by the transmission of information from the sensory thalamus directly to the amygdala. The cortical pathway, or 'high road', responds more slowly, since information is passed from the sensory thalamus to the cortex and then to the amygdala. However, it more accurately represents the nature of the stimulus. Rolls has argued that LeDoux's 'low road' probably does not apply to most complex stimuli, but instead applies only to simple stimuli, such as tones – or perhaps evolutionarily prepared stimuli, such as sight of a snake. More complex stimuli require cortical processing before information about them is transferred to the orbitofrontal cortex and amygdala for the assignment of reinforcement value. The orbitofrontal cortex modulates amygdala activity and can suppress or override stimulus–reinforcement associations established in the amygdala. (*See* **Amygdala**)

Lesions of the amygdala prevent fear conditioning, which suggests that the amygdala is a primary structure involved in emotional function. Current concepts of the amygdala view it as a threat detector. Whalen theorizes that the amygdala monitors the environment for stimuli that signal an increased probability of threat. Although they indicate the presence of threat in the environment, fearful cues may be ambiguous in terms of the source of the threat. As a result, ambiguous stimuli that convey fear encourage processing of the contexts in which they are present, because they derive their meaning from their immediate surroundings. Lesions to the amygdala interfere with the ability to learn about both specific cues and contextual stimuli. In this vein, Whalen suggests that the amygdala facilitates activity in brain regions that encode contextual stimuli, such as the hippocampus. Indeed, hippocampal damage prevents the conditioning or association between contextual cues present with discrete stimuli and emotional states.

The ventral striatum, particularly the nucleus accumbens, has a primary role in motivational circuitry and reward-related behavior. The nucleus accumbens integrates inputs from the prefrontal cortex, amygdala, and the ventral tegmental area (which provides dopamine input). Dopaminergic input to the nucleus accumbens may play an important part in the reinforcing effects of substances of abuse.

Studies of Emotion in Humans

Studies in humans, particularly of people with brain damage, point towards a basis of emotional function similar to that in nonhuman animals. The most famous patient in the study of emotion, Phineas Gage, sustained damage to the frontal lobe, including the ventromedial prefrontal cortex, when a tamping iron pierced his skull in 1848. He changed from being a moral, upstanding man and a hard worker to spouting profanity, showing little regard for social conventions, and behaving

irresponsibly. In general, damage to the lower middle portion of the frontal lobe (as in Phineas Gage) is associated with impulsive, disinhibited behavior, consistent with its modulatory influence on subcortical structures, including the amygdala. In contrast, damage to the upper portion of the frontal lobe is associated with amotivational behavior (i.e. failure to initiate behavior) consistent with the likely role of the dorsomedial frontal cortex in planning and executing goal-directed behavior.

Damasio has theorized that feedback from the body contributes to emotional experience. People with ventromedial frontal lobe damage lack physiological signs of emotional response, such as the skin conductance response (a measure of arousal), but they do have a conscious body state representation. As demonstrated by Bechara and colleagues, these patients also exhibit poor decision-making in gambling tasks in which risk-taking and reward assessment is involved. In particular, people without brain damage show electrodermal responses to risky choices when participating in the gambling task, prior to conscious awareness of how the game works, whereas people with ventromedial frontal lobe damage do not show such physiological responses and never learn the strategy of the gambling task. There is evidence that other brain regions, including the amygdala, and somatosensory cortices (S1, S2, and insula) are part of this neural system underlying the generation of somatic feedback. The insula has a particularly important role in detecting visceral sensations. Consequently, Damasio suggests that somatic feedback or 'markers' provide important information about the current state of the body to the brain, and influence subsequent decision-making.

Patients with bilateral amygdala damage but intact hippocampi show deficits in recognizing certain facial expressions of emotion, particularly fear and anger, although facial identification is unaffected. Patients with hippocampal damage but intact amygdalas display unconscious emotional conditioning, but have no memory for the conditioning events.

Studies of people with epilepsy have provided insight into the neural basis of emotion, particularly negative emotions, which possibly are related to the adaptive significance and greater elaboration of varieties of negative emotions. Psychomotor epilepsy is often rooted in abnormal electrical activity in the temporal lobe. Prior to seizure activity patients report an 'aura', which is characterized by negative emotions such as fear, anger, and dejection, as well as by positive emotions such as affection and ecstasy. During psychomotor epileptic seizures, which often begin in the amygdala, patients report experiencing fearful feelings.

Functional imaging studies are beginning to reveal the neural substrates of emotional disorders. Activity in paralimbic structures, which include the anterior cingulate, orbitofrontal cortex, insula, and temporal pole, appears to differ in people with depression and certain anxiety disorders compared with controls. These brain structures are intermediate between limbic structures and neocortex in their phylogenetic origin, and are involved in coordination of memory and higher-level emotional functions. Mayberg, for example, proposes that major depression is associated with dysfunction of specific subregions of the anterior cingulate cortex, and that recovery from depression is associated with a reversal of some of these effects. A similar pattern of dysfunction has been observed in individuals with post-traumatic stress disorder (PTSD). In response to trauma-related stimuli, the amygdala and certain paralimbic structures such as the orbitofrontal cortex are more activated in the brains of individuals with PTSD. Owing to learning related to the trauma, individuals with PTSD may have a lower threshold in the detection of fearful stimuli by the amygdala. Importantly, the anterior cingulate was found to not be activated in individuals with PTSD in response to trauma-related stimuli. This may be related to the numbing of emotional experience that many PTSD patients report. (*See* **Anxiety Disorders**; **Affective Disorders: Depression and Mania**)

Thus, these regions subserve a variety of functions, including the integration of cognitive and emotional functions via infusion of cognitive functions with emotional significance. This could help to explain, for example, how cognitive functions may be altered in the context of depression or anxiety. Notably, there is overlap in the neural circuitry implicated in emotional disorders and in substance abuse. Breiter and colleagues demonstrated in people addicted to cocaine that this drug activates a number of limbic and paralimbic structures, including the nucleus accumbens, caudate, putamen, insula and cingulate, and deactivates the amygdala and temporal pole.

Emotion Measurement in Humans

A variety of methods are used to measure emotional function in humans. Subjective methods include self-report (by questionnaire, structured or open-ended interview, response to emotion induction or other experimental tasks) and behavioral observation. Psychophysiological data indirectly

tap into neural function through peripheral indices such as muscle activity (electromyography) and autonomic nervous system activity, measured by electrodermal or skin conductance activity, heart rate, pupillary dilation, and the startle reflex (eyeblink). Psychophysiological measures are aligned more closely with dimensional models of emotion than with the discrete emotion theory because there is insufficient evidence for a specific profile of psychophysiological measures for particular emotions. For instance, activity of the corrugator muscle, which lies under the eyebrow and creates a furrowed brow, is associated with negative emotion, whereas activity of the zygomatic muscle, which lies under the cheek and raises the corners of the mouth during smiling, is associated with positive emotion. Arousal is positively correlated with both electrodermal activity and pupillary dilation, pleasantness is related to both heart rate increases and decreased startle response, and unpleasantness is related to pupillary dilation and an enhanced startle reflex.

Neuroimaging methods used in the study of emotional function include electroencephalography (EEG), single photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). In several PET and fMRI studies of induced emotion, both pleasant and unpleasant pictures activated the thalamus and medial prefrontal cortex more than neutral pictures did. Most studies point towards brainstem structures, the amygdala, hypothalamus, basal forebrain, ventromedial prefrontal cortex, cingulate cortex, and orbitofrontal cortex as active in neural circuits of emotion in a variety of emotional states. (*See* **Neuroimaging**)

On the basis of neuroimaging evidence, particularly that obtained with EEG, Davidson has theorized that there is hemispheric asymmetry or lateralization of emotions. People with greater left prefrontal cortical activation report greater positive and less negative affect and respond more strongly to positive compared with negative film clips than people who exhibit greater right frontal activation, who show the opposite pattern. Thus, left prefrontal activity is proposed to be related to approach or appetitive tendencies and right prefrontal activity is related to avoidance or aversive tendencies. Some studies, however, do not support this model. Issues to be resolved include the state versus trait nature of these hemispheric associations, and the time course and contexts in which this pattern is observed.

There are dissociations or loose coupling among the different components of emotion. Consequently, there is some question as to whether emotion represents a unified concept. Thus, one view holds that although data acquired using different methods is correlated, it should not be assumed that the findings all relate to a single causative influence or neural basis of emotion. From the same data, others conclude that there is a physiologic system mediating emotion, and this system was designed to have loosely coupled components that allow for optimal flexibility. For instance, it is adaptive in certain high-arousal situations to dampen one's subjective emotional responses. As more becomes known about the neural bases of emotion, these debates will move towards resolution.

CONSCIOUS AND UNCONSCIOUS EXPERIENCE OF EMOTION

It is now well established that people can display emotional behavior in the absence of concomitant emotional experience. Emotional responding can be elicited unconsciously, which allows for rapid responding in dangerous situations (fearful or angry stimuli both indicate danger), even before the stimulus is consciously perceived, conferring an evolutionary advantage. In his work on priming, Ohman used a backward masking procedure in which the fearful stimulus is presented for a very brief period, followed by a neutral stimulus of longer duration. Ohman demonstrated that fear-relevant stimuli are more resistant to extinction than fear-irrelevant stimuli, and people show autonomic responses to conditioned angry faces without conscious recognition of the stimuli. Concordantly, Whalen found bilateral amygdala activation and deactivation during unconscious processing of fearful and happy faces, respectively. In addition, the sublenticular substantia innominata, which reciprocally connects the amygdala and the hypothalamus, was activated during unconscious processing of both happy and fearful faces. Morris, Ohman, and Dolan extended this finding in a PET study examining neural activity during the conscious and unconscious processing of aversively conditioned angry faces. The main findings were that the right amygdala was activated during unconscious processing and the left amygdala was activated during conscious processing of the conditioned faces. These findings are consistent with the thesis that unconscious processing of emotional stimuli occurs primarily at the subcortical level, where more basic, evolutionarily old functions are executed.

These findings are to be contrasted with the activation of paralimbic structures observed in studies

of the conscious experience of emotion. LeDoux argues from animal research that emotional experience is represented in working memory. Human neuroimaging studies have demonstrated that the rostral anterior cingulate cortex and the medial prefrontal cortex participate in the representation of emotional experience, and lesions to these areas produce blunting of emotional experience. The conscious experience of emotion permits planning and flexibility of response, which would benefit long-term survival. It is likely that the structures needed for the conscious experience of emotion are not emotion-specific, which could explain the variability observed across individuals in the extent to which emotion is consciously experienced.

EMOTION AND MEMORY

Cahill and McGaugh have demonstrated in animals that the amygdala is involved in the formation of enhanced declarative memory for emotionally arousing events. The amygdala is not a site of long-term memory storage, but serves to influence memory storage processes in other brain regions, such as the hippocampus, striatum, and neocortex. Human studies show that administration of a drug that blocks the effects of noradrenaline (norepinephrine) decreases the enhancement of memory by emotional arousal. Imaging studies in humans demonstrate that activity in the amygdala while viewing emotional films correlates highly with memory of the films. Studies of emotion-dependent memory in healthy volunteers suggest that episodic memory, which reflects conscious awareness of one's personal experiences, appears to be organized along emotional lines. In other words, it is easier for one to recall emotionally significant memories if one is in a similar mood to the original experience.

INDIVIDUAL DIFFERENCES IN EMOTION

There is abundant research on variability across individuals in how they evaluate emotional stimuli, respond to emotional stimuli, and experience subjective feelings of emotion. From the perspective of the neural bases of emotion, pharmacological and neuroimaging work is quite informative.

For example, Depue and colleagues have demonstrated in humans that hormonal and affective response to a drug that stimulates the neurotransmitter dopamine through blockade of the reuptake transporter is associated with the personality trait of extraversion. Extraversion reflects the tendency to experience positive emotions based on sensitivity to rewarding stimuli, such as enjoying and valuing close interpersonal bonds, pursuing leadership roles, behaving assertively, and experiencing a subjective sense of potency in accomplishing goals. (*See* **Neurotransmitters)**

In an MRI study of personality influences on brain reactivity to emotional stimuli, Canli and colleagues found that extraversion was correlated with brain reactivity to positive picture stimuli in both cortical (frontal, temporal, including the cingulate gyrus) and subcortical (amygdala, caudate, putamen) regions, while neuroticism, or the tendency to experience anxiety, was correlated with brain reactivity to negative pictures in left frontal and temporal cortical regions. Extraversion was uncorrelated with response to negative pictures, relative to positive pictures, and neuroticism was uncorrelated with response to positive pictures, relative to negative pictures. Importantly, Canli and colleagues propose that studies of individual differences in the patterns of neural activity during emotional states provide a potential explanation for inconsistent findings across studies of emotion.

It is typically assumed that patterns of neural activity during emotional states are activated similarly across individuals, but evidence suggests that there is significant variability in the neural bases of emotion.

CONCLUSION

Much has been learned about the neural substrates of emotion from animal studies, observations in patients, and functional brain imaging studies in healthy volunteers and clinical populations. The fundamental constituents of the neural circuitry mediating emotion are being defined with increasing precision, and the neural basis of the interactions between emotion and cognitive functions is increasingly being understood. However, the precise mechanisms by which the neural networks mediating emotions work to orchestrate the range of normal and abnormal emotional responses in humans remain to be determined.

Encoding and Retrieval, Neural Basis of

Intermediate article

Lars Nyberg, Umeå University, Umeå, Sweden

CONTENTS

Cognitive theories describe encoding and retrieval as two distinct but interacting memory processes. This way of characterizing encoding and retrieval processes converges with analyses of their neural basis in that encoding and retrieval seem to engage specific as well as common brain areas.

INTRODUCTION

Encoding and retrieval are two fundamental memory processes. Encoding refers to the acquisition of information into memory, and retrieval to the use of previously encoded information. Retrieval can be *implicit* in the sense that previously encoded information affects subsequent behavior even though no conscious attempt is made to retrieve that information. Here, focus is on *episodic* memory retrieval as measured by tasks such as recall and recognition. Such tasks require *explicit* retrieval of previously encoded information in the sense that one has to think back to a previous study episode and retrieve information that was acquired at that particular time and place. Episodic information can be verbal or nonverbal; it can involve sensations of smell, taste, and touch; and it can represent emotional states.

THEORIES OF ENCODING AND RETRIEVAL AND THEIR INTERACTION

The division of the learning/memory process into encoding and retrieval (and an intermediate storage stage) became a major issue during the 1960s. Studies by Tulving and colleagues set the stage for subsequent empirical and theoretical work on retrieval processes. In a very influential paper (Tulving and Pearlstone, 1966), it was demonstrated that if encoding (and storage) conditions are held constant, the amount of information retrieved depends on the retrieval conditions.

During the 1970s, a considerable amount of research was focused on encoding. Much of this work was inspired by the *levels-of-processing* framework (Craik and Lockhart, 1972). In this framework, encoding was described in terms of various processing levels, and deeper processing was suggested to lead to better retention than shallow processing. It became clear that intention *per se* is not crucial for effective encoding but rather the way information is processed.

Another important topic of research during the 1970s concerned the interplay between encoding and retrieval processes. One set of findings gave rise to the *encoding specificity hypothesis* (Thomson and Tulving, 1970), by showing that retrieval cues are effective to the extent that they overlap with the encoded information. Another set of findings qualified predictions from the levels-of-processing framework by showing that deeper processing at encoding does not always lead to superior retention. Rather, what is optimal processing at encoding is dependent on the retrieval conditions. These findings formed the basis for the *transfer appropriate processing* principle (Morris *et al*., 1977). The importance of interplay between encoding and retrieval processes is also salient in other theoretical accounts, such as Kolers' procedural viewpoint (Kolers, 1973).

Encoding–retrieval interplay has a central role in contemporary accounts of dissociations between measures of retrieval, most notably dissociations between explicit and implicit retrieval. Based on a classification of retrieval measures as 'conceptually-driven' (dependent on the encoded meaning of information) or 'data-driven' (dependent on the perceptual match between encoding and retrieval) (Jacoby, 1983), Roediger and colleagues have put forward a transfer-appropriate account of such dissociations (Roediger *et al*., 1989).

CAN ENCODING AND RETRIEVAL BE DISTURBED SEPARATELY? LESION AND PHARMACOLOGICAL EVIDENCE

A fundamental question in the study of the neural basis of encoding and retrieval is whether encoding and retrieval can be selectively affected by brain damage. Here it should be noted that it is difficult to isolate the effects of brain damage to encoding or retrieval processes. If a lesion is made/has occurred prior to encoding and an effect is noted on subsequent retrieval performance, it is not clear whether the lesion affected encoding or retrieval processes. If a lesion occurs after encoding and prior to retrieval, it is still difficult to conclude that it affected retrieval processes. This is because there is evidence that consolidation of information in memory goes on for some time after the initial encoding. Moreover, it is possible that the lesion affected sites for memory storage rather than sites involved in the retrieval of stored information. With these caveats in mind, some suggestions regarding process-specific effects of brain damage will be considered.

Organic amnesia is characterized by dysfunctional episodic memory. This syndrome can result from lesions in the medial temporal lobes, diencephalon, or the basal forebrain. Collectively, these sites have been referred to as the 'expanded' limbic system (Markowitsch, 2000). This system, or various combinations of its constituent parts, has been associated with the transfer of incoming registered information for long-term memory storage. It has been proposed that the limbic structures can be regarded as 'bottleneck structures' in the sense that bilateral damage to any of them will lead to anterograde amnesia (Markowitsch, 2000).

Limbic regions may also play a role in retrieval. Several studies indicate that damage to limbic structures impairs retrieval of recent episodes, but it is a matter of debate whether retrieval of remote events is also affected. Moreover, specific regions in the infero-lateral prefrontal cortex and in the temporo-polar cortex (especially in the right hemisphere) seem to be critical for retrieval. Lesions to this regional combination result in retrograde amnesia (Markowitsch, 2000).

In a recent study (Rossi *et al*., 2001), repetitive transcranial magnetic stimulation was used to transiently interfere with prefrontal brain activity during encoding and retrieval of pictures. It was found that the left dorsolateral prefrontal cortex was crucial for encoding, whereas the right dorsolateral prefrontal cortex was crucial for retrieval. This study provides strong evidence that encoding and retrieval can be disturbed separately, and highlights the role of prefrontal regions in this regard (cf. the section below on differences in functional brain activity).

Psychopharmacological studies also provide some hints that encoding and retrieval processes can be disturbed separately. A much-studied class of drugs is benzodiazepines. These drugs facilitate the transmission of gamma-aminobutyric acid (GABA), which is the major inhibitory neurotransmitter in the brain. Administration of benzodiazepine drugs before the encoding of new information leads to poor retention. By contrast, if the drug is administered at the test phase, performance is not affected (Curran, 2000). A similar effect has been observed for scopolamine, which acts as a cholinergic blocker. The observed pattern of effects suggests that these drugs impair encoding processes rather than retrieval processes, possibly by affecting the ability to form item–item or item–context associations (Curran, 2000).

ARE THERE SEPARATE NEURAL SYSTEMS FOR ENCODING AND RETRIEVAL?

The results from lesion and pharmacological studies indicate that brain damage or drug administration can have selective effects on encoding and retrieval processes. These patterns of results provide tentative support for the existence of separate neural systems for encoding and retrieval. Additional evidence comes from functional neuroimaging studies. In these studies the neural correlates of encoding and retrieval can be studied separately, and hence it can be explored whether there are distinct encoding and retrieval systems in the brain. Two main classes of functional neuroimaging techniques are hemodynamic methods and electromagnetic methods. This discussion is limited to hemodynamic registrations by positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

FUNCTIONAL NEUROIMAGING STUDIES

PET and fMRI rely on the changes in cerebral blood flow that accompany neural activity. To identify changes in brain activity that are associated with a process of interest, it is common to measure activity in at least two conditions (experimental and control condition). These conditions are carefully matched in all respects, except for the process of interest. By subtracting out brain activity associated with the

control condition from that associated with the experimental condition, it is possible to isolate brain regions associated with the process of interest. In what follows, a summary of results from PET and fMRI studies of encoding and retrieval is given (Cabeza and Nyberg, 2000).

Encoding

Episodic encoding is associated with the left prefrontal cortex and medial-temporal lobe regions. Left prefrontal activation has been observed for intentional encoding and also for incidental encoding (e.g. comparisons of deep and shallow semantic tasks). Medial-temporal activation during encoding has been related to novelty detection. There is some evidence that medial-temporal regions interact with material-specific regions during encoding (e.g. occipito-temporal regions during picture encoding), and that the laterality of encoding-related activity is modulated by material.

Retrieval

Retrieval is strongly associated with right prefrontal and medial parietal activation. Increased activity has also frequently been observed in the medial-temporal cortex and in the cerebellum. Activity in some regions is higher during successful than unsuccessful retrieval, whereas other regions' activity tends to be unaffected by level of retrieval or increase during more demanding (and less successful) retrieval conditions.

Differences and Similarities

As indicated above, encoding and retrieval have been associated with different regions of the frontal cortex, with encoding being associated with left prefrontal regions and retrieval with right prefrontal regions. This asymmetric involvement of prefrontal regions during encoding and retrieval is captured by the HERA (Hemispheric Encoding/Retrieval Asymmetry) model shown in Figure 1 (Nyberg *et al*., 1996).

In addition to encoding–retrieval differences, several studies have reported overlap in activation patterns for encoding and retrieval (Nyberg, 2002). One example is that encoding and retrieval of spatial locations activate overlapping regions in the 'where-pathway' as shown in Figure 2 (Persson and Nyberg, 2000). Such overlap suggests that formation and recovery of memory representations engage the same brain regions. This possibility is in line with the view that memories are represented in a distributed fashion in/near regions that are involved during initial perception/encoding.

CONCLUSION

Encoding and retrieval are two distinct, but highly interactive, memory processes. The neural bases of these processes are only beginning to be understood. At this stage, there is converging evidence that encoding and retrieval engage specialized neural systems. There is also evidence that specific association areas are engaged during encoding of specific information as well as during subsequent retrieval of the same information. Areas where encoding and retrieval processes meet in the brain may represent storage sites.

Epilepsy

Introductory article

W McIntyre Burnham, University of Toronto, Toronto, Ontario, Canada

CONTENTS

The term epilepsy refers to a group of neurological disorders characterized by spontaneous, recurrent seizures. In most cases drug therapy is effective, but intractable epilepsy can have a profound effect on quality of life.

INTRODUCTION

The epilepsies are a group of neurological disorders characterized by spontaneous, recurrent seizures. About 1% of the population has epilepsy at any given time, and about 4% of the population will have epilepsy during their lifetime. Another word for epilepsy is 'seizure disorder'.

Seizures themselves are periods of self-sustained neural hyperexcitation. During a seizure, the neurons of the brain cease their normal activities and begin to fire in massive, synchronized bursts. Blood flow to the brain is increased, an6d there is a greater use of glucose and oxygen. After seconds or minutes, when the inhibitory mechanisms of the brain regain control, the seizure ends. During a seizure the hyperactivity in the brain can be seen as a series of spikes, or spikes and waves, in electroencephalographic (EEG) recordings: these are called the 'electrographic' seizure. The behavior of the patient during the epileptic attack – which may or may not be convulsive – is called the 'clinical' seizure. If the clinical seizure involves muscle spasms, it is called a 'convulsion'. It should be noted that many clinical seizures are nonconvulsive. Other terms for seizure are 'attack' and 'ictus'. The terms 'preictal', 'ictal' and 'postictal' refer to events that occur before, during and after a seizure; 'interictal' refers to events that happen between seizures.

To be classified as epilepsy, seizures must be spontaneous, meaning that there is no outside cause for the attack. Seizures caused by fevers in children (febrile seizures), by convulsant drugs or by metabolic imbalances are not considered to be epilepsy. Seizures must also be recurrent. A single seizure – estimated to occur in about 10% of the population – is not considered to be epilepsy: two or more seizures must occur before epilepsy is diagnosed.

It is important to note that seizures do not equal epilepsy. Every brain has a 'seizure threshold', and every brain will generate a seizure if it is subjected to a high level of excitatory stimulation. In most people the seizure threshold is high, and seizures do not occur spontaneously. People with epilepsy are distinguished by the fact that their brain – or a part of their brain – has a seizure threshold so low that from time to time the brain's own activity triggers an attack. This low seizure threshold is always present, and stimuli that would not affect an ordinary person, such as hyperventilation or flashing lights, will sometimes trigger a seizure in a person with epilepsy.

ONSET OF EPILEPSY

The onset of epilepsy can occur at any time during life. In many patients seizures begin in childhood, often before the age of 15 years. If seizures begin later, during adulthood, they may indicate the presence of an expanding tumor in the brain. In recent years – perhaps because people are living longer – there has been an increased onset of seizures in elderly people. Many of these are thought to be the result of small strokes.

FREQUENCY OF SEIZURES

The frequency of seizures varies enormously. Some patients may experience only a few seizures during the whole course of their life. At the other end of the spectrum are patients who experience many seizures every day.

EFFECT ON LIFE

In general, seizures do not constitute a major medical emergency. They are not painful, and except for the condition known as 'status epilepticus' (see below), they do not harm the individual. Admittedly, there are risks. People with seizures sometimes injure themselves as they fall, and if seizures are frequent they are advised not to swim alone, to shower rather than to bathe, and to avoid high places and the edges of subway platforms. In general, however, the risks of seizures are manageable.

Seizures often have social and economic effects on life, however, that go far beyond their medical importance. Seizures may be frightening to watch, and people who have public seizures face both social and economic discrimination. The impact that seizures have on life thus relates to whether public seizures can be controlled. If seizures are responsive to medication, the patient may never have another attack. Such patients have to take medication regularly, but if they do so, epilepsy will have little effect on their life. If seizures are only partly responsive to medications, however, the patient will live a fairly normal life, but will continue to have some attacks. If they occur in public, the patient will probably have some social and economic problems. In most countries, drivers' licences are canceled with the first seizure. The licence is usually returned if the patient is seizure-free for a certain period (often a year). A patient who has even one seizure a year, however, may never be able to legally drive again, which may severely limit the possibilities of employment. If seizures are drug-resistant, they will continue to occur despite the best drug therapy. Children with drug-resistant seizures often have serious problems at home and at school, while adults are frequently unemployed or underemployed. Serious emotional problems may develop, and there is a risk of suicide. These patients must turn to nonpharmacological therapies, such as surgery, the ketogenic diet and vagal stimulation (see below).

CLASSES OF EPILEPTIC SEIZURE

There are a number of different types of epileptic seizure, some of which occur primarily in childhood. Table 1 sets out the international classification of epileptic seizures, formulated in 1981 by the International League Against Epilepsy. The following discussion is limited to four types of seizure commonly seen in adults.

Table 1. International classification of epileptic seizures, formulated in 1981 by the International League Against Epilepsy

- I *Partial (focal, local) seizures*
  - A Simple partial seizures (consciousness unimpaired)
    - With motor signs
    - With somatosensory or special sensory symptoms
    - With autonomic symptoms or signs
    - With psychic symptoms
  - B Complex partial seizures (consciousness impaired)
    - Simple partial onset followed by impairment of consciousness
    - With impairment of consciousness at onset
  - C Partial seizures evolving to secondarily generalized seizures
    - Simple partial seizures evolving to generalized seizures
    - Complex partial seizures evolving to generalized seizures
    - Simple partial seizures evolving to complex partial seizures, evolving to generalized seizures
- II *Generalized seizures (convulsive or nonconvulsive)*
  - A Absence seizures
    - 1 Typical absences
    - 2 Atypical absences
  - B Myoclonic seizures
  - C Clonic seizures
  - D Tonic seizures
  - E Tonic–clonic seizures
  - F Atonic seizures (astatic seizures)
- III *Unclassified epileptic seizures*

Modified from: Proposal for revised clinical and electroencephalographic classification of epileptic seizures. *Epilepsia* 1981; **22**: 489–501.

Generalized Seizures

In generalized seizures the whole brain is involved in epileptic activity (EEG 'spiking') during the attack, and consciousness is usually lost.

Absence seizure

Absence seizures (formerly called 'petit mal' seizures) are nonconvulsive. The clinical seizure consists of a few seconds of blank staring and immobility, while the electrographic seizure consists of 'three per second spike and wave' activity in the EEG. Consciousness is lost, and the person has no memory of the attack. After the attack the person resumes whatever he or she was doing, and may be unaware that an attack has taken place. These mild seizures usually start in childhood, and may be outgrown by the teenage years. While each seizure is mild, absence seizures can occur many times each day, and children may have trouble following what is going on around them.

Tonic–clonic seizure

The second common type of generalized seizure is the tonic–clonic seizure (formerly called 'grand mal' seizures). These are the dramatic convulsive seizures that people think of when they hear the term 'epilepsy'. The clinical seizure involves a convulsion which consists of stiffening of the whole body (tonus) and then jerking of the whole body (clonus). The electrographic seizure consists of constant spiking in the EEG. Consciousness is lost, and the patient will have no memory for the period of the attack. After the attack – which lasts a few minutes – the person is comatose for a short time (postictal coma) and then may be conscious but confused. After that, the person returns to normal, perhaps being able to go back to work, or wanting to lie down or sleep.

Partial Seizures

In addition to the generalized epilepsies, there are two types of 'partial' epilepsy (formerly called 'focal' epilepsies). The term 'partial' indicates that, at least at the onset, only part of the brain is involved in epileptic activity (EEG spiking). The person is usually conscious during a partial seizure, although consciousness may be impaired. Partial seizures are often nonconvulsive.

Simple partial seizure

During simple partial seizures (formerly called 'cortical focal' seizures), epileptic spiking is limited to one part of the brain. The symptoms of the seizure depend on the part of the brain activated by the epileptic discharge. They are very variable: for instance, they may involve an experience of flashing lights, a buzzing sound, a bad smell or taste, or a feeling of fear. If a motor area of the cortex is involved, convulsive jerking (clonus) will be seen on the opposite side of the body. The person is conscious throughout the seizure, and will remember it afterwards.

Complex partial seizure

In complex partial seizures (formerly called 'temporal lobe' or 'psychomotor' seizures), epileptic spiking is often seen on both sides of the person's brain in the temporal lobe areas. During such seizures the person does not convulse, and does not lose consciousness – however, consciousness is said to be impaired. The person is nonresponsive and seems to be out of contact with the environment. Repetitive meaningless movements may occur, such as lip smacking or fumbling with the clothes (automatisms). Although not unconscious, the person will have no memory of the attack, possibly because the memory mechanisms in the both temporal lobes are involved. Complex partial seizures are the most common type of seizure in adults.

Auras and Prodromes

A simple partial seizure may spread through the brain (generalize) to become a complex partial attack or a tonic–clonic attack. The simple partial seizure – which is remembered – is then termed an 'aura' or warning. It is important to distinguish auras – which are simple partial seizures – from prodromes. Prodromes are signs, recognized by the person or the person's family, that a seizure is going to occur later in the day. Like auras, prodromes precede seizures, but, unlike auras, they do not involve seizure activity.

Status Epilepticus

Very long seizures, or seizures that repeat without the patient regaining consciousness, are termed 'status epilepticus'. Status can consist of a prolonged period of absence seizures, partial seizures or tonic–clonic seizures. Nonconvulsive status is not considered a major medical emergency. Convulsive status, however (i.e. tonic–clonic status), may lead to brain damage or death if it is not terminated. Epilepsy associations often suggest that families should call for an ambulance if a tonic–clonic seizure has not stopped within 5 min.

EPILEPTIC SYNDROMES

An attempt has been made to fit epileptic seizures into larger classifications or epileptic syndromes. An epileptic syndrome includes not only a seizure type (or types), but also a prediction about the time of seizure onset, a possible cause, a prognosis for control, and, in some cases, a likely response to a particular medication. One example is juvenile myoclonic epilepsy: in this syndrome the seizures consist of isolated muscle jerks (myoclonus) and tonic–clonic attacks. Onset is between ages 8 years and 18 years. The young person is perfectly normal except for the seizures, which often occur in the morning, just after waking. There is often a history of juvenile myoclonic epilepsy in the family, and the cause is believed to be genetic. There is a good response to anticonvulsant drugs, especially valproate. Other well-known epileptic syndromes include West syndrome, which has its onset in the first year of life, and Lennox–Gastaut syndrome,

which usually begins between the ages of 1 year and 8 years. These serious epileptic syndromes involve intractable seizures, an abnormal interictal EEG and in most cases mental retardation. However, many seizures do not fit into any recognized syndrome.

CAUSES OF EPILEPSY

In about 30–40% of people with epilepsy, there is a clear-cut structural abnormality in the brain. These abnormalities include scars, tumors, infections, areas of improperly developed cortex (cortical dysplasia) and blood vessel (arteriovenous) malformations. Cases of epilepsy where there is a clear abnormality in the brain are described as 'symptomatic'. They are often hard to control with anticonvulsant medications. Table 2 indicates the frequency of different causes of epilepsy found in a large American study.

In about 60–70% of people with epilepsy, the brain appears to be entirely normal. In these people the abnormality causing the seizure is assumed to be an ionic or biochemical imbalance. Cases of epilepsy in which the brain appears to be entirely normal are described as 'idiopathic', and their cause is generally thought to be genetic. The term 'cryptogenic' is sometimes applied to cases of epilepsy where no clear brain abnormality can be found, but where there are symptoms that resemble those of the symptomatic epilepsies. It is assumed in these cases that an abnormality exists, but that it cannot be found.

Genetic Factors

There is a genetic factor in most cases of epilepsy. Both the partial and the generalized epilepsies show significant hereditability. In most cases of epilepsy, however, the genetic contribution is not a simple one.

The simplest mode of inheritance is inheritance involving a single gene. This is often called Mendelian inheritance, and the rules that govern dominant and recessive Mendelian inheritance are well understood. In other cases, inheritance is dependent on a number of genes, and is described as 'multifactorial'. The rules governing multifactorial inheritance are much less clear. In most cases of epilepsy inheritance is multifactorial. The disorder tends to 'run in families', but does not follow simple Mendelian rules. The contribution of multifactorial genetics is clearest in the idiopathic epilepsies, where there is no structural abnormality in the brain. These are generally considered to be genetic disorders. What is inherited may be a collection of mild abnormalities, related to several different genes. None is sufficient to cause epilepsy by itself, but in combination, they contribute to a chronic low threshold.

There is a genetic predisposition even in cases of symptomatic epilepsy, where the seizures are related to a structural abnormality, such as a scar on the brain. Some people with such scars develop epilepsy, whereas others with similar scars do not. Again, the genetic predisposition seems to be multifactorial.

People with seizures often wonder whether their seizures will be passed along to their children. With multifactorial epilepsies, the chance of transmission is about 6% overall. It is about 9–12% if the epilepsy is idiopathic.

Table 2. The frequency of causes of epilepsy in a large American study

Cause	*Frequency (%)*
No clear cause (idiopathic epilepsy)	68.7
Known cause (symptomatic epilepsy)	31.3
Cerebrovascular disease	13.2
Developmental	5.5
Brain trauma	4.1
Brain tumor	3.6
Cerebral infection	2.6
Degenerative disease	1.8
Other	0.5

Based on Annegers JF (1994) Epidemiology and genetics of epilepsy. *Neurologic Clinics* **12**: 15–29.

The Genetic Epilepsies

In some epilepsies genetic factors have a much greater role. These are the epileptic syndromes that relate to single gene mutations, the inheritance of which follows Mendelian rules. More than 140 genetic epileptic syndromes are now recognized; most of them are rare.

In some cases a single gene abnormality gives rise to a subtle change in the brain, which is otherwise normal. Some of these subtle changes have been found to be abnormalities in ion channels, which has given rise to the concept of the genetic epilepsies as 'channelopathies'. These epileptic syndromes are idiopathic: an example is juvenile myoclonic epilepsy. Within this class there are a number of benign syndromes. In a benign syndrome, seizures appear in childhood, but spontaneously disappear as the child grows older. Examples are benign familial neonatal convulsions

and benign rolandic epilepsy. In other cases of inherited epilepsy, the genetic abnormality gives rise to a major malformation of the brain. These epilepsies are described as 'symptomatic'. An example is tuberous sclerosis: in this condition the brain is malformed, and the child frequently suffers from mental retardation and intractable seizures. Tuberous sclerosis is often a cause of West syndrome. In still other cases, the inherited defect is a metabolic abnormality. This makes the brain unable to metabolize some compound produced in neurons. The compound gradually builds up over the years, until it interferes with neural function. A child with this type of genetic abnormality will be normal at first, but later, as the compound begins to compromise brain function, will experience a progressive loss of mental function, intractable myoclonic seizures, and eventually death. These serious symptomatic syndromes are known as progressive myoclonus epilepsies and sometimes as 'storage diseases'. Lafora disease and Baltic myoclonus epilepsy are examples of progressive myoclonus epilepsies.

With epilepsies related to a single gene, the possibility of transmission to children is high. Families afflicted with genetic epilepsies should seek genetic counseling.

Finally, in some cases epilepsy is caused by genetic abnormalities that are not inherited but arise during fetal development. Examples are Rett syndrome, which involves retardation and seizures, and Down syndrome, in which seizures occur in about 15% of cases.

TREATMENT

Drug Therapy

The most common therapy for epilepsy is treatment with anticonvulsant drugs. It is almost always the first therapy to be tried. The term 'anticonvulsant' is something of a misnomer, since many seizures do not involve convulsions. Some writers, therefore, prefer the terms 'antiepileptic' or 'antiseizure' drug. 'Anticonvulsant', however, is still the term most widely used. A wide variety of anticonvulsant drugs are available. Among the most commonly prescribed are ethosuximide, used for absence seizures, and phenytoin and carbamazepine, used for tonic–clonic and partial seizures. Phenobarbital (phenobarbitone) is an older drug, sometimes used for tonic–clonic and partial seizures. Valproic acid and clonazepam are wide-spectrum drugs, effective against many different seizure types. Table 3 lists the most commonly prescribed anticonvulsant drugs, grouped according to use. In addition to the standard anticonvulsants, a number of new drugs have been introduced, including lamotrigine, gabapentin, topiramate, vigabatrin, levetiracetam, zonisamide and oxcarbazepine. These drugs are available in some countries, but not in others. While the new drugs generally have fewer side effects than the older drugs, it is not yet clear that they are more effective at stopping seizures. They are considerably more expensive than the older drugs.

Table 3. Commonly prescribed anticonvulsant drugs

Type of Seizure	*Drug*
Absence seizures	Ethosuximide
Tonic–clonic and partial seizures	Carbamazepine
	Gabapentin
	Phenobarbital (phenobarbitone)
	Phenytoin
	Primidone
Broad-spectrum drugs (absence, tonic–clonic and partial seizures)	Clonazepam
	Lamotrigine
	Sodium valproate, valproic acid
	Topiramate
Status epilepticus (administered intravenously in hospital)	Diazepam
	Lorazepam

Modified from Burnham WM (1998) Antiseizure drugs. In: Kalant H and Roschlau WHE (eds) *Principles of Medical Pharmacology*. New York: Oxford University Press.

Anticonvulsant therapy is begun cautiously. At the initial consultation of a patient experiencing seizures, the physician first searches for the cause of the attacks. If the seizures are the result of an active disease process such as an expanding tumor or a brain infection, the physician treats the disease rather than prescribing anticonvulsant drugs. If no active pathological condition is found, the physician prescribes anticonvulsant drug therapy. The first step is to establish which type of seizure is occurring. This is important, because different types of seizure require different drugs. Drugs used to treat tonic–clonic seizures may make absence seizures worse, and vice versa. It is particularly hard to distinguish between some of the nonconvulsive seizure types, such as absence and complex partial seizures. The distinction, however, is important, since they require different medications.

In current practice the medical management of seizures will begin with a single drug (monotherapy). If the first drug fails, the physician may try another single drug before going on to drug

combinations (polypharmacy). With most anticonvulsants, it is wise to start treatment with a low dose, and gradually build up to the full therapeutic dosage. Drug doses are commonly adjusted on the basis of 'blood levels'. After the patient has started taking the medication, a blood sample is taken to determine whether the dose administered has produced blood concentrations within the therapeutic range. If concentrations are not in the therapeutic range, the dose may be adjusted. It is important to note, however, that some patients achieve seizure control with blood levels below the therapeutic range, while other patients fail to show toxicity with blood levels above it. In these patients there is no need to adjust dosage to therapeutic levels: in the long term, patient response – not blood levels – should determine dosage.

The anticonvulsant medications do not cure epilepsy. They simply suppress seizures on a temporary basis. Patients must continue to take their medication, once, twice or three times daily, sometimes for the rest of their lives.

The success of drug therapy varies from patient to patient. When appropriate drugs and dosages are administered, therapy is completely successful in about 60% of patients. These patients may never have another seizure. In these cases of complete seizure control, after 2 years and if the EEG is normal, the patient may be offered the choice of gradually discontinuing medication. This is a serious decision, since the patient should not drive for 3–6 months after the drugs are discontinued. About half of these patients find that they have 'outgrown' their epilepsy, and that the drugs are no longer necessary.

Another 20% of patients are only partially responsive to drugs. These patients have fewer attacks while on medication. Unfortunately, about 20% of patients have seizures that are completely resistant to drugs – 'refractory' or 'intractable' seizures.

While any type of seizure can be intractable, intractability is most often seen in association with structural brain abnormalities, or when certain types of seizures are involved. The seizures associated with two rare childhood syndromes, West syndrome and Lennox–Gastaut syndrome, are frequently intractable, as are those associated with complex partial epilepsy. The intractability of complex partial seizures presents a major therapeutic problem, since these are the most common seizures in adults. If two appropriate single drugs have been tried and have failed to control the seizures, there is a good chance that the seizures will be intractable. The patient may then be given a combination of two or more drugs, but even polypharmacy may not stop the attacks. Other, nondrug therapies should then be considered.

Nondrug Therapies

If the patient suffers from intractable partial epilepsy, and attacks always start in the same spot in the brain (the 'focus'), the physician may suggest surgery. The most common surgical treatment for seizures involves removal of the site in the brain that initiates the attacks. If the patient is suffering from complex partial seizures of temporal lobe origin, the surgeon might remove the anterior part of one of the temporal lobes (temporal lobectomy). Surgery may stop the seizures altogether, or may make them more controllable with medication. Other surgical procedures are corpus callosotomy, where the surgeon cuts the connections between the left and right cortex, and multiple subpial resection, where the surgeon makes many small cuts in an area of epileptic cortex that is too important to be removed (e.g. the speech center).

Another therapy for intractable seizures is the ketogenic diet. The ketogenic diet is a high-fat diet containing adequate protein and limited carbohydrate. In its classic form, the diet consists of three or four parts of fat to one part of everything else that is eaten. Patients may find the diet unpalatable, and it is difficult to maintain, since all of the patient's food must be weighed and measured. The ketogenic diet, however, stops seizures in about a third of patients who have found drug therapy ineffective, and decreases seizures in another third. Owing to worries about the diet's nutritional effects, patients usually stay on the diet for only 2–3 years. Traditionally the diet has been used in children, although reports suggest that it is effective in adults as well. The diet's mechanism of action is unknown.

A third treatment for intractable seizures is vagal stimulation. A device similar to a cardiac pacemaker is permanently implanted in the patient's chest muscle, and used to stimulate the vagus nerve, which originates in the brain. For unknown reasons, stimulation of the vagus nerve suppresses seizures in some patients. Vagal nerve stimulation is not as effective as surgery or the ketogenic diet, but it is an alternative to consider when the other therapies fail.

Therapy for the Emotional Consequences of Epilepsy

Intractable epilepsy has major emotional consequences. These must be dealt with if the seizures cannot be stopped.

Seizures involve a frightening loss of control, which occurs at random, unpredictable intervals. People with intractable epilepsy, therefore, often suffer a major loss of self-confidence. This is compounded by social rejection, economic decline, and the side effects of the anticonvulsant drugs. It is estimated that about 50% of children with intractable epilepsy suffer from emotional disturbances – often anxiety or depression – severe enough to require therapy. The numbers are probably similar for adults with intractable epilepsy. The emotional problems related to seizures are responsive to therapeutic drugs, and in particular to antidepressants. Unfortunately, these problems are seldom recognized or treated. Therapy centers on seizure control, and emotional problems are often overlooked. Patients with emotional problems should talk to their doctors and ask for help.

CONTRIBUTIONS OF EPILEPSY RESEARCH TO NEUROSCIENCE

Much of our knowledge about the organization of the human neocortex originally came from the study of simple partial seizures. When epileptic discharge activates a part of the brain, the seizure that occurs reflects the function of that brain area. When the visual cortex is involved, for instance, the patient sees flashing lights; when the auditory cortex is involved, the patient hears a buzzing sound. In the late nineteenth century, the British neurologist Hughlings Jackson worked out the organization of the human somatosensory and motor areas on the basis of simple partial seizures. Much of what he deduced was later confirmed by Penfield and Jasper, working at the Montreal Neurological Institute, and using electrical impulses to stimulate the exposed brain of waking patients during seizure surgery.

CONCLUSION

Epilepsy is a common neurological disorder, usually treated with anticonvulsant drugs. With the current drugs more than half of patients are seizure-free, and others have fewer seizures. Roughly 20% of patients, however, obtain no benefit from drugs, and these patients must seek other forms of therapy. It is the job of clinicians and researchers to find better therapies for people whose epilepsy is intractable. It is the job of the general public to develop tolerance and positive attitudes toward people whose seizures cannot yet be controlled.

Face Cells

Intermediate article

Martin Tovée, Newcastle University, Newcastle upon Tyne, UK

CONTENTS

Face cells are neurons in the primate visual system that seem to be specialized for face recognition.

INTRODUCTION

It has been known since the 1970s that there are neurons in the monkey visual system that are sensitive to faces. These face cells have been studied in most detail in the anterior inferior temporal (IT) cortex and the upper bank of the superior temporal sulcus (STS), but they also occur in other areas such as the amygdala and the inferior convexity of the prefrontal cortex (Figure 1).

Characteristically, the optimal stimuli of face cells cannot be deconstructed into simpler component shapes (Wang *et al*., 1996). In general, these cells show virtually no response to any other stimulus tested (such as textures, gratings, bars, and the edges of various colors), but respond strongly to a variety of faces, including real ones, plastic models, and video display unit images of human and monkey faces. The responses of many face cells are invariant to size and position; the cell's response is maintained when there is a change in the size of the face, or if the position of the face within the cell's receptive field is altered. Face cells do not respond well to images of faces that have had the components rearranged, even though all the components are still present and the outline is unchanged (e.g., Perrett *et al*., 1992). Face cells are even sensitive to the relative position of features within the face; particularly important is inter-eye distance, distance from eyes to mouth, and the amount and style of hair on the forehead (e.g., Young and Yamane, 1992).

Moreover, presentation of a single facial component elicits only a fraction of the response generated by the whole face, and removal of a single component of a face reduces, but does not eliminate, the response of a cell to a face. This suggests that the face cells encode holistic information about the face, because the entire configuration of a face appears to be critical to a cell's response.

ORGANIZATION OF FACE CELLS

Studies that have combined optical imaging with single cell recording have revealed a patchy distribution of cellular activity on the cortical surface in response to faces, consistent with face cells being organized into functional columns (Wang *et al*., 1996). However, the imaging also showed that rather than discrete columns with little overlap, there was significant overlap in activity to different face orientations (Figure 2). This may mean that stimuli are mapped as a continuum of changing features (Tanaka, 1997). Such a

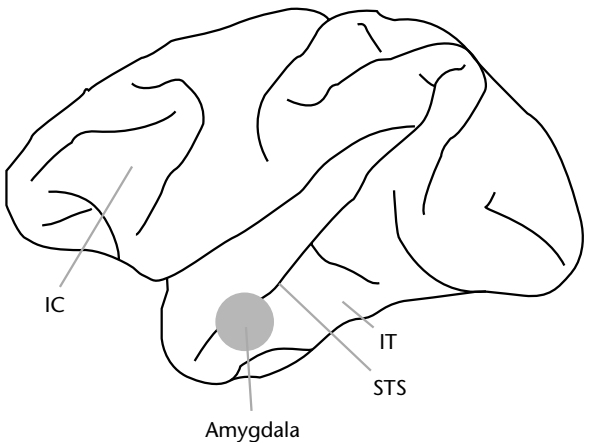

Figure 1. The cortex of a rhesus monkey showing the principal sites in which face cells have been reported: the inferior temporal cortex (IT), the superior temporal sulcus (STS), the amygdala (which is located within the temporal lobe), and the inferior convexity (IC) of the prefrontal cortex.

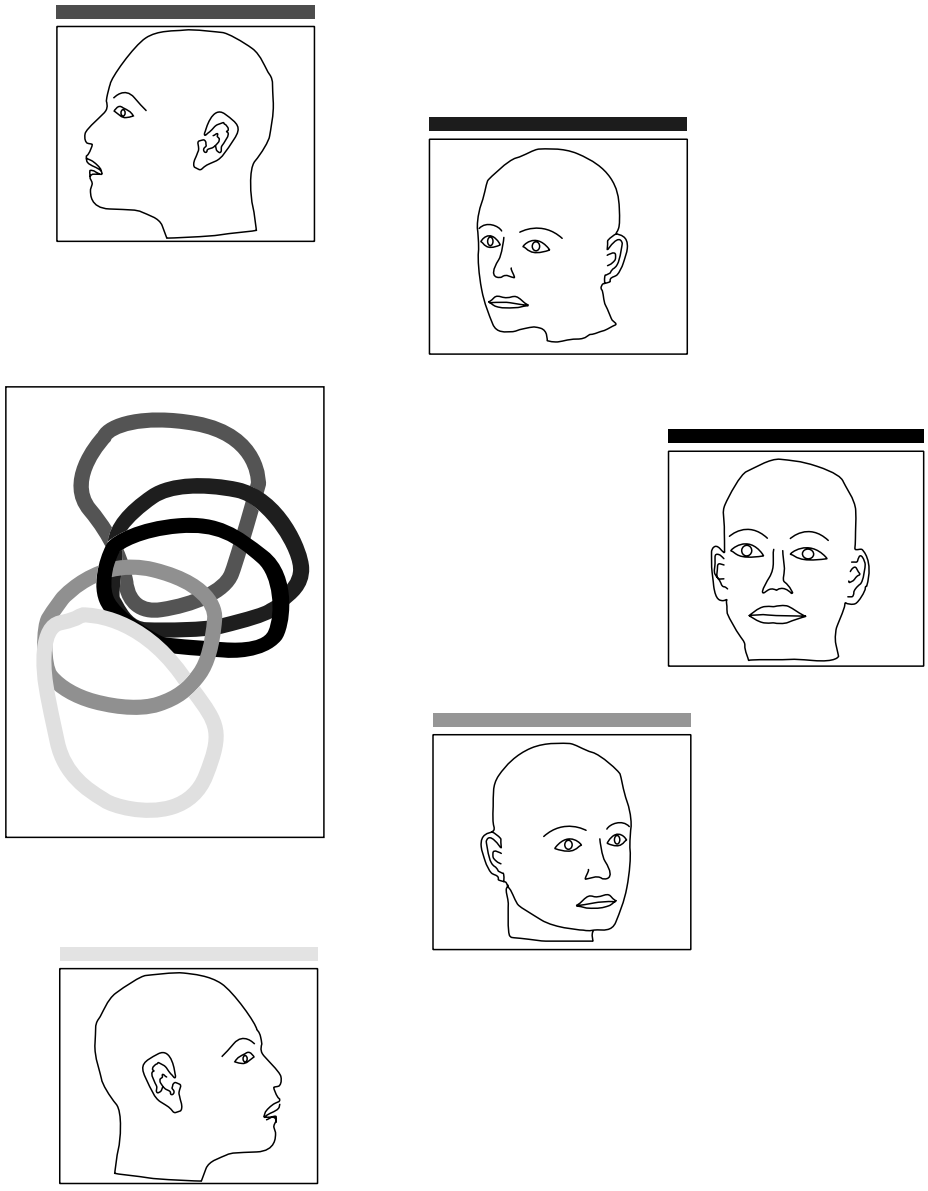

Figure 2. [*Figure is also reproduced in color section*.] Spatial pattern of activation on the surface of the inferior temporal cortex to successive presentations of a head viewed at different angles. The color of the strip above the image of the head indicates which activation pattern corresponds to which head (from Wang *et al*., 1996).

continuous map could produce a broad tuning of cortical cells for certain directions of feature space, which would allow the association of different, but related images, such as the same object from different viewpoints or under different illumination. This would obviously be an important mechanism in the development of a stimulus-invariant response.

However, feature space is a vast multidimensional area in which even the simplest 'real world' stimulus will possess a wide variety of elementary features, such as depth, color, shape, orientation, curvature, and texture, as well as specular reflections and shading (Young, 1995). Thus, a continuous representation would have to be reduced in some way to fit the limited dimensions possible in the cortex. Ultimately, a columnar organization is more likely, with cells in several columns responsive to stimuli that have features in common, and becoming jointly active as appropriate, a scheme that can also give rise to stimulus invariance.

FUNCTIONAL DIVISIONS: IDENTITY, EXPRESSION, AND DIRECTION OF GAZE

Faces can vary in a number of 'dimensions', such as identity, expression, direction of gaze, and viewing angle. Different populations of face cells seem to be sensitive to specific facial dimension, and insensitive to others. For example, Hasselmo *et al*. (1989) studied face cells in the STS and anterior IT cortex with a set of nine stimuli consisting of three different monkey faces, each displaying three different expressions. Neurons were found to respond to either dimension independently of the other. Cells that responded to expressions tended to cluster in the STS, whereas cells that responded to identity clustered in the anterior IT cortex. Further investigation has shown that there are also face cells in the STS that are responsive to gaze direction and orientation of the head (both of which are cues to the direction of attention) rather than expression (Hasselmo *et al*., 1989; Perrett *et al*., 1992). There seem to be five 'classes' of face cell in the STS, each class tuned to a separate view of the head – full face, profile, back of the head, head up, and head down (Perrett *et al*., 1992). There are an additional two subclasses, one responding to the left profile and one to the right profile.

Consistent with this finding of an anatomically segregated, functional specialization in processing different dimensions of facial information, removal of the cortex in the banks and floor of the STS of monkeys results in deficits in the perception of gaze direction and facial expression, but not in face identification (Heywood and Cowey, 1992). Perrett *et al*. (1992) suggested that the STS face cells may signal social attention, or the direction of another individual's gaze, information clearly crucial in the social interactions of primates.

Other face-cell populations also seem to be responsive to a specific dimension. The face cells in the amygdala seem to be sensitive to facial expression and may have a role in influencing and activating the emotional state of the monkey (Rolls, 1992). The face cells in the prefrontal cortex are sensitive to facial identity and seem to play a role in working memory (O'Scalaidhe *et al*., 1997). The functional organization of the different face-cell populations suggests the existence of a neural network containing processing units that are highly selective to the complex configuration of features that make up a face, and which respond to different facial dimensions (Gauthier and Logothetis, 2000).

There seem to be some homologies between the human and monkey face-processing systems. An area of the fusiform gyrus in humans has been implicated in face identification and may be the homologue of the face area in anterior IT cortex. There is also a region in the STS of both humans and monkeys that appears to be important for the processing of eye gaze and other facial expressions. Additionally, the human amygdala is active during the viewing of emotional facial expressions, particularly fear, which would be consistent with the finding of face cells responsive to expression in the monkey amygdala.

FACE CELLS AND THE POPULATION CODE

Face cells appear superficially to resemble the infamous 'grandmother cells' of the visual recognition system. These cells were described as being at the top of a processing pyramid that began with line and edge detectors in the striate cortex and continued with detectors of increasing complexity until a unit was reached that represented one specific object or person, such as your grandmother, leading to the name by which this theory became derisively known. This idea had two serious problems. First, the number of objects you meet in the course of your lifetime is immense, much larger than the number of neurons available to encode them on a one-to-one basis. Second, such a method of encoding is extremely inefficient as it would mean that there would need to be a vast number of uncommitted cells kept in reserve to code for the new objects one would be likely to meet in the future.

Although individual cells respond differently to different faces, there is no evidence for a face cell that responds exclusively to one individual face (e.g., Young and Yamane, 1992; Rolls and Tovée, 1995). Face cells seem to be part of a distributed network for the encoding of faces, just as other cells in the IT cortex probably make up a distributed network for the coding of general object features. Faces are thus encoded by the combined activity of populations, or ensembles, of cells. The representation of a face would depend on the emergent spatial and temporal distribution of activity within the ensemble (e.g., Rolls and Tovée, 1995; Rolls *et al*., 1997). Representation of specific faces or objects in a population code overcomes the two disadvantages of the grandmother cell concept. The number of faces encoded by a population of cells can be much larger than the number of cells that make up that population; so it is unnecessary to have a one-to-one relationship between stimulus and cell.

Second, no large pool of uncommitted cells is necessary. Single cell experiments have shown that the responses of individual neurons within a population alter to incorporate the representation of novel stimuli within the responses of existing populations (e.g., Rolls *et al*., 1989).

The size of the cell population encoding a face is dependent on the 'tuning' of individual cells: that is to say, how many or how few faces do they respond to? If they respond to a large number of faces, then the cell population of which they are a part must be large to signal accurately the presence of a particular face. A large cell population containing cells responsive to a large number of faces is termed 'distributed' encoding. If a cell responds to only a small number of specific faces, then only a small number of cells in the population is necessary to distinguish a specific face; this is termed 'sparse' encoding. Single cell recording experiments in monkey IT cortex have found that the face cells are quite tightly tuned and show characteristics consistent with sparse encoding (Young and Yamane, 1992; Abbott *et al*., 1996).

ARE FACE CELLS SPECIAL?

It has been suggested that face cells are a 'special' dedicated system that has arisen owing to the importance in social primates of facially conveyed information (Tanaka, 1997). All other nonface objects are represented by the distributed activity of a large number of cells selective to the different components that make up these objects. Each of these active cells (sometimes called elaborate cells) responds to only a comparatively simple shape; but across a population of cells responsive to different simple shapes, the representation of a complex object can be developed. In this framework, the face cell is qualitatively different from the neural representation of any other object class. Alternatively, there may be a 'plasticity' in the representation of visual stimuli. If you only have to make comparatively coarse discriminations, such as between different categories of objects (for example, cat versus dog), then this may be mediated by a distributed code across populations of elaborate cells. However, if you have to make fine, within-category discriminations, such as between faces, then a population of cells may become specialized for this purpose – in which case face cells are only special to the extent that they are an example of the neural machinery necessary to mediate within-category 'expert' discriminations (Tovée, 1998).

To resolve this question, one would have to train a monkey to become expert in recognizing and discriminating within a category of objects sharing a number of common features. Logothetis and Pauls did just that. They trained monkeys to discriminate within two categories of computer-generated three-dimensional shapes: wire frames or spheroidal 'amoeba-like' objects (Figure 3). The animals were trained to recognize these objects presented from one viewpoint and were then tested on their ability to generalize this recognition. Single cell recording from the anterior IT cortex during this recognition task revealed a number of cells that were highly selective to familiar views of these recently learned objects (Logothetis and Pauls, 1995; Logothetis *et al*., 1995). These cells exhibited a selectivity for objects and viewpoints that was similar to that found in face cells. They were largely size- and translation-invariant, and some cells were very sensitive to the configuration of the stimuli. In short, these cells showed the same response properties as face cells, but to computer-generated object categories.

These results suggest that the properties displayed by face cells can be duplicated for other

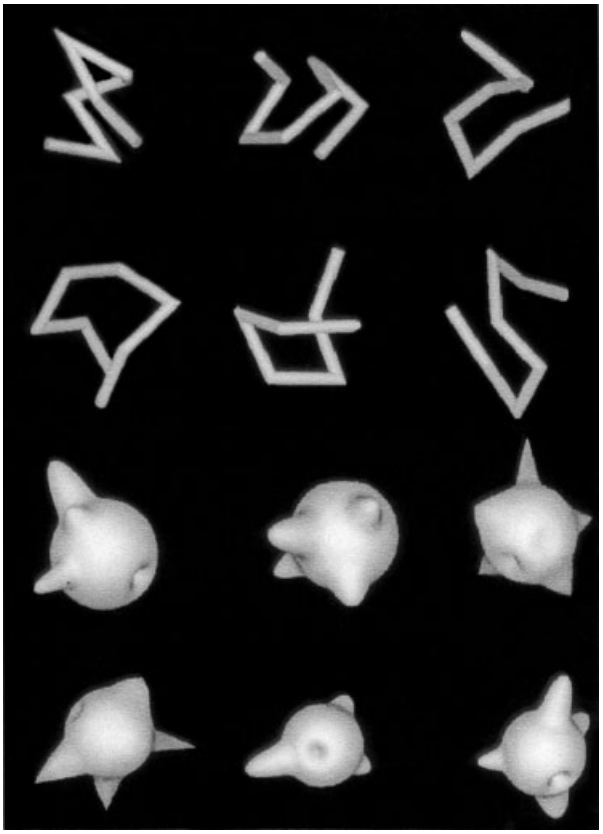

Figure 3. Examples of the wire-frame objects and 'amoeba-like' blobs used by Logothetis and Pauls (from Gauthier and Logothetis, 2000).

object categories which require fine within-category discrimination over a sustained period. Face cells are only 'special' because of the difficulty of the task in discriminating and interpreting facially conveyed information that requires a dedicated neural network. Equally difficult tasks can produce also a similar neural substrate to mediate this discrimination.

Face Perception, Neural Basis of

Intermediate article

Shlomo Bentin, Hebrew University of Jerusalem, Jerusalem, Israel

CONTENTS

There is neurophysiological evidence to support the existence of a specific neural mechanism in the extrastriate cortex, which is tuned to detect physiognomic information in the visual field and form a mental image, capturing those aspects of the face that enable us to distinguish it from other faces, a stage that is considered to precede personal identification.

INTRODUCTION

The outstanding expertise of humans in recognizing faces has led scientists to suspect that this perceptual process is based on dedicated neural structures. Indeed, face recognition in humans has often been paralleled to phonetic perception, as opposite poles on a hemispherical asymmetry continuum. Whereas the latter has been attributed to dedicated structures buried in the supra-temporal plane of the left hemisphere, the normal processing of faces has been assumed to engage primarily (but not exclusively) posterior-temporal structures in the right hemisphere. The view that the neural structures that are devoted to face perception are also *exclusively* dedicated to this process is controversial. In this article I shall review evidence suggesting that neural structures are implicated in face processing, and discuss their domain specificity. In particular, I shall focus on perceptual processes aimed at constructing a visual representation that is sufficiently detailed and complete to allow unequivocal categorization and identification of the face.

Current models of visual perception distinguish between levels of integration and representation in the visual system (Marr, 1982; Biederman, 1987, 1995; Ullman, 1995, 1996). Despite differences in emphasis and general approach, all of these models assume that the categorization of visually presented stimuli is based on the formation of a mental representation, which is reconstructed from changes in light energy impinging on the retina. Whereas the initial detection of these changes, in terms of edges between different levels of illumination, contrast, orientation and color, is performed in the striate and peristriate visual cortices, it is well accepted that the process of integrating the basic visual primitives into higher-level visual representations is a product of extrastriate neural mechanisms, most of which are distributed along the parvocellular ventral pathway of the visual system, the so-called 'what' pathway. To remind the reader, sensory information from the primary visual cortex reaches the temporal and parietal lobes to form two relatively (but not completely) separate pathways (Ungerleider and Mishkin, 1982; Desimone and Ungerleider, 1989). One of these is the 'where' system, which passes dorsally in the extrastriate cortex to end in the posterior parietal lobule (and additional ramifications to the frontal lobe). This is the dorsal, magnocellular pathway, which contains cells that are particularly sensitive to the stimulus location in space, and to movement. The other pathway is the 'what' system, which passes ventrally in the extrastriate cortex to reach the inferior temporal cortex, which includes (among other structures) the inferotempral gyrus (IT), the occipito-temporal (fusiform) gyrus, the lingual gyrus and the superior temporal sulcus (STS). This is the parvocellular ventral pathway, which contains cells that are involved in the formation of object-oriented, category-specific visual representations (Van Essen and Deyoe, 1995).

NEUROPSYCHOLOGICAL EVIDENCE

Evidence that faces are processed by dedicated neural mechanisms located in the ventral and inferior-temporal regions comes from a number of different sources. The most notable of these are neuropsychological observations of patients with impaired face recognition (prosopagnosia), electrical activity of single cells recorded in monkeys and of cell assemblies recorded in humans (either directly from the cortical surface or on the scalp

surface), and imaging of brain activity using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

Although in most cases of acquired prosopagnosia (impaired face recognition due to brain damage) face-processing deficits are often the most conspicuous aspect of a more general visual agnosia (Gauthier *et al*., 1999a), there are a few reports of prosopagnosic patients whose ability to recognize objects remained intact (McNeil and Warrington, 1993; Farah *et al*., 1995, 2000; Bentin *et al*., 1999). Conversely, there are reports of patients suffering from associative object agnosia whose face recognition ability was spared (Moscovitch *et al*., 1997). The double dissociation between face and object recognition suggests that the two abilities may be neurologically as well as functionally distinct.

EVIDENCE FROM SINGLE-CELL STUDIES

Single-cell recordings in the monkey demonstrated the existence of cells in the temporal lobes that are tuned to respond selectively to monkey (as well as human) faces, but not to other complex and emotion-arousing stimuli such as snakes, spiders or food (Perrett *et al*., 1987, 1990; Desimone, 1991; Gross, 1992; Logothetis and Scheinberg, 1996). Face-selective cells were predominantly found in the superior temporal sulci (STS) and inferior temporal gyri (IT), as well as in the amygdala and the inferior convexity of the prefrontal cortex. Whereas some of these cells responded more vigorously to isolated eyes than to whole faces, other cells responded only to the entire face-view configuration – that is, they were sensitive to the holistic face shape rather than to the existence of individual features. The selectivity of these neurons for faces was maintained despite changes in stimulus size and position. Furthermore, many of these cells responded only to particular orientations of faces or particular directions of gaze. A detailed investigation revealed five types of face-specific cells in the STS, each being maximally responsive to one view of the head, namely full face, profile, back of the head, head up and head down. In addition, two subtypes have been discovered that respond only to left profile or only to right profile, which confirms that these cells are involved in the structural analysis of the face, rather than in representing specific social or emotional responses that faces might elicit (Perrett *et al*., 1985). In summary, the activity of single cells in the monkey suggests that with regard to visual analysis of faces, there is some specificity in the IT and STS. The sensitivity of different cells to different stimulus characteristics suggests a high degree of specialization, providing a complex mechanism of face encoding in the extrastriate cortex. However, the fact that the same cells respond to human faces as well as to within-species (monkey) faces also suggests a high degree of neural plasticity and susceptibility to visual experience.

NEUROIMAGING EVIDENCE

Suggestive as they are, data characterizing the visual system of the monkey cannot be immediately generalized to humans. Indeed, from a phylogenic perspective we see a continuous trend of *reduced* specialization of individual cells, at least in the primary visual cortex. Fortunately, modern technology has enabled the recording of stimulus-linked brain activity in humans. In particular, functional brain imaging using PET and fMRI, and the recording of event-related potentials (ERPs), have yielded pertinent data that suggest face-processing specificity.

The distribution of hemodynamic changes in brain tissue is correlated with neural activity, because elevated metabolism requires more oxygen. Since oxygen is transported to the tissue by hemoglobin cells, the amount of blood flowing through a particular region correlates with its relative activity. PET and fMRI are two techniques which may reveal task-related changes in regional cerebral blood-flow. A series of PET studies suggested that there is posterior-ventral localization of face-specific visual processing (Huxby *et al*., 1996). For example, in one of the first attempts to isolate components of face processing from the processing of objects and nonsense shapes it was found that, compared with nonsense gratings and sinusoid shapes, both faces and objects activate extensive areas in the occipito-temporal cortex. However, whereas this activation was more pronounced in the right hemisphere for faces, it was greater in the left hemisphere for objects (Sergent *et al*., 1992). More recently, fMRI studies have provided a more detailed description. Faces activated the fusiform and middle occipital gyri, the lateral occipital sulcus and more anteriorly the superior temporal sulcus (STS), and this activation was greater in the right than in the left hemisphere (Kanwisher *et al*., 1997; McCarthy *et al*., 1997) (see also Figure 2). In addition, fMRI studies showed distinct activation for perceptual categories other than faces in regions adjacent to the face areas. Although the neuroimaging studies were consistent in showing neuroanatomical specificity for face processing (but see

Gauthier *et al*., 1999b; Gauthier *et al*., 2000), they did not establish when such processing occurs. A tentative answer to the time-course question is provided by the ERP studies.

ELECTROPHYSIOLOGICAL EVIDENCE

The flow of ionic currents across the cell membranes of active neurons and glia cells produces electrical potentials that can be recorded from the cortical surface or from the scalp by disk electrodes (several millimeters in diameter) and represented in the electroencephalogram (EEG) as voltage as a function of time. ERPs are processing-induced changes in these potentials – changes that are time-locked to the brain event that elicited them. These changes become conspicuous on the background of the ongoing EEG following the averaging of designated time epochs that encompass the onset of the stimulus under investigation and are time locked to it. ERPs are usually defined in terms of polarity relative to a neutral reference, onset and peak latency, peak or mean amplitude, and scalp distribution. Recorded non-invasively on the scalp, this technique can be used to investigate normal functioning of the human brain. However, scalp recording does not allow firm conclusions to be drawn about the location of the relevant active structures in the brain. One way to (partly) overcome this limitation is to record the ERPs directly from the cortical surface (and/or from deeper structures) when such invasive recordings are clinically indicated. In a series of studies, investigators at the Yale New Haven Medical Center examined the neural specificity for face processing by recording the electrical activity directly from the ventral and lateral cortex of the temporal lobes. This procedure was possible in patients with medically refractory epilepsy who were implanted with electrodes for localizing the focus of the seizures.

Extensive and systematic electrophysiological investigation of about 100 patients revealed discrete regions in the human extrastriate cortex which were activated by faces but not by other categories of visual stimuli such as cars, flowers, human hands, butterflies or printed words (Allison *et al*., 1999; McCarthy *et al*., 1999; Puce *et al*., 1999). A region was considered to be face specific if the amplitude of any of the ERP components (or a combination of them) recorded at this site was at least twice as large in response to a face than in response to other stimulus categories (note that the same criterion was used to determine the face selectivity of single cells). From a total of more than 7500 recording sites (across patients), about 100 sites were face specific. Most importantly, whenever a component was significantly larger in response to faces, its amplitude was similar across all other stimulus categories (Figure 1). Consistent with the fMRI studies, the vast majority of these sites were clustered on the ventral occipito-temporal cortex, and some were found on the posterior lateral surface of the temporal lobes. A further differentiation of the face-specific ventral sites was between the posterior clusters and an anterior cluster, with no overlap between them. Whereas the posterior ventral and lateral face areas were bilaterally distributed, the anterior face area was only found in the right hemisphere.

Face specificity was evident during three latency windows (from stimulus onset). The earliest face-specific component was a robust negative (compared with the reference) potential that peaked at around 200 ms (N200). This component was elicited in the posterior ventral and lateral face areas. Its amplitude was similar in men and in women, and its latency was slightly more delayed in men than in women, probably reflecting the relatively larger brains in men. The second face-specific component was a positive potential with an average peak of about 350 ms (P350). It was recorded bilaterally from the posterior ventral face area, bilaterally from the lateral face area, and in the right hemisphere from the anterior ventral face area. The third face-specific component was a sustained negativity (N700) observed in the waveforms elicited at about half of the sites at which the N200 was face specific, but also at some sites where the N200 was not specific to faces.

The response properties of this neuronal activity were examined in a series of experiments. In general, the results of these investigations were similar to those obtained by recording face-specific activity of single cells. Neither the N200 nor the N700 were sensitive to the color of the face or to its size. Moreover, all face-specific components were similar in response to unfamiliar and famous faces. Face inversion (i.e. presenting the face upside down) had a complex effect, depending on the location of the face in the visual field. Compared with the face specificity of single cells in the monkey, the human N200 was more species-selective. Although faces of cats and dogs elicited an N200 response which was significantly larger than that elicited by non-face stimuli, the amplitude of this N200 was half the size and its latency was significantly delayed compared with the response to human faces. This pattern was replicated in scalp recordings, in which human and primate but not other animal faces elicited a distinctive component, the N170 (Bentin

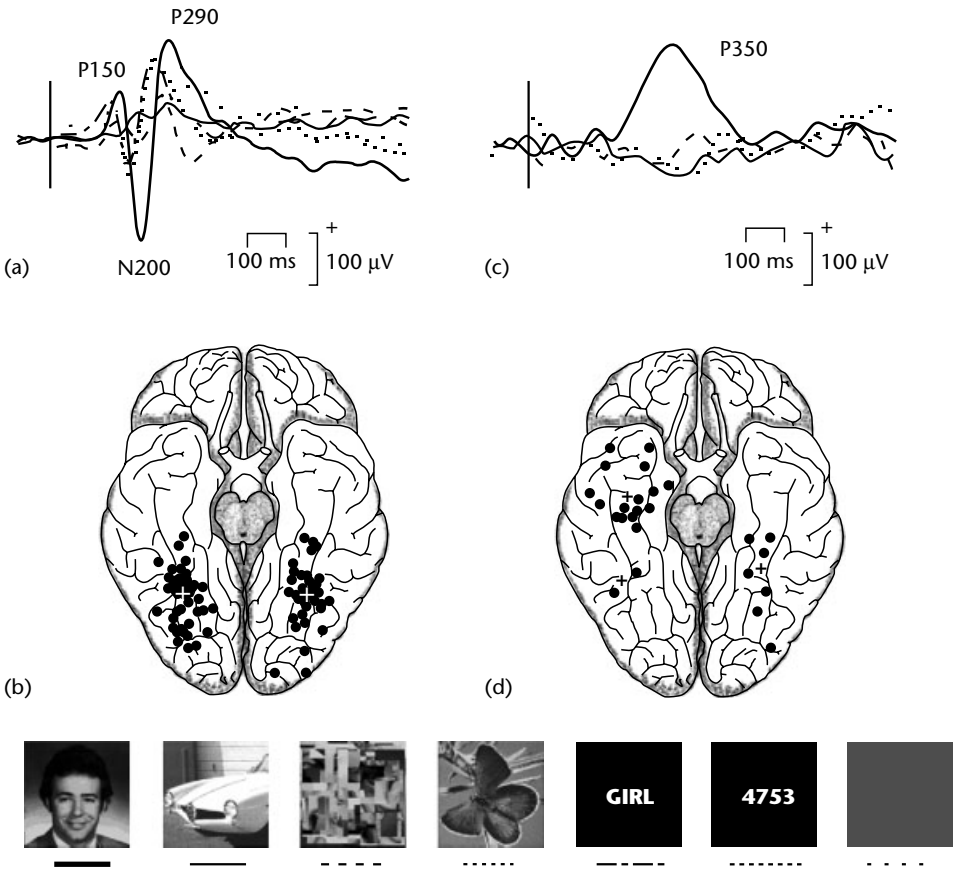

Figure 1. Face-specific ERP components recorded on the cortical surface. (a) N200 and its adjacent positive peaks. (b) Face-specific sites (black dots) in the posterior-ventral temporal lobes. (c) Face-specific P350. (d) Distribution of the P350. Note the unilateral right hemisphere distribution of the anterior sites. (Data provided courtesy of Dr Aina Puce.)

et al., 1996; Carmel and Bentin, 2002). Taken together, the ERP results suggest that the face-specific components recorded on the surface of the fusiform gyrus as well as those recorded from the posterior inferior temporal gyrus (IT) and those recorded on the scalp are associated with neuronal mechanisms that analyze the structural representation of the face, forming its internal representation, and that they are not involved in within-category face identification.

Additional results from intracranial as well as scalp recordings have revealed some characteristics of the face-encoding process. Behavioral and neuropsychological evidence strongly indicates that face identification is based on a holistic process – that is, the gestalt configuration of the face is analyzed first, whereas the analysis of individual face components (if necessary at all) is a late process, independent of face identification (Tanaka and Farah, 1993). Nonetheless, the possibility that the holistic process on which identification is based is only part of a more complex face-encoding mechanism that may also include the analysis of face parts has not been ruled out. Indeed, the finding that despite its significant detrimental effect on face identification, face inversion does not have dramatic effects on either the N200 or the N170 suggests that impeding configurative analysis of the face has only a minor influence on the activity of the face-encoding neuronal process with which these ERP components were associated. To investigate this hypothesis, the sensitivity of the N200 to face parts was directly examined. The results demonstrated that the N200s elicited by isolated eyes, lips, noses or face contours were significantly distinct from those elicited by objects such as cars, flowers and items of furniture, which suggests that the associated neuronal mechanism processed face parts (whether internal or external) as face-like rather than as object-like stimuli. Yet at all face-specific sites the N200 amplitude was reduced relative to that elicited by full-face gestalt. Moreover, as for inverted or degraded faces, the N200 latencies to face parts were significantly longer than those to full faces, suggesting

that analysis of unusual or partial views of a face requires additional processing time. However, the fact that neither the latency nor the amplitude of the N200 to faces is the linear sum of the response to face parts does not support a hierarchy of processing in which face-part cells send their output to a next stage of face processing. It is possible that individual face components are analyzed in parallel by other neuronal mechanisms, and that the accumulated information is integrated by the face-specific mechanism manifested in the N200. The latter hypothesis is supported by the finding of certain regions, lateral to the ventral face-specific N200 sites, which respond preferentially to face components, particularly eyes. These part-sensitive sites are primarily located in the inferior temporal gyrus, at the border between the ventral and lateral cortex. Given their location and the orientation of the cellular columns in that part of the cortex, their activity probably accounts for the modulation of the face-specific N170 recorded on the scalp. Indeed, one of the most consistent findings is that the amplitude of the N170 elicited by isolated eyes is significantly larger and its latency is longer than the N170 elicited by full faces.

Is the face-specific encoding modulated by top-down processes engaging previous knowledge, contextual information and expectations? A series of intracranial as well as scalp recordings designed to answer this question revealed a complex pattern of results. On the one hand, the intracranial recorded N200 was not significantly affected by

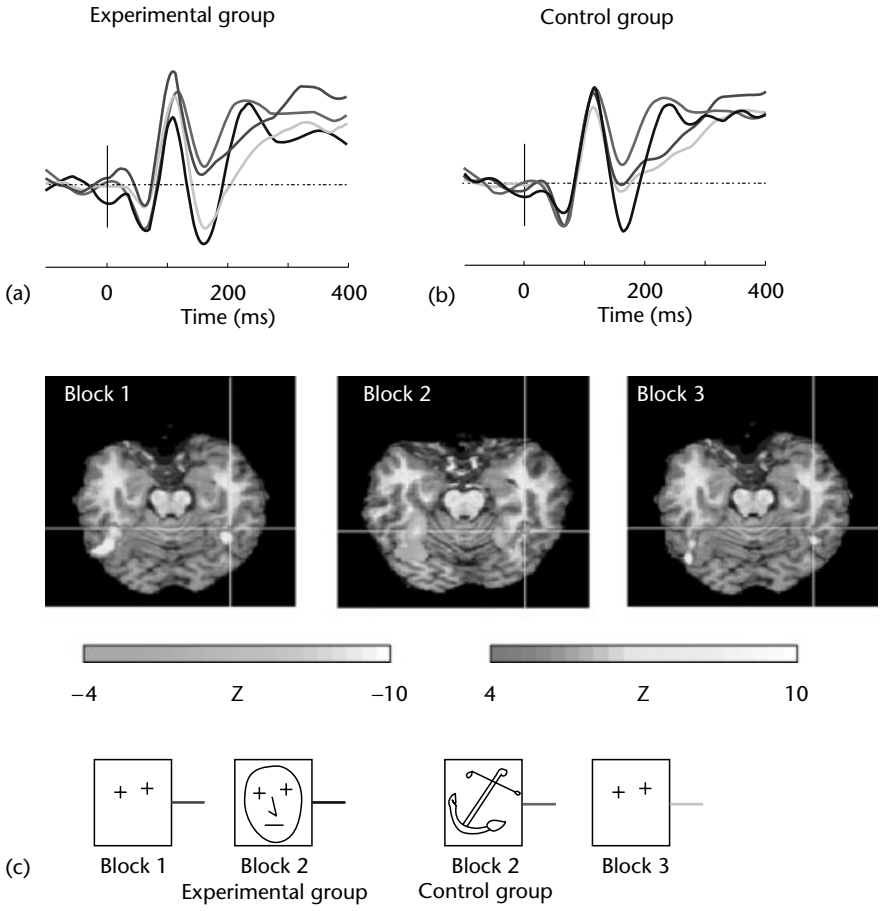

Figure 2. [*Figure is also reproduced in color section*.] Priming effects on face-specific neural activity. (a) The ERPs elicited by two crosses seen in block 1 resemble those elicited by objects. The same stimuli seen in block 3, after a face context was suggested, elicit an N170 similar to that elicited by faces. (b) If objects rather than faces are presented in block 2, the face-specific mechanism is not switched on. (c) Priming effects seen by fMRI. Note in the middle panel the right-hemisphere-lateralized activity elicited by faces (warm colors), and the bihemispheric activity elicited by objects. The two crosses shown in block 1 activate areas similar to those activated by objects. When provided with a face context, the same stimuli activate more restricted areas, albeit bilateral ones. (The fMRI data were collected at the Max-Planck Institute of Cognitive Neuroscience in collaboration with Axel Mecklinger, Yves von Cramon and Angela Friederici.)

stimulus repetition, showing no habituation. It was identical for familiar and unfamiliar faces, and it was not affected by semantic priming. On the other hand, the scalp N170 seems to be sensitive to conceptual influences. First, it is elicited as efficiently by schematic drawings of faces as by natural faces, provided that the schematic representation is simple and clear (Sagiv and Bentin, 2001). Secondly, whereas simple pairs of lines do not normally elicit an N170, they would do so if the subject was primed to interpret the lines as eyes in a schematic face (Figure 2) (*see* Bentin *et al*., 2002).

SUMMARY

The neurophysiological data suggest that faces are encoded in the human visual system by a specialized neural system located in the lateral posterior fusiform gyrus and inferotemporal gyrus. Some of these areas (particularly those located in the fusiform gyrus) probably process the face as a gestalt. The more lateral sites appear to be sensitive to face components, particularly the eyes. The shorter latency of the scalp-recorded N170 relative to the intracranial N200 suggests that the processing of the face parts starts slightly earlier than processing of the gestalt. Yet the exact relationships between these two components of the face-encoding system are unclear. Whether the face-specific activity is a manifestation of an innate module, as the visual preference of infants for faces suggests, whether it is imperative and domain specific, as is suggested by the insensitivity of the N170 to task-relevance of the face (Carmel and Bentin, 2002), or whether this is the manifestation of a change in visual processing induced by expertise (e.g. from an analytic, part-based strategy to a holistic strategy), as is suggested by some behavioral studies (Gauthier and Tarr, 1997) and ERP studies (Tanaka and Curran, 2001), has yet to be established.

Fragile X Syndrome

Introductory article

Louise W Gane, MIND Institute, University of California, Davis, California, USA

CONTENTS

Fragile X syndrome (FXS) is a leading cause of mental retardation, associated with a broad spectrum of involvement, ranging from mild emotional problems or learning disabilities through all levels of mental retardation. Since 1991 it has been known that the disorder is caused by a single gene on the X chromosome.

INTRODUCTION

Fragile X syndrome (FXS) is the leading cause of *inherited* mental retardation. It is associated with a broad spectrum of involvement, ranging from mild emotional problems or learning disabilities through all levels of mental retardation. One in approximately 4000 males in the general population is affected with FXS. A similar number of females will also experience problems, but females are generally less affected than males. Since 1991 it has been known that the disorder is caused by a single gene on the X chromosome. In some people, this gene undergoes a change that causes an expansion in the gene which leads to FXS. The growth of knowledge with regard to FXS has been incremental, covering a span of 60 years, and is still continuing.

CLINICAL FEATURES OF FRAGILE X SYNDROME

The classic physical features of FXS include a long face, prominent ears, prominent chin, large head circumference, high arched palate, and loose flexible joints. Many of the physical features are associated with the connective tissue problems linked with FXS. Low muscle tone, hyperextensibility, hernias, scoliosis, and flat feet are common. Young children affected with FXS are often floppy and have recurrent ear infections, sinusitis, and/or gastric reflux. Sleep problems in childhood are common. Children with the disorder often show rapid growth. However, as adults, stature is usually short. Girls with FXS are at risk of precocious puberty. At puberty, large testicles are often seen in males. Mitral valve prolapse (a heart condition) is found in 50% of males who have FXS. The commonest neurological problem associated with the disorder is seizures, which occur in 20% of affected males and approximately 5% of affected females.

Girls with FXS often have the same physical findings as boys. However, since the physical findings in girls are more subtle, they can easily be overlooked.

The classic behavioral features associated with FXS are present in early childhood. Language delay, hyperactivity, and short attention span are often noted by the second or third year. Rapid and repetitive speech patterns are associated with the syndrome. Repetitive patterns of behavior, such as watching the same video or television program over and over again, are also characteristic of the disorder. Often both boys and girls with FXS will have difficulty in making direct eye contact. In addition, shyness, anxiety and over-sensitivity to environmental stimuli, often expressed in tantrums, are commonly seen in children with FXS. These tantrums may also be associated with changes in routine or environment, crowded situations, overstimulation and/or too much activity. In addition, autistic-like features are associated with FXS, including poor eye contact, shyness, social anxiety, hand biting, hand flapping, hand posturing, and repetition of speech and/or behaviors.

Girls are very likely to have behavioral difficulties related to shyness and anxiety. Sometimes the latter can become incapacitating and lead to lack of verbal communication with selected people. In addition, short attention span (with or without hyperactivity) and impulsivity may be seen in girls with FXS.

Approximately 20–30% of children with FXS will be diagnosed with true autism. Those who are more severely cognitively impaired and those

who are non-verbal or very late in developing speech are more likely to be diagnosed with autism and FXS. However, children who have FXS and autism or FXS with autistic-like features respond well to therapeutic interventions. The latter should include speech and language therapy and occupational therapy that emphasizes sensory integration therapy. In addition, applied behavioral analysis (ABA) and discrete trial training with positive reinforcement may help some of these children. With such interventions, children who have autism and FXS will often outgrow the dual diagnosis and no longer meet the criteria for autism.

The classic cognitive profile of FXS includes impairment of understanding of information provided from other sources, remembering sequential information that is given verbally, and the ability to think abstractly or complete tasks that require complex reasoning. Object memory is a strength, as is simultaneous processing. This means that learning from their experiences at home and school as well as those with whom they interact are very helpful to individuals with FXS. Mathematical skills are weak in both males and females with the disorder. However, early strengths in language and long-term memory are seen, and these are often reflected in the social abilities and sense of humor of affected individuals. In addition, many of those with FXS have strong copying and mimicking skills which strengthen their ability to learn, particularly in the early school years.

Approximately 50–70% of females with FXS will have an IQ in the low or borderline range (70 to 85). However, 30–50% of females with the disorder will have a normal IQ (above 85). However, of these females who have an IQ in the normal range, 60% will have emotional or behavioral problems. These problems often take the form of shyness, anxiety, mood swings, and/or problems with mathematics. However, tasks involving attention, organizational skills, and the ability to inhibit impulses will also often reflect the difficulties experienced by females.

GENETIC BASIS OF FRAGILE X SYNDROME

The gene responsible for FXS is located near the end of the X chromosome, (Xq27.3), and is known as the *F*ragile X *M*ental *R*etardation 1 (FMR1) gene. Although everyone has the FMR1 gene, in some people it undergoes a mutation. The mechanism of the change is such that the gene will expand in one place where there are normally a number of repeats involving two (cytosine (C) and guanine (G)) of the four chemical bases (nucleotides) of which a gene is composed. These repetitions are referred to as *CGG repeats*. This repeat characteristic means that FXS is also referred to as a *trinucleotide repeat disorder*. When the change occurs in the CGG repeats, the number of such repeats becomes larger. The increase in the number of CGG repeats will continue to be transmitted from one generation to the next as the X chromosome containing the gene change is passed on to offspring. The FMR1 gene change will increase dramatically in repeat size when it is passed to a child through a female. Eventually the mutation will jump to a large expansion of over 200 CGG repeats (full mutation), and the child will have FXS. One in 259 women carry the FMR1 gene change, with the CGG repeats ranging from 55 to 200. When the repeats are in this range, the gene change is called a *premutation*. One in 755 men carry the premutation. This means that those men and women who are carriers of the premutation are not affected cognitively by the FMR1 gene. However, women who carry the premutation are at risk of having a child with the 'full mutation' (more than 200 repeats) and affected with FXS.

With expansion of the CGG repeats to more than 200, the FMR1 gene within the cell is no longer able to produce normal levels of the *F*ragile X *M*ental *R*etardation *P*rotein (FMRP) which is required for normal brain development. It is this lack of FMRP that leads to FXS.

GENETIC COUNSELING AND TESTING FOR FRAGILE X SYNDROME

When an individual is diagnosed with FXS, it is important that all family members receive genetic counseling. Meeting with a genetic counselor enables the relatives to gain an understanding of the condition itself and how the FMR1 gene expands through the generations, and to identify family members at risk of carrying the gene change and having offspring with FXS. The family pedigree obtained by the genetic counselor is a tool that is used to gain a detailed family history, to identify previously undiagnosed family members, and to identify the inheritance pattern within the family and determine which family members should have testing to assess their FMR1 gene status. In addition, the genetic counselor will coordinate the family testing and interpret the test results in a manner that can be understood by all family members.

The genetic counselor can also be instrumental in interfacing with other professionals, advocating in support of the needs of those diagnosed with FXS,

and identifying and helping to meet the needs of other family members. Obtaining the necessary services from the medical, educational, and community services that will be of help to the family is often part of the role of the genetic counselor. He or she is often the person who will first bring the support services to the attention of the family.

It is also the genetic counselor who may be helpful to the family in working through the emotional impact of the diagnosis. Having a child with a genetic diagnosis can have a serious although often temporary effect on self-esteem. Grief over the loss of a healthy child is part of the complicated process of coping with such a diagnosis. Family members may also experience feelings of guilt, blame, embarrassment, stigmatization, denial, disappointment, and loss of expectations that they had for their child. Although it may be a relief to obtain the diagnosis and to know what is wrong, at the same time this may mean that hopes and dreams are shattered and will need to be rebuilt.

When a family member receives the diagnosis of FXS, the reproductive plans of the childbearing generation are affected. Genetic counseling is recommended for any family member who is pregnant or who is considering a future pregnancy. It is at this time that prenatal testing options can be reviewed and family members can make informed choices.

CONCLUSION

FXS is a complex genetic disorder that has already led the way to understanding other genetic disorders. Although the clinical picture of FXS is well defined, the focus of research is on understanding the consequences of the gene change in relation to the clinical findings, and on characterizing the role of FMRP. In addition, better and more specific medical and therapeutic interventions are being sought in order to enhance the potential of all those diagnosed with FXS.

CONTENTS

The frontal lobes (or cortex) serve as the primary bases of social interactions, self-awareness, and the regulation of more modular functions such as perception, memory, and language.

INTRODUCTION

The frontal lobes (or cortex) are considered to be the anatomical area related to the highest of human functions, including the temporal integration of sensory information for the organization of behavior such as memory and language, and the cohesion of thinking and feeling to structure social behavior (Fuster, 1985; Stuss and Benson, 1984).

A HISTORY OF FRONTAL LOBE FUNCTIONS

Conflicting historical opinions about the role of the frontal lobes stemmed from limitations at both the methodological and the conceptual levels. Methodologically, there has been difficulty in identifying patients with selective frontal lobe damage. There is no natural clinical condition (with the possible exception of frontal lobe dementia in its early stages) that produces damage selective to the frontal lobes, making the study of patients with focal frontal lobe damage a formidable logistical problem. Furthermore, some of the cognitive functions dependent on frontal activity, such as language, are intrinsically human, and for these animal models are of only limited use.

Prior to the 1960s, and even later, frontal lobe patients were often not identified until clinical signs were well advanced; overt neurological signs were often absent, and imaging techniques were either not readily available or inadequately sensitive. In such cases many brain regions beside the frontal lobes were often damaged. It was observations in such patients that formed the basis of the 'frontal lobe syndrome'. Research in patients who had undergone a frontal lobotomy provided some localizing information. However, the disorder leading to the lobotomy, such as schizophrenia, confounded these results to some degree.

The conceptual limitations for the study of frontal lobe function were equally formidable. Behaviorism favored an approach without appeal to mental mechanisms. By the early 1950s, interest in behaviorism had waned. Cognitive scientists, with their emphasis on information processing, turned to the deconstruction of higher cognitive processes into smaller and more tractable units. Even then, psychological constructs related to less modular and more integrative functions remained difficult to define, and even more difficult to relate to the frontal lobes. Most early cognitive scientists were 'functionalists' who thought that the underlying brain mechanisms had no direct bearing on the operations of mental processes.

Significant advances towards delineating the roles of the frontal lobes have been made since the 1980s. Technical advances in structural and functional imaging have shifted the focus from the pure study of mental processes to the study of the elemental mental operations of these processes as they relate to specific neural substrates. Such research has revealed a certain degree of anatomical and functional independence among frontal areas.

NEUROANATOMY

The frontal lobes constitute a quarter to a third of the human brain, occupying the region anterior to

the fissure of Rolando and superior to the Sylvian fissure (Petrides and Pandya, 1994). It includes primary motor cortex (Brodmann area 4: generation of movement), premotor cortex (Brodmann area 6: programming of sequential movements) and prefrontal cortex. This review is limited to the prefrontal cortex. The prefrontal cortex is roughly divisible into distinct regions (Figure 1): dorsolateral (Brodmann areas 9–12, 45–47), orbitofrontal (10–15, 47), superior medial (8, 9, 24, 25) and inferior or ventral medial (9–13, 24, 25, 32). A major anatomical factor underlying the functional role of the prefrontal cortex is its reciprocal connections with virtually all other brain regions. The frontal lobes therefore are capable of integrating and influencing all types of information, cognitive and affective.

As a general observation, hemispheric asymmetry within the frontal lobes is relative, and appears to be related primarily to the dorsolateral regions. The medial frontal lobes are functionally divisible in the superior/inferior plane, with minimal evidence of hemispheric asymmetry.

A THEORETICAL FOUNDATION

A general concept accepted by many is that the frontal lobes are related to supervisory or control processes, regulating more posterior/basal systems that are more automatic in nature. In this view the frontal lobes are necessary when new information is being processed, when processing is complex, or when old information has to be analyzed in new ways. Although this distinction between control and automatic processes may be an adequate overall framework, it is too global. Most researchers today agree that the prefrontal cortex cannot be reduced to the function of a single, unitary cognitive processor. New imaging techniques are helping to separate complex cognitive processes into simpler components, as described below. This idea is compatible with the anatomy of the frontal lobes; they are not homogeneous monolithic structures, but are composed of morphologically distinct areas interconnected with each other and with posterior and basal brain regions to constitute complex anatomical networks.

Processes required for traditional neuropsychological tests of frontal lobe functioning are most often related to the dorsolateral frontal lobes. They are not often represented in the inferior medial frontal lobe. The dorsolateral region is most relevant for staying 'on task' and performing normally when the environment is unstructured. Damage to this inferior medial region does affect the understanding of the emotional consequences of behavior, or more generally, the ability to respond appropriately to reinforcers. Patients may fail to alter their behavior when contingencies change, leading to inappropriate behavior and misinterpretation of others' emotions, and under some circumstances may appear to have an 'acquired sociopathy'.

The superior medial frontal cortex, in contrast, is necessary for performance on many commonly used 'frontal' tasks. A major impairment after superior medial damage, left or right, is a reduction in the ability to initiate and maintain actions or processes. The functional deficits after superior medial damage are often similar but less severe than damage to either dorsolateral frontal cortex, since the superior medial regions provide the activation and drive for the functions of these dorsolateral areas.

COGNITIVE FUNCTIONS OF THE FRONTAL LOBES

Anterior Attentional System

Many – if not all – of the functions described in this section on the role of the frontal lobes in attention have also been considered as 'executive' or 'supervisory' processes. We use 'attention' as the term of choice for several reasons. Most importantly, some type of impaired attentional control is clearly evident in most patients with damaged frontal lobes. There is also a conceptual advantage. An 'anterior attentional system' working in conjunction with a posterior attentional system immediately provides a framework for understanding brain functions as integrated networks. Attention is more easily defined operationally than executive functions, and the fractionation of component processes of attentional tasks has provided a new focus for understanding the complexity of the frontal lobes. This assists in moving theoretical positions of the functions of the frontal lobes away from a general unitary process.

The anterior attentional system can be dissociated into different processes related to distinct brain regions within the frontal lobes (Stuss *et al*., 1994; Knight *et al*., 1995; Stuss and Alexander, 2000). Visual directed attention deficits, as evident in neglect after damage to right parietal regions, are also present after frontal lobe damage. The right frontal lobe in particular provides the exploratory-motor functions of a complex directed attention network. The frontal lobes are important for the stability of gaze fixation. Frontal lesions lessen the benefit of preparatory directional cues on location-based

target detection. Malfunction in the regions of the dorsolateral frontal eye field, supplementary motor area, and perhaps the anterior cingulate gyrus, causes a deficit in the inhibition of inappropriate visuomotor responses to distracting external stimuli, and also results in slowness in moving the eyes voluntarily away from a cue. Patients with frontal lobe damage have difficulty detecting relevant

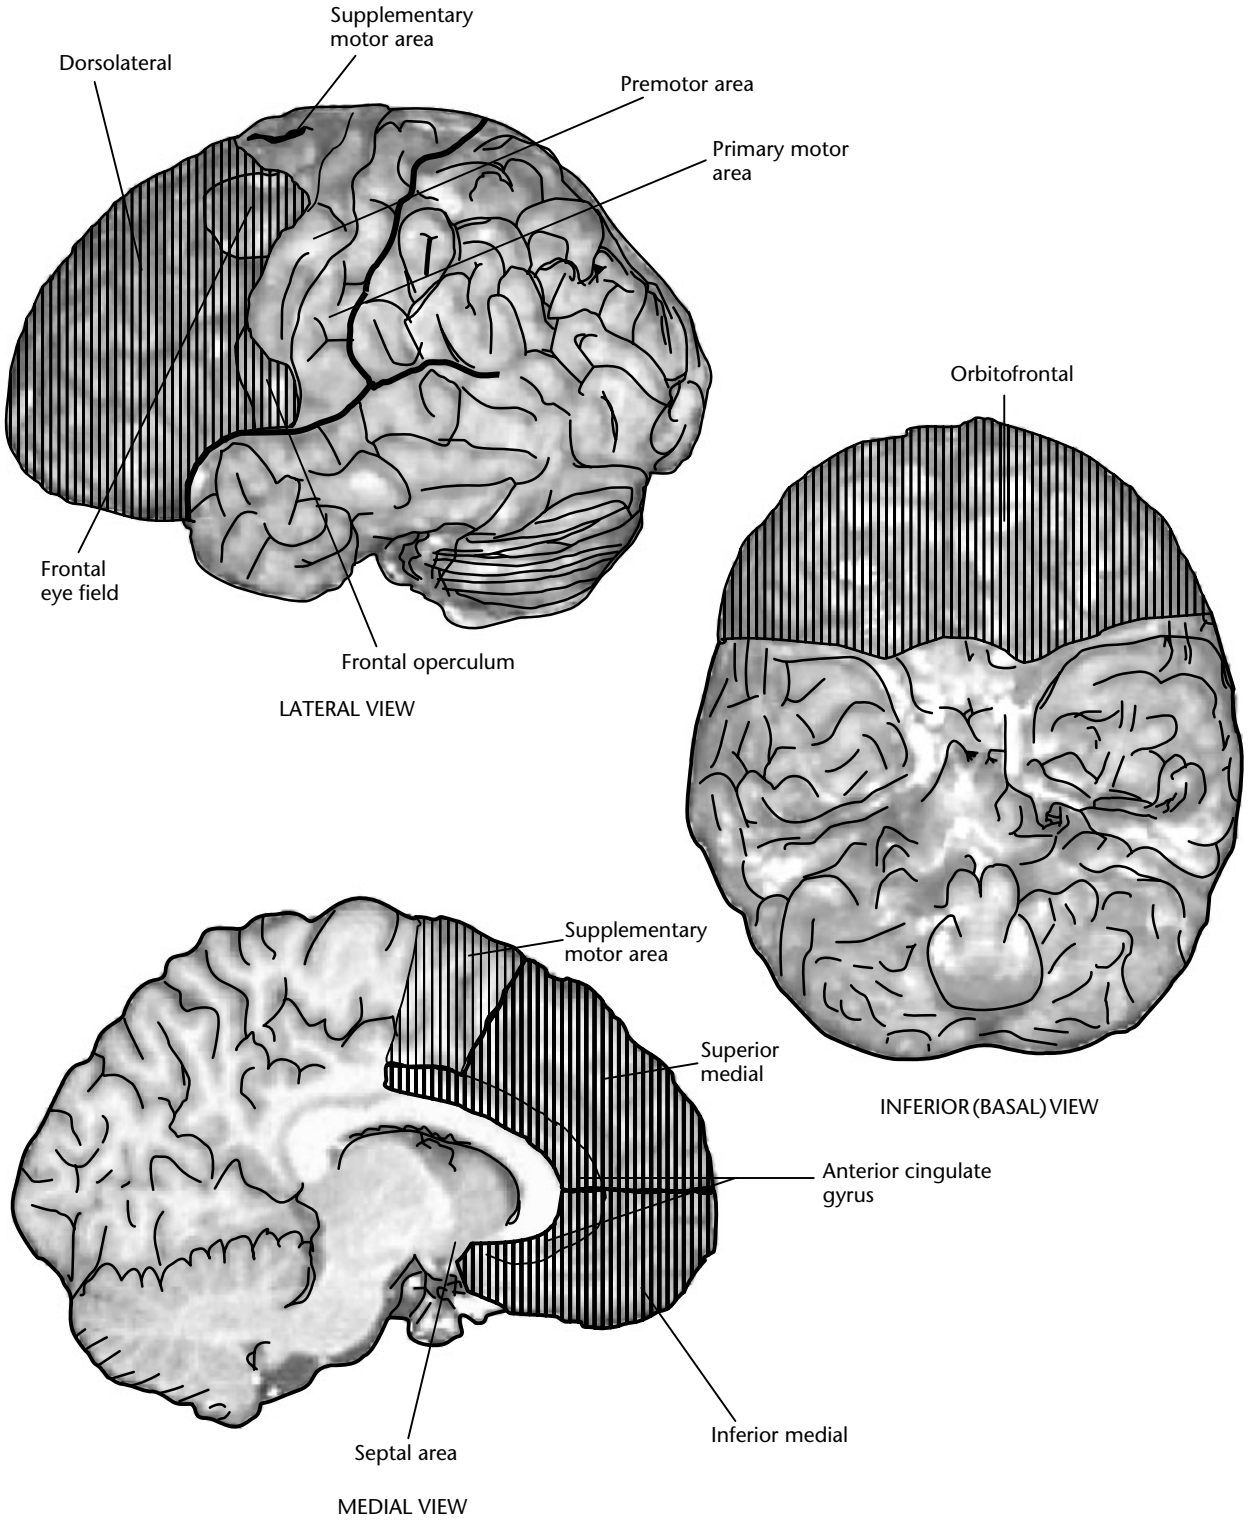

Figure 1. The prefrontal cortex.

stimuli presented on the side contralateral to the lesion. Almost incongruously, electrophysiological responses to unattended stimuli are larger when the stimuli are presented to the side contralateral to the lesion. There is some hemispheric asymmetry in this attentional impairment, with distractibility more noticeable after right dorsolateral frontal lobe lesions.

Patients with frontal lobe damage (particularly on the right) have impairment in sustained attention, defined as the ability to perform a task correctly over a period of time. This appears to be more severe when the task is simple, or stimuli are presented slowly. The frontal lobes are also involved in selective attention, which can be observed in problems of differentiation between novel and familiar stimuli, and in comparisons of attended and unattended information. For example, pathological damage in the anterior cortex diminishes the initial response to novel stimuli. There is also diminished habituation to repeated stimuli.

The frontal lobes also play a role in attentional switching. The Wisconsin Card Sorting Test requires the trial-and-error learning of a criterion by which to sort a deck of cards. After the participant has achieved a defined number of correct responses, the examiner then shifts to a new criterion without warning. Dysfunction in switching categories of response on this type of test is evident after right or left dorsolateral frontal and superior medial, but not inferior medial, lesions. Switching deficits can be observed after inferior medial pathology, however, if the task requires switching initiated in response to affective feedback.

Memory Systems

Damage to the frontal lobes does not normally result in a classic amnesia. The possible exception to this rule involves the septal region, the posterior part of the inferior medial frontal lobe. The septal region is part of the hippocampal and mesial temporal memory system and is often concomitantly damaged with pathological changes to the inferior frontal lobe. Most patients with frontal lobe damage outside the septal region function within normal limits on standard tests of memory such as story recall. However, meta-analysis of focal lesion studies indicates that frontal lobe lesions do affect performance on tasks of free recall, cued recall, and even recognition memory. Functional imaging has identified a role for the frontal lobes in the strategic aspects of semantic and episodic retrieval, and episodic encoding. While the neural networks for these functions have yet to be detailed, there is general agreement that the left frontal lobe is involved in episodic encoding and semantic retrieval, and the right frontal lobe in episodic retrieval.

While the frontal lobes have a role in explicit memory, their function in implicit memory, considered to be more automatic, is less clear. Frontal lobe processes may be necessary in implicit memory, but only under specific conditions which require more strategic search and retrieval, such as word stem (sold—) as opposed to word fragment (s—d-er) completion. This role of the frontal lobes in implicit memory tasks calls into question a simple interpretation of the theoretical dichotomy of control and automatic processes.

Strategic processes in learning and memory

As might be expected from the hypothesized general role of the frontal lobes, the effect of damage to the frontal lobes on memory processes occurs primarily when monitoring and supervision of basic processes is required. This has been called 'working with memory' (Moscovitch and Winocur, 1995) to indicate the influence of the frontal lobe regulatory processes on the more posterior and more automatic memory functions. Following frontal lobe damage, deficits may frequently arise on tasks such as self-ordered pointing, conditional associative learning, metamemory, and memory for source and temporal order. The self-ordered pointing task requires participants to recall which item, out of a defined set of items, they selected on the previous trial in order to avoid selecting the same item consecutively. Conditional associative learning ('if this, then that') requires subjects to form associations between stimuli and responses depending on the context in which they are encountered. Metamemory involves evaluating one's own knowledge to estimate the likelihood that some information is available in memory. In tests of memory for source or temporal order, content or item information is recalled but the details about where this information was encountered (source or context) or the order in which it was presented (temporal order) are lost. To explain the deficits frontal patients exhibit in these complex memory tasks, the processes have to be examined in terms of finer component strategic functions such as subjective organization, self-initiation, monitoring, filtering, and response selection.

Working memory

Working memory tasks involve temporarily holding a small amount of information 'online'. In

research with nonhuman primates, working memory tasks were originally considered to involve only the maintenance of the information over the period of delay to complete a subsequent task when a cue was given. In human research, on the other hand, the concept of working memory incorporated some type of manipulation of information. For example, a task may involve rearranging items during the period of delay in order to list them alphabetically. In both cases, information must be maintained for a brief period in which the information is not available in the environment.

Single cell recording in animals during different kinds of working memory tasks reveal different roles for prefrontal cells. Some cells show an increase in the number of spikes per second firing when a stimulus is presented, others show sustained firing during the delay alone, and still other cells increase firing rate as the end of the delay approaches in anticipation of a response. These cells are organized into local networks to coordinate the three types of information in real time. As in the occipital lobe, there appears to be a cortical columnar organization containing cells with similar roles.

The major role in maintaining information 'online' in the absence of an external stimulus was originally assigned to the lateral prefrontal regions, with regional specificity for the type of information acted upon: location of an object ('where') cells, dorsolateral frontal; identity ('what') cells, ventrolateral frontal. Integration of location and identity information occurred both through organization in overlapping regions of 'what' cells and 'where' cells as well as through 'what and where' cells that respond selectively to the conjunction of location and identity. There is now increasing recognition that this rehearsal or memory maintenance function cannot be completely contained within the prefrontal cortex, but must involve interactions with other regions. For example, systems of frontal and parietal neurons have been reported, with similar cellular recordings and neuroimaging activations in both regions in response to stimuli.

The research in humans has provided a context for a more elaborated position than simple memory maintenance to explain the functional roles related to the firing of specific cells during delays. That is, working memory tests may assess not (or perhaps not just) memory maintenance but executive or higher-level attentional functions. This has also been demonstrated in animal research (Rainer *et al*., 1998). In a task requiring a motor response after a delay if a target stimulus occurred in the same location as a probe stimulus, neurons first fired in the prefrontal cortex, followed by firing in inferior temporal regions responsible for the visual processing of the target. This sequential pattern suggests a 'top down' influence of the frontal lobes on attentional selection in visual processing. There is also context specificity for different cells. Some cells fire during the formation of associations between arbitrary stimuli. Other cells reflect firing in response to the context of the association (i.e., whether a stimulus is currently associated with a reward). Still others show firing that is selective for the type of reward expected within that context. In this more complex formulation there are overlaps between working memory and attentional processes. Such overlaps remain to be fully investigated.

Language

Since the famous case described by Paul Broca, a correlation between frontal lobe damage and language disorders has been accepted. There has been a gradual delineation of the roles of distinct areas within the left and right frontal lobes in communication competence (Alexander *et al*., 1989). The interactive nature of different systems (in the case of language, motor, activation, cognitive, and paralinguistic) for final output are clearly demonstrated in the following examples. For both the left and right frontal lobes, the following descriptions of language disorders will start with the consequences of more posterior frontal region damage and move anteriorly.

Left frontal

Damage to the left inferior motor cortex results in speech (motor) impairment without significant language disorder. If the lesion is considerably more extensive (involving the entire left frontal operculum, posterior sections of the inferior and middle frontal gyri, anterior insula, periventricular and subcortical white matter, as well as putamen, head of the caudate and anterior parietal region), the classic Broca aphasia results with motor (articulation), language (e.g., word finding, agrammatism) and activation (language fluency) deficits. A smaller lesion of inferior frontal operculum, lower motor cortex and adjacent white matter yields a 'small Broca' aphasia, highlighted by dysarthria, initial muteness and subsequent slowness, and language impairment that is similar to but less severe than in Broca aphasia. Damage anterior to the lower motor cortex, superior and anterior to the operculum, or in white matter underlying the operculum, results in normally articulated speech but a verbal output that

is primarily sparse and delayed. Superior medial damage, probably including the supplementary motor area and anterior cingulate gyrus, affects speech activation primarily. When damage involves the left anterior lateral area and polar medial areas, the language deficit is predominantly 'paralinguistic'. Impairments in reasoning, spontaneous utilization of complex syntax, repetition of sentence form, and omissions of elements are often observed. Inferior medial damage does not result in any language or speech activation disturbance.

Right frontal

Damage to the right frontal lobe does not cause aphasia in normal right-handed individuals. Although the localization is not as exact as in the left frontal lobe, damage to the right frontal areas can affect communication in a manner analogous to the left frontal lobe, with motor, cognitive, activation, and formulation impairments. Posterior lateral frontal and subcortical damage alters the affective prosody of language, resulting in flat, monotonous speech. If the pathological change is similar to the small Broca aphasia, deficits appear to occur in the pragmatics of communication such as sustaining attention to communication. Right superior medial damage affects initiation of speech in a manner similar to the left superior medial area. Finally, in more anterior regions, deficits in humor appreciation, sarcasm, critical self-assessment, and establishing a coherent narrative context for communication may result. Confabulation has been described as a consequence of medial damage, particularly on the right.

SOCIAL BEHAVIOR, PERSONALITY, AND SELF-AWARENESS

Defective comportment, a profound apathy, deficient social interactions, and impaired interpersonal skills often constitute the most striking observations in patients with frontal lobe damage, particularly bilateral damage to the orbital frontal (ventral medial) areas. Certain evidence points to a possible preeminent role of the right frontal lobe in many of these functions. The deficits may be such that significant others may consider the individual not to be the same person, as in Harlow's classic description of the case of Phineas Gage – 'he was no longer Gage'. Performance on measures of intelligence and standard neuropsychological tests, including traditional frontal lobe cognitive tests, is often normal. The impairment is most often elicited in real life situations, where the environment is less constrained.

The behavior of some patients with ventral medial frontal lobe damage has been described as an 'acquired sociopathy'. There is indeed a superficial similarity to sociopathic behavior. The patient may have impaired ability to understand and take into account the feelings of others (empathy), and may lack or fail to demonstrate appropriate feelings (sympathy). Behaviors may appear totally self-interested. Patients with frontal lobe damage may be humorless, or conversely show inappropriate jocularity. At other times, there may be impulsive outbursts of anger, or inappropriate, irresponsible and sometimes risky behavior. In frontal lobe patients, however, there is usually no considered decision underlying such behavior, and no deliberate deception. Moreover, the behavior may be demonstrated only under certain conditions such as unstructured environments.

These behaviors can be experimentally demonstrated. Patients with right frontal lobe damage in particular do not appreciate the subtleties of humor as in jokes that depend on a 'twist' at the end, although they can grasp slapstick humor. These same types of patients, particularly if the damage is to inferior medial, find it difficult to take the perspective of others to understand or guide their own behaviors. They may not grasp the implications of any *faux pas* they make. While such functions also require cognitive capacity of different kinds, these deficits do not seem to be reducible to cognitive impairment.

The frontal lobes (with a particular emphasis on the right frontal lobe) are most important for higher levels of awareness. They provide the ability of the individual to use past personal knowledge to understand current behaviors, and to select and guide future responses to integrate the personal self into a social context. This self-reflective ability has been called autonoetic (self-knowing) consciousness, and is considered to be important for episodic memory – that memory related to personal, warm, and emotionally relevant past episodes (Wheeler *et al*., 1997). Frontal lobe patients may have dulled or absent affective responsiveness to past memories. New personal memories may be acquired only via the semantic memory system.

CONCLUSION

Understanding the functions of the frontal lobes remains a formidable task. Future progress will depend on the successful advances in, and integration of, many areas of knowledge and technology: comparative psychology, cognitive neuropsychology, neuropsychiatry, structural and functional

imaging, and neuropsychopharmacology. Discussions will center not on the functions of the frontal lobes but on the role of the frontal lobes in any variety of human behavior.

The ultimate challenge is to use this knowledge for the rehabilitation of patients with damage to the frontal lobes. Efforts in this arena are very much in their infancy. Effective rehabilitation must target the specific deficits resulting from damage to different frontal brain regions. For example, sustained attention deficits after right dorsolateral frontal damage may be assisted by the use of intact left frontal self-verbalization abilities. A combination of 'top down' and 'bottom up' strategies should be employed. In many cases, the use of external environmental support may be partially or completely necessary, taking over the role of the frontal lobes of these patients to compensate for their deficits.

Golgi Staining

Introductory article

Arnold B Scheibel, UCLA Medical Center, Los Angeles, California, USA

CONTENTS

Golgi staining describes a group of methods that depend on the reaction of chromate salts with heavy metals, usually silver or mercury, to reveal the nerve cell body and all of its processes for microscopic study.

INTRODUCTION

The earliest attempts to understand the organization of the nervous system during the first half of the nineteenth century were based on teasing apart small fragments of brain tissue with dissecting needles, either in dilute saline (salt) solutions, or with the addition of small amounts of chromic acid or potassium dichromate solution which tended to weaken the adhesive forces between the cells (today, small amounts of detergent solution would be used). Microscopic studies of these preparations often revealed the cell body and the beginnings of its extensions (dendrites and axons). However, the visibility of these structures was poor since they were virtually as transparent as the aqueous (water-based) medium in which they were suspended.

At the beginning of the 1870s, brain tissue began to be stained (colored) with dyes such as carmine and salt solutions such as gold chloride which made certain parts of the neural components more easily visible. Shortly thereafter, it was found that tissue fixation (inactivation of tissue enzymes and hardening) in dichromate solution followed by sectioning (cutting a number of thin sections of the tissue), staining in hematoxylin and selective removal of excess stain produced a reliable way to visualize all myelinated fibers. However, the fibers became invisible when the myelin sheath was lost as the fiber approached its synaptic (terminal) field. The introduction of aniline stains – chemically basic stains which selectively bind to acidic portions of the cell such as deoxyribose nucleic acid (DNA) and ribonucleic acid (RNA) – also helped reveal a number of structures internal to the cell body and its dendrites. However, there was still no single technique that could reveal the cell body and its entire retinue of dendritic and axonal processes.

DISCOVERY OF THE GOLGI STAIN

The term 'Golgi' has become generic for a group of histological staining methods that rely on exposing neural tissue to solutions of chromate or dichromate salts, followed by heavy metal ions, either silver (e.g. in the form of $AgNO_3$ solution) or mercury (e.g. as $HgCl_2$). The method was first reported by a young Italian physician, Camillo Golgi, in a single paragraph of a short paper he published in 1873 on the cerebral cortex. Golgi was working at that time as resident physician in a hospital for 'incurables' at Abbiategrasso. He is certain to have realized the extraordinary power of the method he described, a method that was to invigorate and restructure our knowledge of brain organization. And yet, we have no clear report of how the revolutionary technique was discovered.

A frequently told, probably apocryphal, version suggests that an overzealous cleaning woman threw some pieces of the young histologist's dichromate-fixed tissue into a refuse jar containing discarded silver nitrate solution. The next morning an angry Golgi rescued the tissue, and while trying to assess the damage, discovered a few nerve cells stained in their entirety. Another, more likely, story suggests that he stumbled on the method while using silver in an attempt to impregnate (stain) the pial (protective) membrane on dichromate-hardened brain tissue.

In either event, he proceeded to describe, in the most complete detail yet achieved, the structure of many kinds of neurons in the central nervous system, their dendrite ensembles and axonal ramifications. Unfortunately, the technique remained cranky and unpredictable as Golgi used it, and

he went on to draw several incorrect conclusions from his material – conclusions that were to start one of the early epic intellectual struggles in neurohistology.

Major improvements in the Golgi method were made by a young Spanish professor of histology, Santiago Ramón y Cajal. He was the first to demonstrate the benefit of using brain tissue from embryonic or young animals, before the myelin sheaths (fatty insulating coverings) of axons were laid down. In addition he was one of the first to add osmic acid to the dichromate fixative, thereby changing Golgi's familiar 'slow method' involving several weeks or months of fixation in dichromate to the 'rapid method' wherein fixation in the osmic–dichromate solution occurred in a few days. The increasingly powerful results of this modified method revolutionized our knowledge of the fine structure of the nervous system, and in its new form attracted histologists from all over Europe and America. So widely was the method used and on such a variety of tissue that one investigator suggested, 'Next we will Golgify potatoes'.

It is not difficult to understand why 'Golgimania' swept through the community of neural investigators towards the end of the nineteenth century. There in all their beauty and delicate complexity were a small number of nerve cells and neuroglia (physiological support cells), each appearing as a black silhouette with all its branches and connections depicted on a pale translucent background. Ramón y Cajal described the appearance as that of 'Chinese ink drawings on transparent Japanese paper'. For the first time one could trace out the course of individual elements (axons or dendrites) from their source, often to their termination. Basic questions about the pathway and nature of connections in the brain could be answered simply by looking, drawing and photographing (Figure 1).

EFFECT OF THE DISCOVERY OF THE GOLGI STAIN ON NEUROSCIENCE

The main strength of the Golgi stain lies in its ability to reveal all the components of the nervous system, including neurons, neuroglia and blood vessels. Moreover it does so in a selective manner, so that only a few of each may be visualized in any one microscopic field. This is advantageous since if all elements were stained, the investigator could see only an inextricable tangle of cells and their processes.

In Golgi's hands the method clearly revealed the differences between axons and dendrites, the multiplicity of nerve cell types and the variety of patterns generated by cell processes. He described the difference between cells with long (projective) axons (Golgi type I) and those with short (local circuit) axons (Golgi type II), a differentiation that continues to be basic to our understanding of how nerve cells are connected into circuits. He erred in claiming that his material proved that all dendritic and axonal processes flowed together or fused, forming a continuous network of processes, or syncytium.

Ramón y Cajal's research was summarized in a great two-volume work *Histology of the Nervous System* now translated into English by the Swansons and published by Oxford University Press. Among his discoveries we may enumerate the mode of termination of axons, the axonal growth cone, development of the concept of polarity and one-way conduction along nerve cell circuits, dendritic spines, the first diagrams of reflex pathways, and the suggestion that learning might depend on the selective strengthening of synapses, an idea that would be reformulated by Donald Hebb in 1949 and become the basis for modern learning theory.

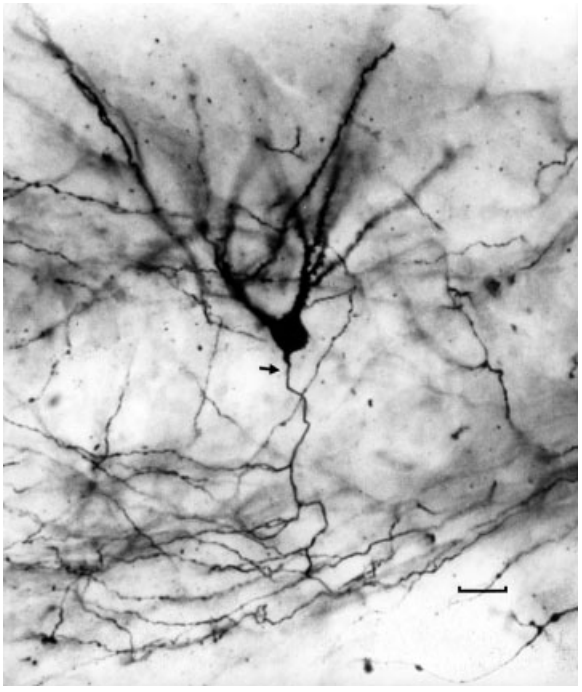

Figure 1. Microphotograph of a small neuron (granule cell) in the dentate gyrus of the hippocampus of a young cat stained by the rapid Golgi method. This is a thick section (100 μm) and several of the dendrites become blurred as they leave the focal plane of the photograph. The axon (arrow) develops a complex series of branchlets (axonal plexus) typical of many local circuit neurons. Bar, 10 μm.

However, the most important single achievement by Ramón y Cajal was undoubtedly his defense and elaboration of the neuron theory. In contradistinction to those (including Golgi) who claimed that dendritic and axonal processes flowed together to form a continuous syncytium or reticulum, Ramón y Cajal became a spokesman for the group of investigators who believed that each neuron was an individual element and that communication from neuron to neuron occurred across small gaps between axons and dendrites or cell bodies, forming junctions called synapses (a functional term originally suggested by the English physiologist Sherrington). Ramón y Cajal made brilliant use of his Golgi material in defending this idea. Since the actual dimensions of the gap or synaptic cleft were of the order of 20–40 nm and therefore below the resolution of the best light microscope, he had to reason from a few special cases, including a special gear-like synapse in the cerebellum. In 1906, Golgi and Ramón y Cajal shared the Nobel prize for physiology or medicine, awarded for their contributions to the fine structure of the nervous system. In his Nobel address Golgi used data from his method to defend the syncytial or reticularist theory; Ramón y Cajal, using material similarly stained by the method of Golgi, defended the neuron theory. (The two men never spoke to each other again.) It took another half-century before the electron microscope with its vastly increased resolution revealed that the neuronists were generally correct and that most interactions between nerve cells occurred across a synaptic cleft. The complex chemistry of neurotransmitters operating across these clefts, and the equally complex study of membrane physiology and receptor-channel structure which provide substrate to these activities, now constitute one of the most active fields of investigation in neuroscience.

It might be added that as in all hotly contested arguments, the truth was finally found to lie somewhere between the two opposing positions. Careful electrophysiological analysis of synaptic interactions supported by electron microscopy has revealed another type of synaptic junction (the gap junction) in which the two apposing neuronal membranes (the presynaptic and postsynaptic elements) are only 2–4 nm apart. Protoplasmic bridges cross this tiny space. Ions flow directly through these minute bridges (connexons) and no chemical neurotransmitters are necessary. The increased rapidity of conduction across these gap junctions fits them for certain types of interactions where flexibility of response seems less important than speed of response.

ROLE OF THE GOLGI STAIN IN MODERN NEUROSCIENCE

Today, the field of neuroscience is rich in histological techniques which seem capable of directly, or indirectly, answering almost any question put to them. There are methods that can trace an axon from the cell body of origin to its terminations or from its termination back to its source; immunohistochemical techniques that can selectively identify by antigen–antibody reaction any one (or several) of literally thousands of chemical substances of which the cell is made up; injection techniques that can outline the individual cell body and all its processes with remarkable clarity; and molecular techniques (*in situ* hybridization) that can identify the very RNA which the cell uses in constituting and maintaining itself – to name only a few. Yet the Golgi technique remains uniquely viable and useful because of the range of its applications.

Since the 1950s Golgi methods have been increasingly used in evaluation of pathological changes in brain tissue, including epilepsy, the senile dementias, degenerative processes such as Parkinson and Huntington diseases, schizophrenia, autism and various retardation syndromes. Refinements in techniques have made it possible to study Golgi stained material at the light microscope level, and then through resectioning, to isolate specific cell groups or even specific synaptic zones for study under the electron microscope.

Of at least equal significance has been the application of Golgi methods to quantitative neurohistology. Through proper selection methods, and increasingly aided by computer technology, it is possible to make quantitative studies of dendrite length, branching pattern and number, and to compare these over several brain areas, or between brains. Similarly, it is possible to follow, quantitatively, the changes in neurons during development and maturation and to describe the variation in dendrite length and complexity as the organism is exposed to enriched (or deprived) sensory input. Literally any perturbation of brain function that involves a physical change in axonal and dendritic size and pattern is available for quantitative description through the use of Golgi-stained tissue.

The enormous power of the Golgi method is essentially a latent one, depending on the interpretative gifts of each particular investigator. The method is almost endlessly adaptable and its constantly broadening usefulness to qualitative and quantitative neurohistology and neuropathology suggests that it will remain relevant in an

increasingly molecular age, as long as investigators have the ingenuity to put new questions to it.

Hebb Synapses: Modeling of Neuronal Selectivity

Intermediate article

Harel Z Shouval, Brown University, Providence, Rhode Island, USA

CONTENTS

Hebb synapses are modifiable synaptic connections that increase their efficacy when the presynaptic and postsynaptic neurons are coactive. Such a learning rule has appealing computational properties but is not stable. Several modifications have been proposed to stabilize this rule. There is mounting experimental evidence that modifiable synapses exist in brain and form the basis for learning, memory and some aspects of development.

INTRODUCTION

Information processing in the brain is carried out by networks of neurons. Neurons are linked to other neurons by synaptic connections, which convey information from one neuron to another. These synaptic connections are plastic, that is their strength can be altered. The prevailing hypothesis is that the major mechanism underlying learning, memory and many aspects of development is synaptic plasticity. Therefore it is interesting to know what rules govern these changes.

The first influential proposal was made by Donald Hebb in 1949, long before any direct evidence existed about such changes. Hebb's original abstract hypothesis was formed to account for results of experiments such as classical conditioning. This idea was generalized and developed over the years in order to overcome flaws in the original formulation and to account for an increasing number of experimental results. Today, modifiable synapses with modification rules that follow generalizations of Hebb's postulate are often termed Hebb synapses. A combination of experimental and theoretical work in neuroscience is providing mounting evidence that Hebb synapses are indeed the basis for learning memory and many forms of neural development.

HEBB'S ORIGINAL POSTULATE

Hebb originally postulated that:

> When an axon in cell A is near enough to excite cell B and repeatedly and persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency in firing B, is increased. (Hebb, 1949)

How can such a rule produce learning? A simple scenario (Figure 1) is the case of a classical conditioning experiment: a dog hears a tone and is then given a food reward; when the animal is given a food reward it salivates; if this is repeated many times the tone alone becomes sufficient to cause salivation. Suppose that neuron A is an auditory neuron that responds to the tone, and neuron B is a neuron that is activated by the food reward and contributes to triggering salivation. According to Hebb's postulate, pairing of the tone, which causes neuron A to fire, and the food reward, which causes neuron B to fire, will cause a strengthening of the synaptic connection from neuron A to B. Eventually activation of neuron A will be sufficient for activating neuron B, even without a food reward. Thus this rule can account for how the tone alone eventually causes salivation, owing to the conditioning procedure.

Mathematically the Hebb rule can be formulated as:

$$\Delta w_i = \eta x_i y \quad (1)$$

where w_i is the strength of the synaptic weight connecting the presynaptic neuron i to the postsynaptic neuron, Δw_i is the change of this synaptic weight in each learning step, x_i is the activity state of the presynaptic neuron i, y is the activity of the postsynaptic neuron and η is a learning-rate constant (Figure 2a). It is simplest to think of the variables x_i and y as binary variables that are equal to

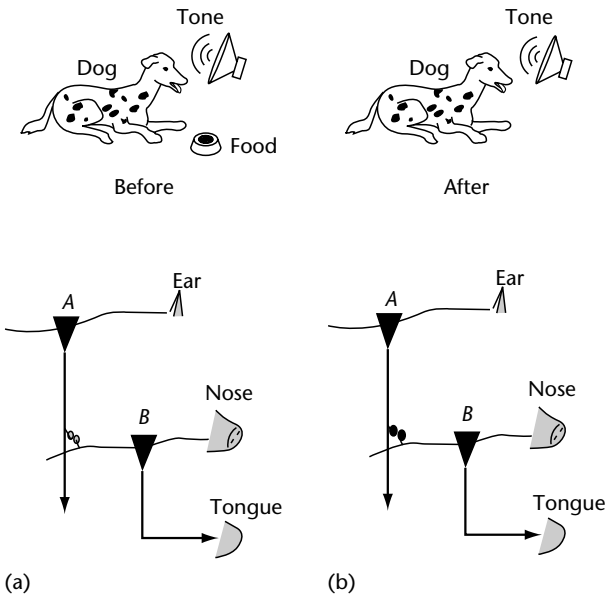

Figure 1. A dog who is presented with food will normally salivate. If the food reward is paired with a tone (a), the dog learns to associate the tone with the food. Eventually (b) the tone will be sufficient to cause the dog to salivate, even in the absence of the food reward. Hebb's postulate can account for this learned association. Neuron A, which responds to the tone, is initially weakly connected to neuron B which responds to the food and drives salivation (a). Pairing the food with the tone will result in an enhancement of the Hebbian synapse connecting neuron A to neuron B (b). Thus activity of auditory neuron A becomes sufficient for activation of neuron B, producing salivation.

1 if the neuron fires, 0 if it does not. It is also possible to think of these variables as continuous variables that correspond to the firing rate of these neurons.

As we have illustrated, the Hebb rule may account for classical conditioning. There are many types of learning tasks, but we will concentrate here on the ability of learning rules to produce selective neurons. Selective neurons are neurons that respond strongly only to a subset of the inputs they receive. Neuronal selectivity is the rule for most cortical neurons; moreover, if neurons responded equally to all inputs they could not perform computations. For example, neurons A in the conditioning example above would be active all the time, hence the dog would salivate all the time.

INSTABILITY OF HEBB'S RULE AND POSSIBLE SOLUTIONS

The Hebb rule, as formulated above, has some fundamental flaws. In particular, under many conditions it would not produce selective neurons. The variables we have used (x_i, y, η) are positive numbers, as a result weights can only grow. Even if the activity of a presynaptic neuron is very weakly correlated with that of a postsynaptic neuron, any small correlation due to spontaneous activity would cause synapses to grow indefinitely. As this is not physiologically plausible, additional constraints must exist. If a simple constraint is imposed, that all synapses have a maximal saturation value, eventually all synapses would attain that maximal value. If all synapses attain their maximal value a neuron will not be selective. One solution is to modify the Hebb rule so it will allow for both decreases and increases in synaptic weights. A simple generalization that produces increases as well as decreases in synaptic weights is the correlation rule of the form:

$$\Delta w_i = \eta(x_i - x_0)(y - y_0) \tag{2}$$

where x_0 and y_0 are constants (Figure 2b). In the absence of saturation limits synaptic weights will either increase or decrease indefinitely. With saturation limits, synaptic weights will converge to either the upper or lower saturation limit. Neurons employing this rule can become selective if the appropriate choice of an environment, constants (x_0, y_0) and saturation limits are chosen (Linsker, 1986).

Synaptic Competition

Another way of preventing the growing weights problem is to assume that the sum of all synaptic weights cannot exceed a constant, possibly because of a restricted amount of some resource (Stent, 1973). Such was the approach used by von der Malsburg (1973) when he used a modified Hebb rule to model the development of orientation selective cells in visual cortex. As a result, when the Hebb rule causes some synapses to increase their synaptic efficacy, the synaptic efficacy of other synapses would decrease. This rule (Figure 2c) implicitly required that the sum of synaptic weights be known to every synapse in the neuron and that after every Hebbian update the value of each synapse would be divided (normalized) by the sum of synaptic weights. A more plausible, local rule has been postulated by Oja (1982). The Oja rule uses a local decay term that causes the sum of the square of the weights $(\Sigma_i\, w_i^2)$ to converge to a constant value. The Oja rule has the form

$$\Delta w_i = \eta(x_i y - w_i y^2) \tag{3}$$

The decay term, which stabilizes this learning rule,

can cause synaptic depression in synapses that exhibit no presynaptic activity: this is referred to as heterosynaptic depression. This approach for preventing the growing weights problem is often called synaptic competition – that is, synapses compete for limited resources (Stent, 1973).

The synaptic competition approach seems to be supported by a set of ocular dominance plasticity experiments. Cells in the visual cortex of cats are mostly binocular; that is, they respond to inputs from both eyes. If one of these eyes is sutured shut during the animal's first months of life (monocular deprivation) the deprived eye rapidly loses its effect on cortical cells (Wiesel and Hubel, 1965). This probably stems from a depression in the synaptic efficacies of synapses connecting cortical cells to afferents from the deprived eye. In contrast, if both eyes are sutured (binocular deprivation) a much slower disconnection occurs (Wiesel and Hubel, 1965). These results are often taken as evidence that synaptic competition does indeed occur.

The Sliding Modification Threshold

An alternative mechanism to prevent the growing weights problem has been proposed by Bienenstock, Cooper and Monro (the BCM rule; Bienenstock *et al*., 1982). This rule (Figure 2) assumes that for moderate levels of postsynaptic activity ($y < \theta_m$) synaptic weights are depressed, whereas for larger levels ($y > \theta_m$) they are potentiated. In both cases presynaptic activity is required for synaptic plasticity, that is both potentiation and depression are homosyaptic. Mathematically the rule takes the form

$$\Delta w_i = \eta x_i \Phi(y, \theta_m) \tag{4}$$

where Φ (Figure 2c), which is a function of the postsynaptic activity (y) and had a zero crossing at θ_m, has both potentiation and depression regions, and θ_m is the modification threshold separating the depression and potentiation regions. This rule alone is not stable; in order to stabilize learning the BCM rule assumes a sliding modification threshold. When synaptic weights and activity levels are increased θ_m will increase as well, faster than the growth of activity. This enhances the depression region and reduces the potentiation region thus stabilizing weight growth. If on the other hand significant synaptic depression occurs resulting in a decrease in synaptic activity, the modification threshold would be lowered. Mathematically the modification threshold could be taken to be the temporal average of some superlinear function of postsynaptic activity, for example $\theta_m = < y^2 >_\tau$,

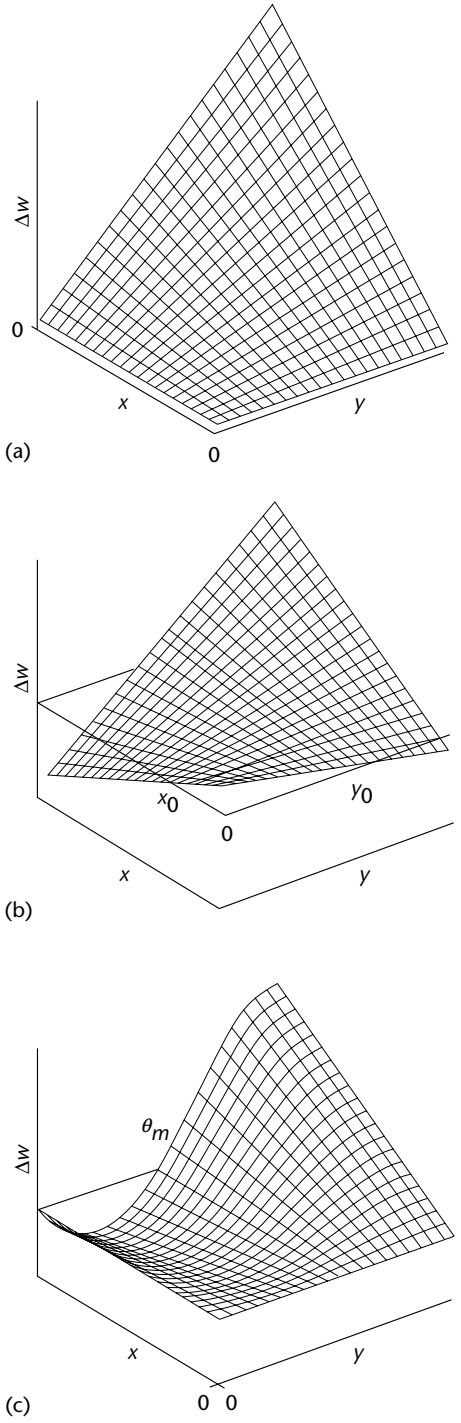

Figure 2. Change in synaptic weights (Δw) due to coincidence of presynaptic activity (x) and postsynaptic activity (y): for the simple Hebb rule (a), described in eqn (1), for the correlational rule (b) described in eqn (2), and for the Bienenstock, Cooper and Monro (BCM) rule (c) described by eqn (4). Note that for the BCM rule, the zero crossing-point (θ_m) is itself a dynamic variable that changes with time.

where < > denotes a temporal average and τ is the time scale of the temporal average.

How can such a modification rule account for paradigms such as monocular and binocular deprivation? A combination of experimental and theoretical work (Rittenhouse *et al*., 1999; Blais *et al*., 1999) has shown that this rule is actually more likely to explain experimental results than rules that depend on synaptic competition.

STATISTICAL PROPERTIES OF HEBBIAN RULES

Different variants of the Hebb rule have different statistical properties. The dynamics of the simple Hebb (eqn (1)) and correlational (eqn (2)) rules are dominated by the second order statistics of their inputs. In the absence of saturation limits the weight vectors become asymptotically parallel to the eigenvector with the largest eigenvalue of a two-point correlation matrix. For the simple Hebb rule (eqn 1), this matrix is simply the cross-correlation matrix of the inputs. The correlational rule (eqn 2) is a somewhat modified version of the input correlation matrix (Linsker, 1986). The Oja rule (eqn (3)) converges to the normalized eigenvector of the correlation matrix. With saturation limits, the stable state is usually dominated by this eigenvector. However, this is a nonlinear system and exact predications are hard to make. If the inputs have zero mean, the first eigenvector is also called the principal component, therefore the Oja rule is often called principal component analysis (PCA). The principal component is a projection in the input space that has the largest variance. For a Gaussian channel, the principal component is the projection that maximizes information transfer.

The BCM rule in contrast depends both on second and third order statistics. For an input space composed of a linearly separable set of vectors the weight vector becomes orthogonal to all vectors but one, thus being maximally selective. For natural input environments it becomes highly selective as well, forming a sparse representation (Blais *et al*., 1998). It can also be understood as a method for finding projections that are highly non-Gaussian (Intrator and Cooper, 1992).

Single cell learning rules can be derived from cost functions that maximize statistical measures such as kurtosis and skew (Blais *et al*., 1998); these can have a roughly Hebbian form. These types of learning rules are closely associated with independent component analysis rules, which try to decompose their inputs into a superposition of independent sources (Hyvrinen, 1999).

EXPERIMENTAL EVIDENCE

There is strong experimental evidence that Hebbian mechanisms exist in cortex. Most research has concentrated on the processes of long-term potentiation (LTP) which is a long-term enhancement in synaptic efficacy due to high-frequency stimulation (Bliss and Lomo, 1973). Homosynaptic long-term depression (LTD) due to low-frequency stimulation has also been observed (Dudek and Bear, 1992). The frequency dependence of these two forms of synaptic plasticity follows qualitatively the form proposed by the BCM theory. Evidence has appeared for existence of the sliding threshold as well (Wang and Wagner, 1999). There is also some evidence of heterosynaptic LTD, as required for synaptic competition (Christie and Abraham, 1992). Recently evidence has appeared that synaptic plasticity depends on the precise timing of presynaptic and postsynaptic spikes (Markram *et al*., 1997). If the presynaptic spike preceds the postsynaptic spike then LTP is induced; if on the other hand the postsynaptic spike comes before the presynaptic spike then LTD is induced.

Pharmacologically blocking LTP and LTD blocks ocular dominance plasticity in visual cortex (Kleinschmidt *et al*., 1987), showing that LTP and LTD are indeed involved in development. Intervention in these processes has also been shown to affect certain types of learning and memory (Morris, 1989).

CONCLUSION

Synapses in the brain exhibit activity-dependent synaptic plasticity. This plasticity is believed to be the basis of learning, memory and many forms of development.

The first influential proposal for a learning rule that can govern these synaptic changes was made by Donald Hebb in 1949; this rule has been the cornerstone for many different theoretical models of synaptic plasticity which have been proposed since then. Hebb's original postulate had several significant problems. Contemporary models of synaptic plasticity overcome some of the problems exhibited by Hebb's original proposal such as the growing weights problem. Different models also have different statistical properties and become selective to different features in the environment.

Plastic synapses have been experimentally characterized in the brain. Their properties are in general agreement with the Hebb postulates as well as with some of the modifications of Hebb's original rule. Further, there is strong evidence that Hebbian plasticity is indeed involved in learning, memory and development.

Hebbian Cell Assemblies

Intermediate article

Yves Frégnac, Unité de Neurosciences Intégratives et Computationnelles, Gif-sur-Yvette, France

CONTENTS

A Hebbian cell assembly is defined as a collective dynamic activity process reverberating in a closed set of recurrent connections, which are part of a larger association network.

INTRODUCTION

This article summarizes the historical foundations and subsequent theoretical and experimental elaboration of a simple activity-dependent algorithm for synaptic plasticity proposed by Hebb in 1949. This algorithm is based on the assumption that the efficacy of synaptic transmission is regulated in a predictive manner by the temporal correlation between pre- and postsynaptic activities. Validation of Hebb's postulate has been sought at different levels of neural integration. Numerous experimental reports show that the same phenomenological rule can be used to predict activity-dependent changes in synaptic efficacy in a variety of neural structures and species, ranging from invertebrate sensorimotor ganglia to vertebrate neocortex (Brown *et al*., 1990; Frégnac *et al*., 1988; Frégnac, 2002).

Hebb's postulate appears to be valid both for individual synapses and for the global dynamics of functional coupling between neurons embedded within densely connected networks. Irrespective of the presence of direct anatomical contacts, its predictive power holds, under certain additional constraints, for functional links measured solely on the basis of spike-based correlations (Ahissar *et al*., 1992). It has also been suggested that similar Hebbian forms of plasticity, acting on different time scales, participate in the transient build-up of mental representations and illusory percepts, as well as in long-lasting associative adaptation in behavior (Von der Malsburg, 1981; Frégnac and Bienenstock, 1998).

PRE-HEBBIAN THEORIES

The most obvious feature of synaptic transmission is the causal relationship between the presynaptic action potential and the amplitude or probability of response in the postsynaptic cell. Philosophers of antiquity theorized how causal relationships between external events could be established in the brain, and they pointed out the necessity of repeating sequences of activation in order for mental links to emerge:

> Acts of recollection, as they occur in experience, are due to the fact that one movement has by nature another that succeeds it in regular order. If this order be necessary, whenever a subject experiences the former of two movements thus connected, he will (invariably) experience the latter. (Aristotle, *De Memoria et Reminiscentia*)

This view, which was also apparent in the writings of empiricist philosophers such as John Locke in the seventeenth century, was not translated into more specific brain-activity-related processes until the end of the nineteenth century. The foundations of association theories in the brain can be traced back to 1890. According to William James, the 'spiritual father' of the American school of experimental psychology, the brain is not constructed to think abstractly, but to ensure a permanent fit between the perception and actions of the organism in relation to its environment. James suggested that the adaptive capacities of the human brain depend on mechanistic laws of association that operate under the guidance of central neural structures such as the cerebral cortex in higher vertebrates:

> When two elementary brain processes have been active together or in immediate succession, one of them, on re-occurring, tends to propagate its excitement into the other. (James, 1890, p. 256)

James imagined a local integration process where one point in the brain had properties of summation and adaptation very similar to those that we now know regulate neuronal integration of synaptic potentials. The memory trace of association between events was thought to depend on competitive processes which could interfere with the result of previous binding operations:

> The amount of activity at any given point in the brain-cortex is the sum of the tendencies of all other points to discharge into it, such tendencies being proportionate (1) to the number of times the excitement of each other point may have accompanied that of the point in question, (2) to the intensity of such excitements and (3) to the absence of any rival point functionally disconnected with the first point, into which the discharges might be diverted.…When two neurons are simultaneously active, their exchanges of dynamic influxes are more intense than the influxes they send to resting regions. (James, 1890, p. 257)

These concepts of association are immediately applicable to an understanding of behavioral learning. Pavlovian classical conditioning is an example of association between events that are sequentially phased. The presentation of a conditioned stimulus (CS) is followed, at a fixed inter-stimulus interval (ISI), by the application of an unconditioned stimulus (US). The repeated presentation of these paired events results in the development of a conditioned response (CR) that is revealed *de novo* after conditioning when the CS is reapplied in the absence of the US. In general, the time course of the conditioned response predicts the temporal occurrence of the absent US or reward, as if it had been applied. To account for the new behavioral repertoire acquired through classical conditioning, Pavlov introduced the analogy of a circuit closure ('Zamykatielnost') – it was as if the repeated CS–US associations had switched on a broken or previously dormant connection.

The concept of associative conditioning was developed in cellular terms by Jerzy Konorski (1948), a contemporary of Donald Hebb, who assumed that 'before a conditioned reflex is established, there exist potential interneuronic connexions, directed from the emitting neuron, or neural center', representing the conditioned stimulus, 'to the receiving neuron or center' whose activity is forced by the reinforcing stimulus (or US). Extending the suggestion originally made by Cornelius Ariëns Kappers in 1921, that new connections could be established by the simultaneous activation of the neural centers fed by the CS and the US, Konorski formulated a detailed law of association transforming these potential interconnections into 'actual' ones:

> When the excitation of a given center is synchronous with the rise of excitation in another center, conditioned excitatory connexions are formed from the first of these centers to the latter. …Conversely, the excitation of a given cortical center synchronized with the fall of excitation in another center results in the establishment of inhibitory connexions between these two centers. (Konorski, 1948, p. 106)

A second field of application of association theories is the transient formation of mental representations during perception or dreams. Here the effect produced by repeated associations is not restricted to sequences of external events, but extends to autonomous activity of the brain. Rather than being transformed into a long-lasting 'mnesic' form, the trace of the association is seen as a reversible facilitation, promoting neural links over the time required for the establishment of the percept (a few hundred milliseconds).

In his seminal essay, 'Le rêve: étude psychologique, philosophique et littéraire', the visionary French neuroanatomist Yves Delage sought to establish the physiological basis of the psychological processes involved in the genesis of mental images or thoughts (Delage, 1919). Impressed by the work of Louis Lapicque on chronaxy and the finding of a vibratory mode shared by both the muscle and the innervating motoneuron, Delage postulated that each cortical neuron exhibits an intrinsic and characteristic periodicity. The relative diversity of intrinsic frequencies adopted by possible future functional partners ('heterochrony') would be dynamically restructured during perception and generate transient and highly synchronized states ('parachrony') among the activated members of the functional assembly.

> Every modification engraved in the neuron's vibratory mode as a result of its co-action with others leaves a trace that is more or less permanent in the vibratory mode resulting from its hereditary structure and from the effects of its previous co-actions. Thus its current vibratory mode reflects the entire history of its previous participations in diverse representations. (translated from Delage, 1919, pp. 118–119)

Unfortunately, we have no way of establishing how influential these different proposals were in the formulation of Hebb's neurophysiological postulate (Hebb, 1949). Nevertheless, it seems important to recognize that this general plasticity rule, which was to become a winner in the growing field of neurobiology, is the composite echo of a diversity of concepts in the field of learning and perception, already shared by many preceding and contemporary scientists.

A NEUROPHYSIOLOGICAL POSTULATE TO BUILD ASSEMBLIES

Interestingly, the major contribution of Donald Hebb as a scientist of the brain is probably not what modern neurobiology now remembers. His physiological association principle was in fact just one of several keystones incorporated in a multilevel model of cerebral functioning during perceptual and learning processes. The primary aim of Hebb's model was to explain the waxing and waning of psychological constructs during a stream of thoughts. The concept of a 'cellular assembly', pivotal to his theory, designates an activity process which reverberates in 'a set of closed pathways'. The postulate of Hebbian synapses was introduced as one of the possible ways to reinforce functional coupling between co-active cells and thus of growing assemblies. Similar hypotheses were developed which allowed cognitive events to be linked to their recall, in the form of temporally organized series of activations of assemblies. Hebb referred to this binding process as a 'phase sequence'. Thus Hebb's neurophysiological postulate, articulated at a late stage in his famous book, *The Organization of Behavior*, appears simply as a putative low-level biophysical mechanism for establishing the persistence of activity among assemblies.

The wording of Hebb's postulate is impressive in its globality and polymorphism, which may explain its predictive power when applied to highly diverse but specific biological systems:

> When an axon of cell A is near enough to excite cell B, and repeatedly or consistently takes part in firing it, some growth process or metabolic change takes part in one or both cells such that A's efficiency, as one of the cells firing B, is increased. (Hebb, 1949, p. 62)

The formulation of Hebb's postulate requires both temporal coincidence and spatial convergence of one neuron on to another, supporting a causal relationship between the afferent activity and the postsynaptic spike. It provides a specific prediction, namely that a period of maintained positive temporal correlation between pre- and postsynaptic activity will lead to an increase in the efficacy of synaptic transmission. Hebb did not indicate whether the modifications responsible for this decrease in 'synaptic resistance' were presynaptic, postsynaptic or both, nor did he describe the biophysical substrate responsible for the modification, leaving an open choice between 'metabolic change' and 'oriented growth'.

Historically, Hebb's postulate referred exclusively to excitatory synapses, probably of the axosomatic or axodendritic type, since at that time inhibitory connections were almost unknown (but see the behavioral generalization made by Konorski, 1948). A symmetrical if not synergetic version of Hebb's postulate was proposed much later for the case of inhibitory synapses (Stent, 1973), where functional coupling can be increased by reducing the strength of inhibitory synapses activated at the same time as action potentials are fired in the postsynaptic cell:

> When the presynaptic axon of cell A repeatedly and persistently fails to inhibit the postsynaptic cell B while cell B is firing under the influence of other presynaptic axons, metabolic changes take place in one or both cells such that A's efficiency, as one of the cells inhibiting B, is decreased. (Stent, 1973, p. 1000)

The use of Hebbian plasticity rules in formal networks does not always follow this distinction between adaptive excitatory synapses and fixed inhibitory weights. Some models introduce inhibitory plasticity as well, and it has been demonstrated analytically that negative weights are required for optimal mapping and memory capacity in associative memories. Thus the 'effective' gain between input and output, defined at an ideal Hebbian synapse, should be allowed to vary between positive and negative boundaries, depending on whether the net effect induced by the input is excitatory or inhibitory. This could be done by assuming that a biological synapse may change in sign, or that the gain of the ideal Hebbian junction reflects the balanced influence of an elementary circuit, composed of dual parallel monosynaptic excitatory and polysynaptic inhibitory connexions (Figure 1).

The possibility of a change in sign may seem unlikely for any single particular synapse, since it violates Dale's principle, according to which a neuron releases the same transmitter at all of its processes. However, unexpected support was found in *Hermissenda crassicornis*, a nudibranch mollusk, during Pavlovian conditioning. Here associative pairing between visual input and iontophoresis of a $GABA_B$ agonist at the axon terminal of a photoreceptor cell transforms the GABA-induced hyperpolarization into a depolarizing postsynaptic potential. Some theoretical studies also proposed that synaptic gain could change sign during development (Bienenstock *et al.*, 1982), and this suggestion was later found to apply to inhibitory neocortical or hippocampal circuits. It has been shown that, early in development, GABA-receptor activation promotes postsynaptic depolarization at a stage when the chloride equilibrium potential (E_{Cl^-}) is less negative than the resting potential.

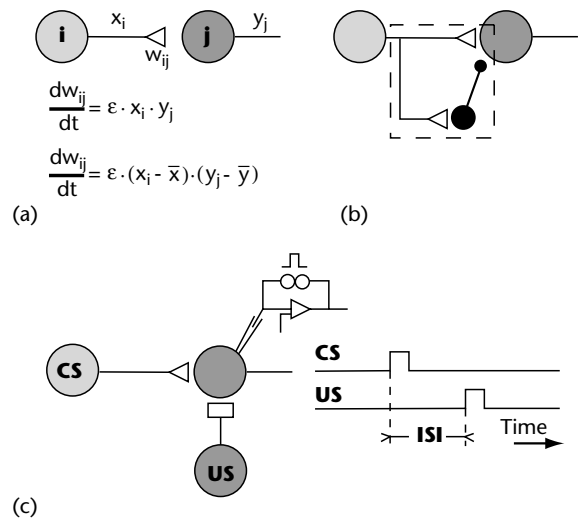

Figure 1. The multiple identities of a Hebbian synapse. (a) Identified monosynaptic connection between a presynaptic axon (open triangle) and a postsynaptic target cell (dark gray). The Hebbian algorithm postulates that the change in synaptic efficacy is given by the product (or logical AND) of pre- and postsynaptic activities at any point in time. The covariance algorithm postulates that the change in synaptic efficacy is given by the product of the differences between the instantaneous pre- and postsynaptic activities from their mean. (b) A dual presynaptic excitatory/inhibitory circuit (dotted box) equivalent to an ideal Hebbian synapse, the gain of which varies between negative and positive boundary values. Open circles and triangles denote excitatory input cell and synapse, respectively. Solid symbols denote inhibitory cell and synapse. (c) A cellular analog of classical conditioning. The Hebbian synapse transmits the neural information fed by the conditioned stimulus (CS). The unconditioned stimulus (US) activates the postsynaptic cell in an all-or-nothing fashion through a non-modifiable synapse or through depolarizing current injection directly applied by the experimenter in the postsynaptic cell (dark gray). The conditioned response stems from the repeated association of the CS input (light gray) followed by the US input activation.

The more classical hyperpolarizing or shunting effect of inhibition is observed at a later stage, when E_{Cl^-} becomes more negative than or equal to the resting membrane potential.

Hebb did not envisage specific forms of use-dependent weakening of synaptic gain, nor did he propose rules to explain plasticity occurring at synapses impinging on the same postsynaptic cell but remaining silent at the time of the association (heterosynaptic plasticity). However, the first cyberneticians who tried to build computational machines incorporating Hebb's principle were faced with the inherent instability of positive feedback and the divergence of synaptic weights. The consequence of this problem of synaptic weight saturation is that any network theory of memory storage based on Hebb's postulate, where associations will be overlaid on common sets of synapses, requires bidirectional, reversible changes in synaptic gain. However, this symmetry in the phenomenological necessity of 'what comes up must eventually come down' should not be taken literally at the substrate level, and there is continuing debate as to whether the molecular processes underlying homosynaptic forms of potentiation and depression are inversely related.

POST-HEBBIAN THEORIES: DYNAMIC BINDING OF ASSEMBLIES AND GRAPH MATCHING

The two main fields of application of Hebb's postulate have been the formation of memory traces during learning, and the self-organization of neural assemblies during development. However, Hebb's theory also addressed perception. Although the dynamic nature of the binding process which is required to form a transient percept had already been predicted by Delage (1919), Peter Milner was probably the first theoretician to propose explicit rules for the composition of assemblies. The repeated activation of a given cell assembly would reinforce synaptic links within this assembly, and in addition would 'prime' a restricted number of cells, allowing future binding and thus composition with other associative processes. The latent labeled (or 'tagged') synapses would remain transiently eligible for further potentiation by the contiguous firing of other assemblies. Repeated sequential activation would reinforce the primed connections, which would then become an integral part of the next active assembly, thereby resulting in second-order associations. Thus their firing would allow the recall of a complete 'phase sequence'. Twenty years later, similar ideas were reworded with the addition of a 'glue' mechanism, namely temporal synchrony, to bind elementary representations into a cognitive 'whole':

> If adjacent, or nearly adjacent, cells interact when excited, in such a way as to synchronize and perhaps intensify each other's activity, this could provide the unifying characteristics that tie the elements of a figure together. At subsequent levels of the pathway, impulses from the cells fired by one whole would arrive as synchronous volleys, whereas impulses from different figures would have a random temporal relationship to each other. (Milner, 1974, p. 526)

A related formalism was revived 7 years later, which postulated fast binding processes during visual shape recognition that depend on ongoing dynamic changes in the temporal correlation of firing between co-stimulated cells. In 1981, Von der Malsburg proposed a 'correlation theory of brain function' which offers a new field of validation for Hebbian associative theories, on a millisecond timescale rather than on the classic developmental scale. The internal representation of mental objects, used in particular in sensory coding and form recognition, here relies on the topological properties of the connection patterns or 'graphs', whose nodes would be formed by the neurons which are co-active at a given point in time. The architecture of the graph, which defines the relational coding within the assembly, would be independent of the physical location of the activated neurons in the brain. According to this view, the representation of a generic object, such as a 'chair', is neither the activation of a grandmother cell nor the activation of a static population code. Rather, it consists of the activation of dynamic links between representation units at distinct levels of a hierarchy, in accordance with composition rules defined at each level. Invariance of the percept with, for example, position or orientation of the 'chair' in the visual field, will be signaled by a homeomorphic match between the graphs representing the various instances of the 'chair' (Frégnac and Bienenstock, 1998).

The neural counterparts of cognitive entities are implemented in the form of high-order statistics of multidimensional spiking processes established over the full network, providing further substrate for compositionality. The theoretical work fostered by Von der Malsburg and colleagues showed that the combined use of 'fast' and reversible Hebbian-like synaptic changes and 'slow' Hebbian plasticity provides interesting properties when applied to a specific type of assembly called 'synfire chains'. The hypothesis of chains of synchrony, first introduced by Moshe Abeles (1982, 1991) and further developed by others (Bienenstock, 1994), implies that at fixed points in time, ensembles of neurons that may be physically far apart in the neural tissue fire together. Re-ordering active units as a function of time, rather than as a function of space or node location in the full network, reveals the sequential recruitment of assemblies firing in bursts.

In their initial version, synfire chains consisted of discrete sequences of pools of neurons in which feedforward conduction times were identical for all connections, from one pool to the next (Figure 2). This is the simplest architecture that guarantees the preservation of synchrony (Abeles, 1991). Simultaneous recordings of cortical single-unit activity in behaving monkeys indeed show that a significant proportion of activity correlated with a specific cognitive task can be described as a wave of synchrony relayed between sets of co-active neurons, with delays ranging from a few to several hundreds of milliseconds (Vaadia *et al.*, 1995). However, debate continues concerning the validity of the statistical analysis (Oram *et al.*, 1999). Bienenstock and colleagues extended this concept to 'synfire braids' (Bienenstock, 1994). They assumed that transient binding will be promoted between polysynaptic circuits whose individual connections have non-uniform conduction times but which, by their composition, satisfy some type of transitivity rule in transmission (Figures 2b and 3a). The reinforced connections linking one set of neurons that are co-active at time t_0 to another set which will become co-active at a later point in time $(t_0 + \Delta t)$ will be those for which the global transmission delay satisfies the same timing constraint Δt. This global delay is defined along any possible polysynaptic path joining the two synfire ensembles by adding each individual delay encountered, and Hebbian processes select out only links for which the global delay is kept constant and equal to Δt. This mechanism, and the possibility that the same neuron could participate in the same synfire chain at different times, allow the graph topology to extend beyond a pure feedforward structure and generate a complex hierarchy of representations (Bienenstock, 1994; see Bi and Poo, 2001 for experimental validation).

This 'Lego-like' interlacing of dynamic assemblies provides neuronal expression of abstract compositional models of cognition based on dynamic binding operations between symbols that are located at various levels of a representational hierarchy (Von der Malsburg, 1981; Hummel and Biederman, 1992; Bienenstock, 1994; Frégnac and Bienenstock, 1998). Relational binding can be specified in a syntactic way (e.g. in terms of perceptual grammar between geometric features for visual object representation and in terms of linguistic features and composition for speech representation) (Shastri and Ajjanagadde, 1993) (Figure 3b).

BREAKING THE SYMMETRY: CAUSALITY RATHER THAN SYNCHRONY

Despite the indiscriminate use of Hebb's rule by experimenters and modelers, it is surprising to note that the temporal specificity of the association

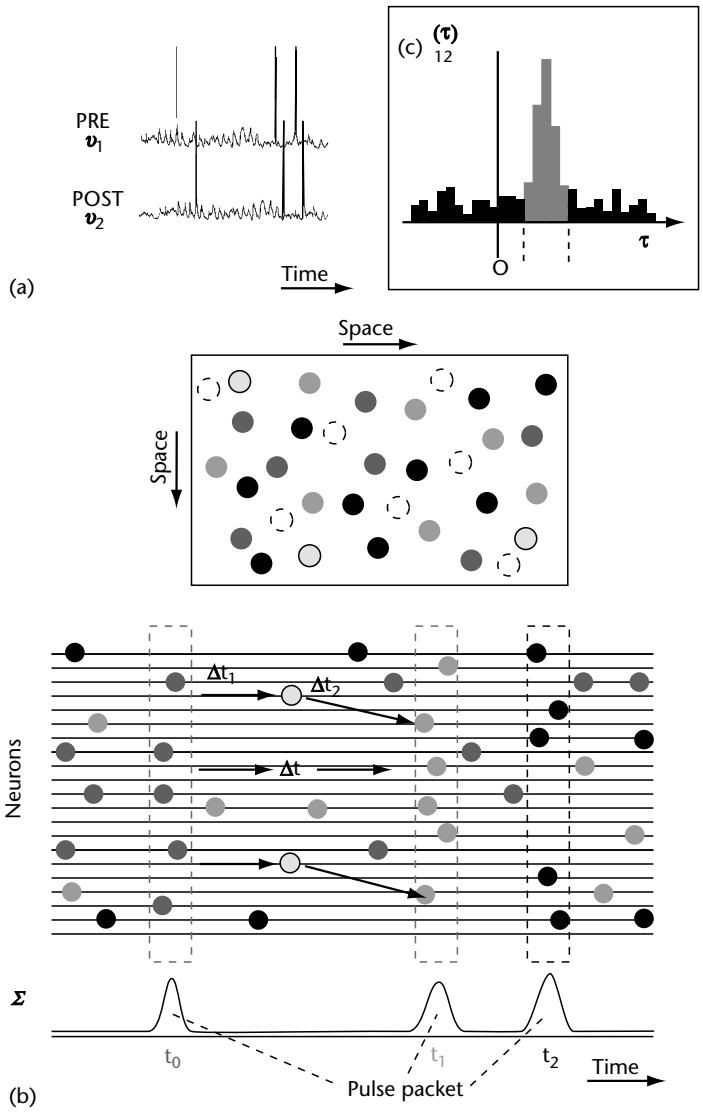

Figure 2. [*Figure is also reproduced in color section*.] Hebbian assemblies and synfire chains. (a) Functional link established between the spiking activity of two cells recorded simultaneously in the same network. In the right inset, the light-gray shaded area in the cross-correlogram indicates the probability that cell 2 (pre) fires at a given temporal delay $\Delta\tau$ after cell 1, and allows the quantification of the 'effective' gain of this functional connection. The effective gain is determined both by the strength of the direct connections between the two units and by the statistics of the firing of the other units influencing the activity of each cell. (b and c) Network dynamics and synfire chains. (b) The physical location of units that are co-active at time t_0, t_1 and t_2 is labeled in red, blue and black, respectively. Open dotted circles denote cells that are randomly active and out of synchrony. (c) Chronogram of the activity of the same units irrespective of their physical location in the network. Transitivity rules constrain the selection of transmission delays corresponding to the polysynaptic connections (via relay cells, shown in yellow) between each set of co-active units. The lower line shows at each point in time the dispersion of activity within each synchrony packet, which remains constant along the chain.

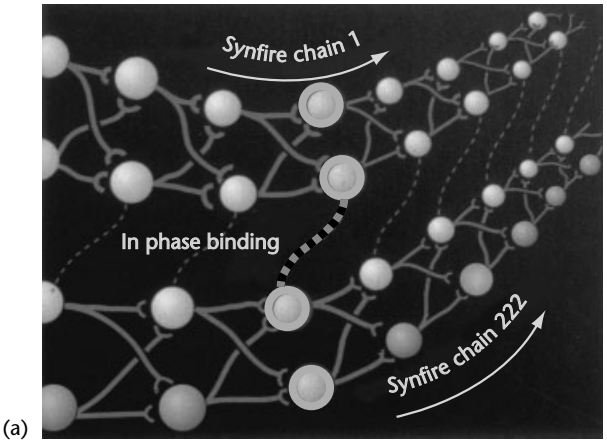
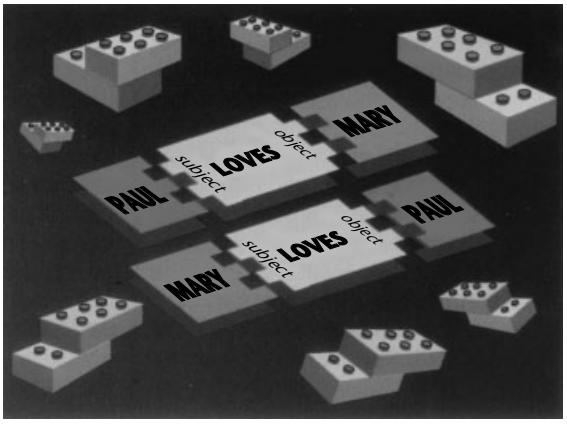
principle itself may have been initially misread. Most applications of Hebbian theories based on pairing protocols highlighted the importance of co-activity, ignoring the interval of a few milliseconds that separates a presynaptic spike from the triggering of postsynaptic activation. For those applications, no temporal ordering was required between pre- and postsynaptic activation. This temporal symmetry may not apply strictly to tetanization protocols where a high-frequency stimulation train is the primary causal event inducing the long-term synaptic change, namely long-term potentiation (LTP) or long-term depression (LTD). However, it is important to observe that associative



(a)



(b)

Figure 3. [*Figure is also reproduced in color section.*] Abstract compositionality in Hebbian assemblies. The same formalism as in Figure 2, applied to neural networks underlying logogenesis (adapted from Bienenstock (1991) with permission). (a) Composition of two synfire chains by specific sets of synapses or neurons (highlighted in pink) interfacing the two activity chains. (b) The 'Lego-brick' analogy is applied to language, where words encoded by individual synfire chains are composed according to syntactic binding rules.

conditioning of a weaker test pathway was usually obtained by applying the test input in phase or in synchrony with the postsynaptic depolarization induced by the tetanized pathway. The most obvious cases of associative learning that depart from co-activity rules are those which require associations between neural events separated by long delays, such as the optimal inter-stimulus intervals (of the order of seconds) of association in classical conditioning (Figure 1c), or between the sample and choice periods in delayed-matching-to-sample comparison tasks (Amit, 1995).

However, the wording of Hebb's original synaptic plasticity principle implies a temporal constraint in the millisecond range – that is, it dictates that presynaptic activity should precede the spike initiation in the postsynaptic element to which it contributes in a causal way ('A's efficiency, as one of the cells firing B'). In this respect, temporally asymmetrical Hebbian and anti-Hebbian rules (Figure 4), which were only introduced in recent years, are in closer agreement with the original concept. Recent research, in some cases using dual patch recordings *in vitro*, in preparations as diverse as cultured hippocampal networks, the developing retinotectal system of frog, the adult electrosensory lobe of electric fish and the sensory neocortex of rat, suggests an even tighter temporal contingency rule (of the order of 10 ms). The temporal order between the onset of the postsynaptic subthreshold potential reflecting the arrival of the presynaptic spike and the postsynaptic spike retropropagating in the dendrite determines whether potentiation or depression occurs (Bi and Poo, 2001; Frégnac, 2002).

The obvious consequence is that models which incorporate spike-timing-dependent plasticity (STDP) rules account most accurately for the emergence of causal chains within neuronal assemblies, and best support phase-sequence learning (Frégnac, 2002). Nevertheless, it is possible that both synchrony and causality are required to promote reverberating assemblies rather than the simple build-up of open-ended chains of feedforward activity, as exemplified by 'synfire chains'. It is plausible that STDP reinforces the progressive establishment of a transmission mode through 'pulse packets', since the asymmetrical nature of this plasticity rule will indirectly control the jitter that could be observed in the timing spread within each pulse packet. Indeed, the STDP rule for selecting connections may be applied to any feedforward pathway – direct or polysynaptic – jumping from one set of co-active units to any other belonging to the same synfire chain, independently of their respective rank with regard to temporal activation. Consequently, the same level of temporal precision in the selection process of individual transmission delays may be preserved all along the chain (within the millisecond range), without the dilution of within-packet synchrony that one might expect from a purely sequential structure.

CONCLUSION

Although synfire chains and graph matching appear to take us far beyond the simple application of local activity-dependent rules of synaptic regulation, it is likely that Donald Hebb would still recognize the heritage of his theory of assemblies

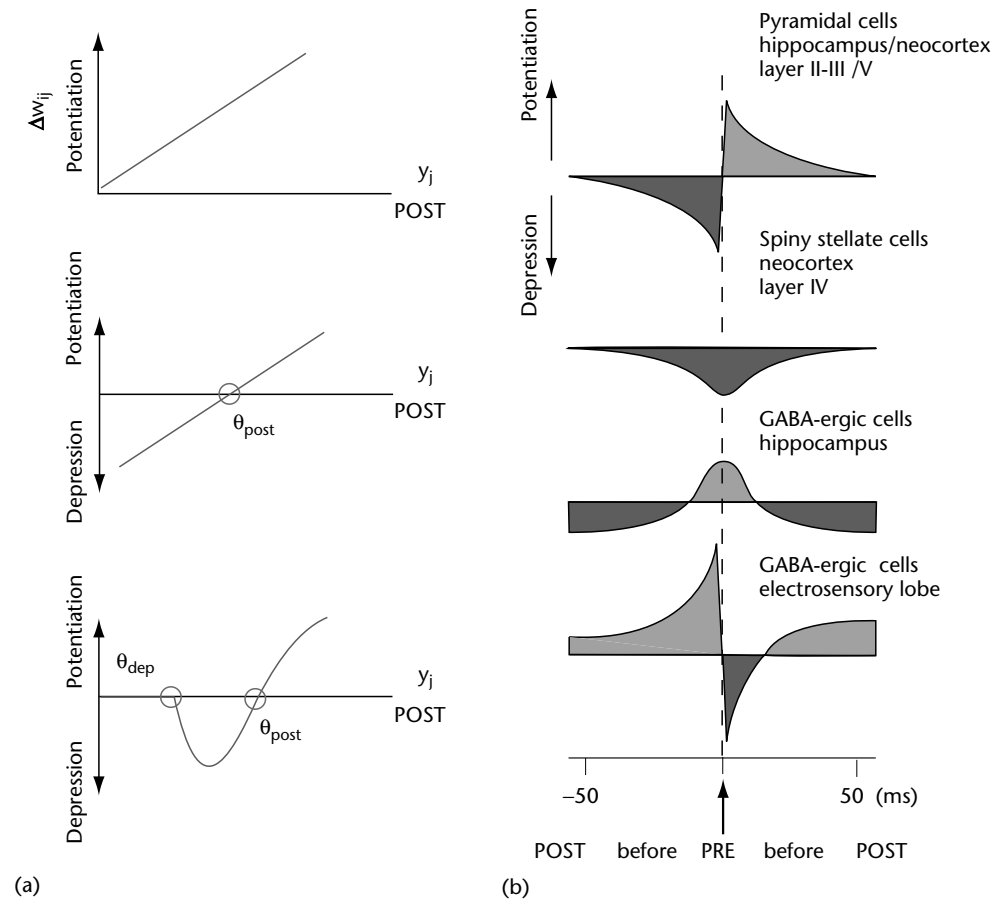


Figure 4. Hebbian synapses and spike-timing-dependent plasticity. (a) Hebb's rule (top) and the most often observed rules of homosynaptic plasticity established in biological networks, *in vivo* and *in vitro* (Frégnac, 2002). Each graph expresses the relationship between the induced synaptic change (positive ordinates for potentiation, negative ordinates for depression) and postsynaptic activity (abscissa) at the time of the association. The slope is proportional to presynaptic activity. The simple Hebbian rule (top) predicts potentiation only. The covariance rule (middle) (Bienenstock *et al*., 1982; Frégnac *et al*., 1988) and A–B–S rule (bottom) (Artola *et al*., 1990) predict both depression and potentiation, respectively, with one (θ_{post}) or two postsynaptic plasticity thresholds (θ_{dep}, θ_{pot}) (Artola *et al*., 1990). (b) Different forms of spike-timing-dependent plasticity rules established *in vitro* in co-cultures and acute slices. The induced synaptic change is expressed as a function of the temporal delay separating postsynaptic firing from presynaptic firing (taken here as the zero-time reference, and indicated by an arrow) that has been imposed during the pairing protocol. From top to bottom: pyramidal cells in the hippocampus or in non-granular layers in the neocortex; granular spiny stellate cells in the neocortex; GABA-ergic neurons in hippocampal culture; GABA-ergic medium ganglionic layer cells in the electrosensory lobe of the electric fish (Abbott and Nelson, 2000; Frégnac 2002).

as a key to perception. Some 50 years later, Hebb's postulate still impacts on fields of research as diverse as empiricist philosophy, associationism, experimental psychology, cybernetics, connectionism, neurocomputing and cellular neurobiology, and it raises the question of the generality of application of the underlying model. Taken in its most general terms, Hebb's principle becomes almost impossible to falsify, and an easy and often made criticism is that the information content that one can derive from its prediction remains poor. However, when Hebb's principle is further constrained by defining pre- and postsynaptic variables adapted to the specific study of a biological network, its predictive power remains surprisingly good, as numerous independent validations have been obtained in extremely diverse experimental preparations. The fact that the same principle still holds whatever application field and biological system is being considered, regardless of the level of analysis chosen and the timescale studied, is perhaps the best argument that Hebbian assemblies constitute a major abstract computational principle for explaining the inner dynamics of the mind.

Hippocampus

Intermediate article

John O'Keefe, University College London, UK

CONTENTS

The hippocampus is a cortical structure located in the temporal lobes of the brain. Its role in memory has been extensively investigated in humans and other animals.

INTRODUCTION

There is universal agreement that the hippocampus, a cortical structure located in the temporal lobes, is involved in memory. Theories of hippocampal function are based on studies of amnesic patients and experimental animals. The cognitive map theory is the most clearly specified and is supported by the most evidence, but the declarative memory and flexible relational theories also have their proponents.

ANATOMY

Historically, the hippocampal formation has been considered to be a part of the limbic system, a set of structures traditionally believed to be constituents of the emotional brain. It was also included in the Papez circuit, a network of structures envisaged by Papez to subserve emotion. As we shall see, there is good evidence that the hippocampal formation and the Papez circuit are not involved in emotion but instead are part of the memory system of the brain. In humans, the hippocampus is an elongated structure lying on the medial surface of the temporal lobe (Figure 1a). In rats, it is more banana-shaped and extends dorsally upwards from the temporal lobes to lie beneath the parietal cortex (Figure 1b). There are two major pathways by which the hippocampus communicates with the rest of the brain: the fornix–fimbria fiber bundle which connects it with the septal nuclei and the hypothalamus, and the perforant path which connects it with the cerebral cortex. The fornix–fimbria conveys information to the hippocampal formation about the animal's movements, attentional and bodily states and takes information from the hippocampus to control movements, in particular those which take the animal towards goals or away from punishments. An important function of the fornical input is to provide both the cholinergic and γ-aminobutyric acid (GABA) inputs which are a necessary condition for the theta electroencephalographic (EEG) state of the hippocampus (see below). Sensory information about the external world enters the hippocampus through the perforant path, which arises in the entorhinal cortex. The entorhinal cortex in turn receives information from other parts of the temporal lobe, in particular the perirhinal and parahippocampal cortices and ultimately from many of the sensory analysing regions of the cerebral cortex. These areas in the parahippocampal gyrus appear to be responsible for at least some aspects of the global amnesia syndrome which follows extensive damage to the medial temporal lobes. The hippocampal return output to the neocortex may provide the context for selection of cortical processing, or the results of hippocampal computations may be stored in a more permanent form there. One suggestion is that the hippocampus provides allocentric spatial information whereas the parietal cortex deals in egocentric spatial information, and this pathway may be the way in which these two different representations interact.

Interestingly, with minor exceptions, a slice taken at any level through the hippocampus of either the rat or the human shows the same internal structure. Figure 1b shows this profile in the rat. As seen in Figure 2, information originating in the entorhinal cortex (EC) flows in one direction through each of the subsections of the hippocampal formation, taking either a slow stopping route or an express route. Information via the slow route passes first to the dentate gyrus (DG), from there to the CA3 field, next to the CA1 field, finally to end in the

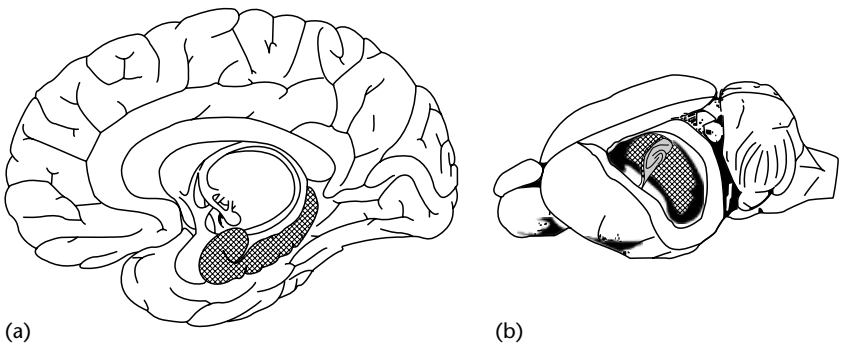

Figure 1. Location of the human (a) and rat (b) hippocampus within the brain (indicated by cross hatching).

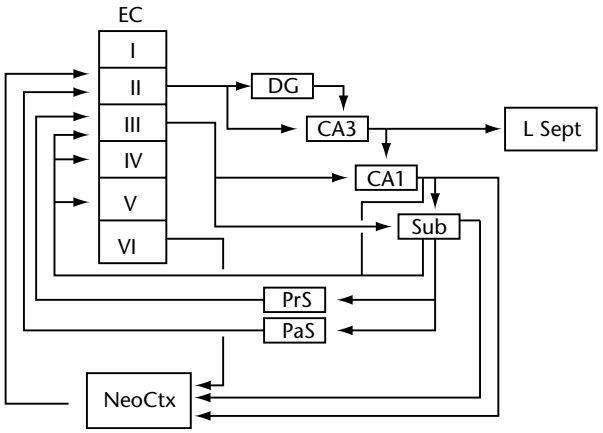

Figure 2. Internal pathways of the hippocampus (after Amaral and Witter, 1995). Abbreviations: EC, entorhinal cortex; DG, dentate gyrus; CA, cornu ammonis; L Sept, subiculum. Alternatively, a rapid transit direct connection exists from the entorhinal cortex to each of the subsections. The function of these separate pathways is not yet clear although there is speculation that different frequencies of entorhinal inputs may take different routes, or that each subfield can compare the information coming via the two routes. It is also not clear yet whether different functions can be ascribed to the different hippocampal fields. For example, the properties of the spatial cells in the different subfields do not seem to vary much, and – with the exception of long-term potentiation (LTP) in the mossy fiber pathway from the dentate to CA3 – the physiological properties of the cells are broadly similar.

THE ROLE OF THE HIPPOCAMPUS IN MEMORY

The Case of H.M.

Interest in the role of the hippocampus in memory stems from the original description of the amnesic syndrome which followed bilateral damage to the medial part of the temporal lobes in the classic case of the patient H.M. (Scoville and Milner, 1957). This patient suffered from severe epileptic seizures which were not well controlled by medication, and underwent surgical removal of the hippocampus and other temporal lobe structures on both sides in an attempt to cure this epilepsy. The patient's seizures were reduced by the operation but he was also left with a severe memory problem. He could no longer acquire new information, and he had lost information which he had acquired prior to the operation. The loss of previous information (retrograde amnesia) was not complete but appeared to extend for a period of 11 years prior to his operation. This patient, who has been tested exhaustively since his operation, fails to remember events or episodes he has experienced, and seems incapable of learning new vocabulary words or facts. Squire (1992) has termed the type of memory lost in H.M. 'declarative memory' to distinguish it from 'procedural memory' which appears to be intact. For example, H.M. can learn new perceptual and motor skills such as those needed to identify line drawings from fragments of the original or to draw images seen in a mirror. One question which arises from the study of patients such as H.M. concerns which structure or structures in the medial temporal lobes are responsible for the amnesia. Are

different brain areas responsible for different parts of the syndrome, or are we dealing with a single system in which damage to any part produces an impairment of all aspects of declarative memory, with greater amounts of damage leading to a denser, but qualitatively similar, amnesia? In order to answer this question it is necessary to look at the memory capacities of patients with damage restricted to parts of the mesial temporal lobe. The reader should be warned, however, that there is always the possibility that small, subtle amounts of damage outside the hippocampal formation might go undetected by even the most sophisticated modern histological or imaging techniques.

Patients with More Restricted Damage to the Hippocampus: R.B., V.C. and Jon

Patients with apparently similar damage restricted to the hippocampus appear to vary in the extent and nature of their memory deficits. For example, some have a recognition memory deficit, while others do not; some have a graded retrograde memory loss, others do not. Nevertheless, one area of agreement is that they all suffer from a deficit in episodic memory.

The patient R.B. suffered anoxic damage to the hippocampus as an adult following a series of heart attacks (Zola-Morgan *et al*., 1986). He died soon after and histological examination of his brain revealed that damage was mainly restricted to the CA1 field of the hippocampus. He showed a much milder amnesia than H.M. and little or no forgetting of information acquired prior to his brain damage. In support of the declarative memory theory, R.B. had a memory deficit when tested by either recognition or recall. The patient V.C. (Cipolotti *et al*., 2001) had a slightly larger lesion which encompassed the entire hippocampal formation but spared the entorhinal cortex and other temporal lobe structures. Like R.B., his memory deficits included public as well as personal events whether tested by recognition or recall. In contrast to R.B., he had an extensive retrograde amnesia as well as a profound anterograde amnesia. Furthermore, there was no indication of a gradation in his retrograde amnesia, his memory for 30-year-old events being as poor as for more recent ones. Both these patients acquired their hippocampal damage as adults. In contrast, the third patient, Jon, is one of three developmental amnesic patients who acquired their hippocampal damage early in life (Figure 3) and whose profile of memory deficit is different from the adult amnesic patients (Vargha-Khadem *et al*., 1997). All three early-onset patients were brought to the clinic by their parents who complained that they were forgetful about events, places and times. However, while they share the difficulties in recalling events of their past with adult amnesics, these patients seem to be much less impaired when required to recognize items they have recently seen. They also seem to be much more impaired in memory for episodes than in their memory for facts, although this dissociation has been less well studied. These findings suggest that some of the deficits seen in adult amnesic patients following hippocampal damage might be due to covert extra hippocampal involvement, or that brain injury to the hippocampal system can be compensated for by remaining intact tissue if the damage occurs early in life.

One interesting facet of the relatively spared recognition memory of these patients is that there are two domains in which they are still impaired: object in place recognition memory, and voice/face associative recognition memory. Extensive testing of the recognition memory capacity of the patient Jon shows that he is normal when asked to remember even difficult associations such as which two doors were seen together, but is very poor at allocentric spatial tasks such as finding his way around a virtual reality environment or identifying the correct location of an object when asked to do so from a viewpoint different from that from which it was originally seen (King *et al*., 2002). In this last task, healthy volunteers appear to solve the problem by imagining their viewpoint rotated to the appropriate location or by rotating the array of objects themselves. An inability to do either might explain the inflexibility attributed to these patients by both the cognitive map and flexible relational theories (see below).

Another interesting aspect of the memory deficit exhibited by many (but not all) people with amnesia is a gradient of retrograde amnesia, such that older memories are relatively spared in comparison to more recent ones. Declarative memory theory proposes that this is due to the memories being shifted from the hippocampus into the neocortex over time by a process of consolidation. In the early years following acquisition of a memory, interactions between the elementary component traces in the disparate regions of the neocortex require hippocampal support, but over time these bind directly to each other and become independent of the hippocampus. An alternative view, put forward by Nadel and Moscovitch (1997), is that some memories, such as those of a personal autobiographical nature, always rely on the integrity of the hippocampus, but that others, such as those

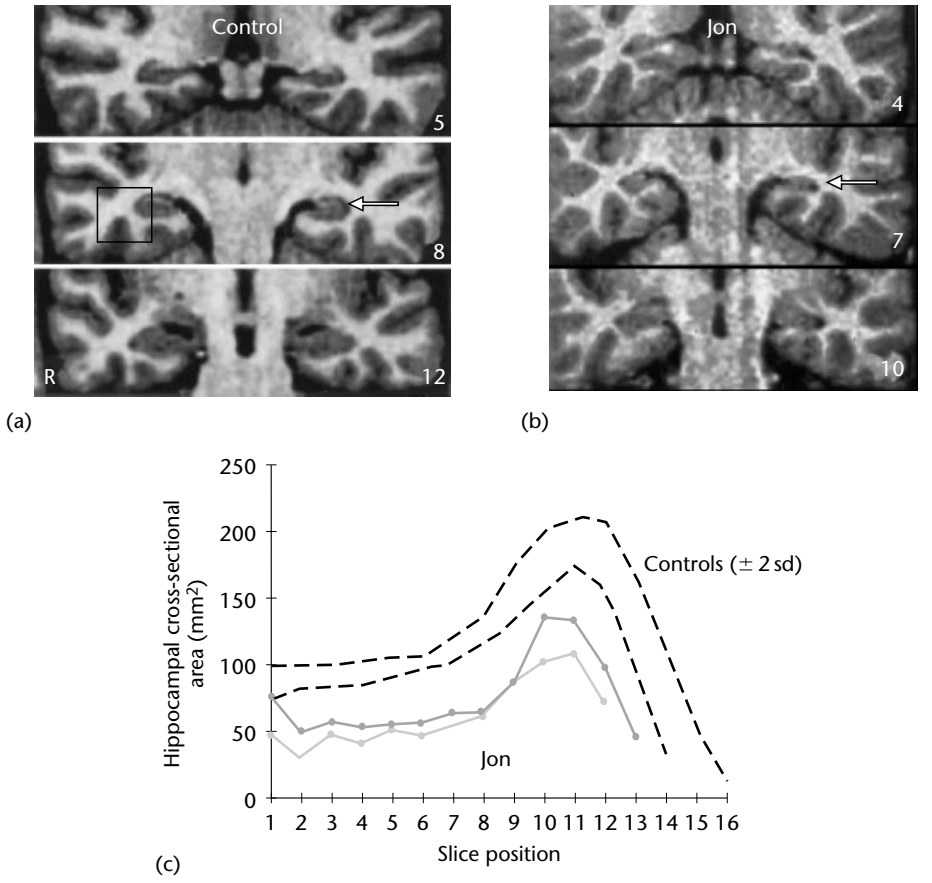

Figure 3. Hippocampal damage in the amnesic patient Jon. Arrows point to the right hippocampus in the control brain (a) and in Jon's brain (b). (c) Cross-sectional area measurements showing a 50% reduction in Jon's hippocampus. Dotted lines show 2 standard deviations of control hippocampal cross-section (after Spiers *et al.*, 2001a).

about public events or personalities, can show a gradient depending on how many times they have been reactivated since acquisition. According to this multiple trace theory, each reactivation lays down a new trace of the memory, rendering the multiply-represented memory less vulnerable to selective damage. The greater the amount of damage outside the hippocampus proper in the medial temporal lobe, the more likely it is that there will be multiple memories and that these nonpersonal memories will show temporal gradients of forgetting. At this stage it is difficult to choose between these two notions but the existence of patients with flat gradients of retrograde amnesia for personal autobiographical memories and results showing equal activation of the hippocampus in imaging studies for remote and recent memories support the multiple trace theory.

ANIMAL MODELS OF AMNESIA

Models of Amnesia in Monkeys

The declarative memory theory suggests that the hippocampus stores information about consciously recallable facts, faces and meanings of words as well as personal episodes. Although it is not possible to interrogate an animal's conscious recollection in the same way as that of the human, Squire and Zola-Morgan have proposed several analogs of declarative memory tasks which can be performed by monkeys. These include the ability to learn several visual discrimination tasks concurrently, delayed retention of object discriminations, delayed response, and delayed nonmatching-to-sample. Performance on all of these tasks is impaired in monkeys with large temporal lobe lesions of the sort that H.M. has. Unfortunately,

more selective lesions of the hippocampus itself produced by using neurotoxins or ischemia do not cause such extensive impairments (Zola-Morgan *et al*., 1992) suggesting that the deficits are due to other areas in the temporal lobe, in particular the perirhinal and parahippocampal cortices which surround the hippocampus. The delayed nonmatching-to-sample task is particularly instructive since it is also a good example of a flexible relational task. On this task, the animal is shown a novel object and must remember it for long enough to avoid it when it is subsequently paired with a second novel object in a forced-choice paradigm. Monkeys with selective hippocampal lesions can perform this task normally with delays over tens of minutes between the first and second presentation of the object (Murray and Mishkin, 1998). Of equal importance, single unit recordings taken from the hippocampus of animals performing this task have reported virtually no neurons selectively responding to the novelty of the object, in marked contrast to neurons in the perirhinal cortex which do show such responses and which are damaged in the large lesions produced in the study by Squire and Zola Morgan. One possible explanation for the absence of a deficit on this task is that it could in principle be solved on the basis of the relative familiarity of the two objects as well as on the basis of the encoding of an episodic memory that a particular object was seen at a particular time in the testing location. This explanation, however, would not account for the absence of single unit responses related to the task.

Models of Amnesia in Rats

A second approach to understanding the role of the hippocampus in memory involves work on the hippocampus of the rat. Here there have been two different approaches. In the first, the functions of the rat hippocampus are considered with respect to the animal's lifestyle and allowances are made for the possibility that additions and/or modifications to the basic system as found in the rat have been made during the course of evolution to produce a more general episodic memory system of the sort which would account for the global memory problems of humans with amnesia. The main theory here is the cognitive map theory. The second approach assumes that the functions of the rat and human hippocampi are the same and seeks to come up with a general function for both: the dominant hypothesis here is the flexible relational theory.

COGNITIVE MAP THEORY OF HIPPOCAMPAL FUNCTION

The original impetus for the development of the cognitive map theory was the discovery by O'Keefe and Dostrovsky (1971) of spatially coded neurons in the hippocampus of freely moving rats. These neurons were named 'place cells' by O'Keefe (1976) who studied their properties in more detail (*See* **Place Cells**). The primary correlate of each place cell is a location in a familiar environment. Different cells code for different locations such that a small group of them provide coverage of an entire environment. Some cells respond solely to location, whereas others incorporate information about objects in that location. Most importantly, the cells signal that the animal has entered the preferred location irrespective of its heading direction: they provide what is termed 'allocentric' spatial information, which is independent of the orientation of the body axis and can be contrasted with 'egocentric' spatial information within which objects are located relative to body-centered frameworks such as the eye, the head or the body. On the basis of these findings, O'Keefe and Nadel (1978) proposed that the hippocampus formed a cognitive map, consisting of a set of place representations which completely cover an environment and which are linked together by vectors that specify the direction and distance between places. The discovery of the head direction cells in the neighboring subicular area a few years later (Ranck, 1984; Taube *et al*., 1990) and the demonstration that the place cell firing rate varies as a function of the animal's running speed (Czurko *et al*., 1999) have provided strong support for the cognitive map theory since they confirm that the information required by a mapping system is available to the hippocampus. Further support for the theory comes from experiments on the effects of damage to the hippocampus on the spatial abilities of rats. As part of their general theory, O'Keefe and Nadel (1978) suggested that there were several ways in which animals could find their way around an environment. In addition to the use of a cognitive map-like representation of the environment, they could also move from one place to another using 'routes'. Routes were viewed as stimulus–response–stimulus (S–R–S) chains similar to those proposed by behaviorists such as Hull to explain all of behavior. They direct attention to specific stimuli in the environment and specify the appropriate behaviors in response to those stimuli.

Let us see how these two types of strategies differ in the way in which they direct an animal to solve a simple T-maze problem, in which an animal in the stem of a T-shaped maze must go to the left-hand arm of the T in order to receive reward. An example of a successful route would instruct the animal to leave the start arm and go to the T-shaped intersection of the maze (S) , turn left and run straight ahead (R) until it came to the food well (S). This can be contrasted with behavior based on the cognitive map, which would identify both the animal's position in the start arm and the location of the goal in its cognitive representation of the maze, and then instruct the motor system to locomote in the appropriate direction for the appropriate distance to reach the goal. When rats are first trained in such a maze they tend to use place hypotheses in the early stages of learning, but then with continued practice the route hypothesis begins to dominate. This can be shown in a simple probe test in which the stem of the T maze is rotated by 180° to lie on the opposite side of the T. This forces the animal to choose between going to the goal location (making the opposite body turn to that usually made), or sticking with a route strategy and making the same body turn (taking it to the opposite arm of the T from usual). The dependence on the hippocampus of place, but not route, strategies has been nicely shown in an experiment by Packard and McGaugh (1996) in which the injection of local anesthetic solution into either the hippocampus or the caudate nucleus (a good candidate for the neural basis of route strategies) was done during probe trials given either just after rats had learned the T maze or following substantial overtraining. Just after learning the rats tended to use place hypotheses and performance was blocked by hippocampal injections; later on, the rats used route hypotheses which were blocked by caudate injections. The blocking of route hypotheses in overtrained animals uncovered place hypotheses which were still intact but overshadowed by the stronger route hypotheses.

The cognitive map hypothesis makes three strong predictions about the behavioral deficit following hippocampal damage: it predicts that animals will lose their allocentric spatial memories, will be unable to navigate to a hidden goal when started from different locations in a familiar environment, and will not explore novel environments or be sensitive to changes in the location of objects in a familiar environment. All three predictions have been consistently confirmed. The best available tests of one-trial spatial memory in the rat are the T-maze alternation test and the Olton radial arm maze. Each trial on the T-maze alternation task consist of two runs. On the first run, one of the arms is blocked, forcing the animal into the other where it is rewarded. On the second run, both arms are available and the correct rewarded choice is the one not visited on the first run. The animals have to remember which arm they were forced to enter on the first run in order to choose correctly on the second. Animals with hippocampal damage are very poor at this task when the delay between the two runs is longer than a few seconds (e.g. Aggleton *et al*., 1986). The Olton maze can be viewed as a more testing elaboration of this. In this task, eight arms radiate from a central platform each with a food well at its peripheral end. At the beginning of each trial there is food in each of the wells but this is not replenished when the animal eats it. The animal's optimal strategy on each trial is to retrieve all of the eight food rewards without reentering any of the depleted arms. There are two versions of the task, one in which the goal arms are identified by their spatial location in the room and another in which each arm contains a distinctive set of cues which the animal can use as an *aide-mémoire* instead of the spatial cues. While normal animals learn either version, animals with hippocampal lesions are very poor at the spatial version but succeed on the cued version (Jarrard, 1993). This implies that they are motivated to solve the task and have preserved motor skills but lack the ability to form the spatial memories needed to solve it. A similar dissociation between their ability to use spatial and nonspatial information can be seen in their navigational performance. The most widely used test of navigation is the water maze task devised by Richard Morris. At the start of each trial, the animal is placed in a pool filled with cloudy water and must escape by swimming to a hidden platform in a fixed location. The start location varies from trial to trial so that the animal cannot simply learn to head in a specific direction or towards a specific stimulus. Raising the platform above the level of the water transforms it into a visible cue which can substitute for information about its location. Rats with hippocampal lesions are deficient on the spatial version of the task but learn the visible cued version as quickly as normal rats (Morris *et al*., 1982).

The last prediction of the cognitive map theory is that rats with damage to the hippocampus should not be sensitive to changes in the spatial layout of objects and should not explore them as do normal rats. This follows from a core postulate of the theory that the motivation for originally building and subsequently altering maps is the cognitive

one of curiosity. Animals build maps either because they have no hippocampal representation of an environment or because there is a mismatch between the stored representation and the current experience of that environment. Recent experiments have shown that hippocampal-damaged rats do not respond to the movement of objects or stimuli in a familiar environment, but that they do respond to the introduction of a new stimulus (Xavier *et al*., 1990; Save *et al*., 1992).

It is clear that the cognitive map theory accounts for the function of the rat hippocampus very well (although, as we shall see in a moment, there have been suggestions that it is not broad enough). How does it deal with the global amnesia seen in humans following damage to the hippocampal formation? The theory begins by acknowledging that the human hippocampus has a wider and more elaborate function than that of the rat. This partly reflects the development of language and consequent lateralization of cortical functions in the human, and the development of a sense of linear time. This latter, assumed to be dependent on the dramatic expansion of the prefrontal cortex in higher mammals, provides a time stamp for each individual visit to a location in the map, forming the basis for memories embedded in a spatiotemporal context or what Tulving has called 'episodic' memories. Most language functions are localized to the left side of the brain and this lateralization is honored by the hippocampal memory system. Historically it has been recognized that lesions of the right human hippocampus result in spatial and visuospatial memory deficits, lesions to the left side result in verbal memory deficits (Milner, 1971; Frisk and Milner, 1990). The cognitive map theory views spatial language as the prototype for all language. Instead of both hippocampi storing the locations of physical objects, as in the rat, the left human hippocampus uses the same system to store the symbols originating in the auditory modality which stand for these representations. In support of this hypothesis, analysis of the meanings of English prepositions shows how they code for the shapes of place fields and the locations of objects relative to other landmarks (O'Keefe, 1996). In this view, the function of the left human hippocampus is to store episodes and narratives. Evidence in support of the lateralization of spatial memory to the right and episodic memory to the left comes from experiments on patients who have had unilateral temporal lobectomies for the relief of epilepsy (Spiers *et al*., 2001b) and from the bilateral hippocampal patient Jon who is deficient in both (Spiers *et al*., 2001a). Further evidence comes from functional imaging studies which show that the right hippocampus is selectively activated during imagined navigation in taxi drivers or in virtual reality environments (Figure 4), while the left hippocampus is more active during episodic memory tasks.

ASSOCIATIVE MEMORY THEORIES OF HIPPOCAMPAL FUNCTION

Alternative explanations of hippocampal function do not dispute its role in spatial memory but seek to broaden its function to include nonspatial associative memory as well. Noting that the cognitive map theory needs to broaden the functions it ascribes to the hippocampus in order to account for the nonspatial functions of the left human hippocampus, they ask whether a broader theory might apply to the rat hippocampus as well. Currently there are two versions of this broader associative theory with some support: configural associative theory (Sutherland *et al*., 1989) and flexible relational theory (Cohen and Eichenbaum, 1993). Configural association theory suggests that the hippocampus binds together two separate representations to make a third 'configured' representation. This would enable an animal to respond differently to the configuration than to either of the elements presented independently, for example enabling it to respond positively to either a light or a tone but not to the combination of the two. While there is some evidence that rats with hippocampal lesions might have difficulties in solving some problems of this nature, two carefully performed experiments (Gallagher and Holland, 1992; Davidson *et al*., 1993) have found them to be normal on these tasks. Both demonstrated that the animals with lesions could learn that a stimulus (e.g. a light) on its own had one valence but in combination with a second stimulus (e.g. a tone) had the opposite valence. These results show that animals can use configurations, and argue for a more restricted role for the hippocampus than that envisioned by the configural association theory. This has been acknowledged by the authors in a more recent paper (Rudy and Sutherland, 1995). The flexible relational theory of Cohen and Eichenbaum views the hippocampus as storing many of the different types of relationships which stimuli or objects can have to each other. Some examples are, 'A is associated with a particular smell', 'A is more desirable than B', 'A came before B in time'. Like the cognitive map theory, the relational theory emphasizes the flexibility of the information stored in the hippocampus, either enabling it to be

used in contexts other than those in which it was acquired or serving as the basis for inferences not explicit in the originally learned relations but deducible from them. The main evidence for this theory comes from lesion and single unit recording experiments in rats. Rats with lesions of the hippocampus or of structures that send fibers to the hippocampus such as the entorhinal cortex or fornix have been reported to fail nonspatial tasks requiring these relational abilities. To take two examples: first, rats are social animals and use their interactions to communicate information about edible foods; after smelling the odor of food on the breath of a familiar rat, a normal rat will choose it in preference to an unknown food. Rats with hippocampal lesions were reported to forget this association faster than normals (Winocur, 1990; Bunsey and Eichenbaum, 1995). In another experiment, the role of the hippocampus in the ability of the rats to carry out transitive inferences was tested. Rats were trained that following the smell of odor A, odor B rather than C was correct, and independently that following odor B, odor D and not E was correct. Subsequently, presented with A followed by a choice between D and E they were able to infer that odor D was the correct choice. Rats with hippocampal damage could learn the original relations but could not deduce the correct inference, suggesting that they lacked the relational machinery (Bunsey and Eichenbaum, 1996).

Unfortunately, the reliability of these findings has not been established by replication in other laboratories. Burton and coworkers (2001) could not reproduce the social transmission of olfactory information finding, and Li *et al*. (1999) found no

deficit in the transitive inference task. Therefore, for the time being, one must suspend judgment on the claim made by these theories that there is a set of non-spatial memory tasks that are reliably failed by animals with hippocampal damage. A similar caveat applies to the results of single unit recording studies which have been adduced to support the relational theory. The simplest type of relationship between two entities is the identity relationship $A = A$. The relational theory should predict hippocampal involvement in tasks which rely on this capacity for reidentification, particularly when the animal is required to act flexibly and make a different response to the two presentations of the object or stimulus. The ideal task for measuring this capacity is the delayed nonmatching-to-sample (DNMS) task in which the animal is rewarded for responding to the first presentation of an item but then must reject it and choose the alternative item on the second presentation. As we have seen above, it was originally believed that animals with hippocampal lesions were deficient at these simple memory tasks (Zola-Morgan and Squire, 1985) but it is now clear that this is not the case for either monkeys (Murray and Mishkin, 1998) or rats (Mumby *et al*., 1996). Furthermore, single unit experiments in primates have failed to find cells reflecting this relationship. The adherents of the relational theory originally claimed this putative deficit as evidence in its favor but no longer view DNMS as a good test of this type of memory.

THE ROLE OF EEG THETA

There are reasons to believe that the hippocampus acts as an integrated structure. One mechanism by which this integration takes place is reflected in the hippocampal EEG. During some behaviors, the electroencephalogram recorded from the hippocampus of rats and other animals exhibits a striking sinusoidal rhythm called the theta rhythm. At other times, the EEG is desynchronized. The behavioral correlates of the theta waves vary slightly among species but in general can be found in response to arousing stimuli and during behaviors that change the animal's location in the environment. Recordings of the theta waves from different parts of the hippocampus suggest they are locked in synchrony and thus may act to bind the hippocampus into one coordinated system. Both pyramidal cells and interneurons fire in bursting patterns with phase relationships to the ongoing EEG theta, indicating that the mechanism that generates theta has functional significance. The interneurons always maintain a fixed phase relationship to the theta waves whereas the pyramidal cells have a more interesting correlate: as the animal enters the place field, the earliest firing of the cell occurs at a particular phase of the theta wave (Figure 5), but as the animal continues through the field each subsequent firing burst moves to an earlier phase of the wave (O'Keefe and Recce, 1993). The best correlate of the phase of firing is the animal's location on the maze and this improves the animal's ability to identify its location by 43% (Jensen and Lisman, 2000). Another important role for theta is in gating the efficacy of afferent inputs in producing long-term potentiation (LTP) and long-term depression (LTD), the phenomena in which a brief train of electrical pulses delivered to the afferent fibers to a cell result in an increased (or decreased) response for periods of hours, or even days (Bliss and Lomo, 1973; Bliss and Collingridge, 1993). When the afferent synaptic input arrives at the theta peak, LTP results; at the trough, LTD (Huerta and Lisman, 1995; Orr *et al*., 2001). We can conclude that the theta system is important in integrating activity across the hippocampus, in acting as a timing device against which place cell activity can be clocked, and in setting up the conditions for synaptic modification.

CONCLUSION

The hippocampus is involved in the storage of memories in both animals and humans. In animals such as the rat the memories are primarily or exclusively spatial, while in humans they include memories for episodes and narratives as well. Evidence for the role of the rat hippocampus in spatial memory comes from place-coded cells recorded there and from the deficits in spatial memory and navigation following damage to the hippocampus. A broader role in other kinds of relations has been suggested for the rat hippocampus but the single unit recording and lesion evidence in support of this position is much less robust than for the cognitive map theory. Both the cognitive map and relational theories agree that the human hippocampus has a broader function than that of the rat and that one of its functions is to store episodic memories. The declarative memory theory takes an even broader view, suggesting that factual and semantic memories in humans are also dependent on the hippocampus. This latter theory clearly captures the functions of the medial temporal lobe as a whole, but recent results suggest that different structures within this lobe subserve different components of the total declarative memory function.

CONTENTS

Quantitative representation of transmembrane ionic currents by the Hodgkin–Huxley equations allows the calculation of nerve-impulse dynamics, including all-or-nothing behavior, threshold, temperature dependence, decremental conduction and the nature of the refractory zone.

INTRODUCTION

In 1952, a detailed study of ionic current flow through the membrane of the giant axon of the squid (*Loligo*) was presented by Hodgkin and Huxley, culminating in a mathematical formulation for the dynamics underlying a nerve impulse. In addition to allowing computations of the ionic permeability and transmembrane voltage of a propagating impulse, their formulation predicts several new features, including an unstable impulse of lower amplitude and speed, threshold conditions for launching an impulse, temperature dependence of propagation, the effects of 'narcotizing' an axon by reducing the maximum ionic conductivities, and the nature of the refractory zone following the passage of an impulse.

SPACE AND VOLTAGE CLAMPING

When conducting their research, Hodgkin and Huxley used the techniques of *space clamping* and *voltage clamping* to characterize a localized patch of squid membrane. Although these terms sound alike, they describe quite different experimental techniques (*See* **Single Neuron Recording**)

Geometrically, a squid nerve is a cylindrical tube of conductive axoplasm encased in a lipid-bilayer membrane, as shown in Figure 1(a). Variations in transmembrane voltage with distance along the structure can be eliminated by inserting a conducting wire longitudinally through the nerve as a terminal for the internal voltage. With such space clamping, the total current per unit area flowing through the membrane is given by an expression of the form

$$\frac{\text{total membrane current}}{\text{membrane area}} = J_{\text{ion}} + C\frac{dV}{dt} \qquad (1)$$

where the first term on the right-hand side represents the transmembrane ionic current per unit area through the membrane, and the second term is the displacement current per unit area through the capacitance of the lipid bilayer.

The term 'voltage clamping', on the other hand, implies the use of a *negative feedback amplifier* to hold the potential difference across a nerve membrane at a fixed value, unaffected by flows of ionic currents.

IONIC CURRENTS THROUGH A PATCH OF SQUID MEMBRANE

Using the techniques of space clamping and voltage clamping, Hodgkin and Huxley were able to measure individually the dynamics of sodium and potassium ion currents. For example, the sodium current consists of two components, namely a *conduction current* that flows in response to the transmembrane voltage difference, and a *diffusion current* that flows in response to the transmembrane difference in sodium ion concentrations on the two sides of the membrane. These two components are proportional to each other because the transmembrane mobility μ_{Na} (which determines the sodium conduction current) is related to the transmembrane diffusion constant D_{Na} (which determines the sodium diffusion current) by the *Einstein relation*, $D_{\text{Na}} = kT\mu_{\text{Na}}/q$, where k is the Boltzmann constant, T is the absolute temperature and q is the electronic charge. In other words:

$$\text{sodium current} = \widetilde{G}_{\text{Na}}(V,t)(V - V_{\text{Na}}) \quad \text{and} \qquad (2)$$

$$\text{potassium current} = \widetilde{G}_{\text{K}}(V,t)(V - V_{\text{K}}) \qquad (3)$$

where $\tilde{G}_{\text{Na}}(V,t)$ and $\tilde{G}_{\text{K}}(V,t)$ are sodium and potassium conductances, and the first and second

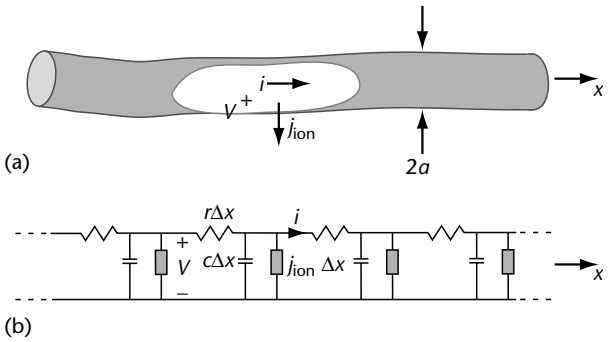

Figure 1. (a) Sketch of a squid axon. (b) A corresponding differential circuit diagram that can be used to derive the cable equation for impulse propagation.

terms in parentheses represent conduction and diffusion current, respectively.

If the membrane is at rest (steady state), the sum of the total sodium and potassium currents must be zero, leading to a *resting potential* V_R which is about 65 mV negative inside the axon with respect to the outside. Measuring the transmembrane voltage V with respect to the resting potential, and counting an increase in the inside voltage as positive, it follows from the Einstein relationship that

$$V_{Na} = 25 \log\left(\frac{[Na^+]_o}{[Na^+]_i}\right) - V_R \tag{4}$$

where $kT/q = 25$ mV at room temperature, $[Na^+]_o$ and $[Na^+]_i$ are the outside and inside concentrations of sodium ions, respectively, and similarly for the potassium ions. Normally $[Na^+]_o > [Na^+]_i$, whereas $[K^+]_o < [K^+]_i$; thus sodium ions diffuse into the axon, whereas potassium ions diffuse out of it.

To determine the individual dynamics of sodium and potassium ions at several fixed voltages, Hodgkin and Huxley first measured the total membrane current as a function of time at those voltages. They then reduced the external sodium concentration ($[Na^+]_o$) to approximately zero, effectively eliminating the inward sodium current and allowing measurements of the potassium current at the same voltages. Finally, subtraction of the second measurements from the first gave the corresponding sodium currents.

When this procedure was completed, it was discovered that the sodium conductance (or permeability) initially rises to a maximum value in less than a millisecond and then decays back to approximately zero over several milliseconds. Thus the dynamics of the sodium ion current at voltage V are represented by the formula

$$J_{Na}(V) = G_{Na} m^3(V,t) h(V,t)(V - V_{Na}) \tag{5}$$

where G_{Na} is a maximum sodium conductance per unit area, m is a 'sodium turn-on' variable and h is a 'sodium turn-off' variable.

Since the potassium conductance was observed to rise without falling back to zero, the dynamics of the potassium ion current at voltage V are represented by the formula

$$J_K(V) = G_K n^4(V,t)(V - V_K) \tag{6}$$

where n is a 'potassium turn-on' variable.

The total ionic current per unit area across the membrane, as expressed in Equation (1), then becomes

$$J_{ion} = G_{Na} m^3 h(V - V_{Na}) + G_K n^4 (V - V_K) + G_L(V - V_L) \tag{7}$$

where the last term is a small 'leakage current' accounting for ionic current missed by the measurements of sodium and potassium components. The empirical relationships governing the dynamics of m, h and n are as follows.

The membrane turn-on and turn-off variables are solutions of first-order rate equations with voltage-dependent parameters. Thus:

$$\begin{aligned} \frac{dm}{dt} &= \alpha_m(1-m) - \beta_m m \\ \frac{dh}{dt} &= \alpha_h(1-h) - \beta_h h \\ \frac{dn}{dt} &= \alpha_n(1-n) - \beta_n n \end{aligned} \tag{8}$$

where at 6.3°C the voltage dependencies of the coefficients are given by the following:

$$\alpha_m = \frac{0.1(25 - V)}{\exp[(25 - V)/10] - 1}$$
$$\beta_m = 4\ \exp(-V/18)$$
$$\alpha_h = 0.07\ \exp(-V/20)$$
$$\beta_h = \frac{1}{\exp[(30 - V)/10] + 1}$$
$$\alpha_n = \frac{0.01(10 - V)}{[\exp(10 - V)/10] - 1}$$
$$\beta_n = 0.125\ \exp(-V/80) \quad (9)$$

in units of milliseconds^{-1} with V measured in millivolts. At other temperatures, changes in these rates are accounted for by multiplying by the following factor

$$\kappa = 3^{(\text{temp}-6.3)/10} \quad (10)$$

where 'temp' is the temperature in centigrade.

The parameters in Equations (1) and (7) are shown in Table 1, where the standard value of V_L has been selected to make the steady-state value of $J_{ion} = 0$ at $V = 0$.

SPACE-CLAMPED ACTION POTENTIALS

Suppose that a length of squid axon is space clamped, and to simplify the arithmetic take this area to be 1 cm^2. Then from Equation (1) the basic equation governing the dynamics of membrane voltage is

$$\frac{dV}{dt} = \frac{I_0(t) - J_{ion}}{C} \quad (11)$$

where $I_0(t)$ is a current injected into the axon by the experimenter and J_{ion} is given in Equation (7).

A short pulse of injected current will begin to charge the membrane capacitance, raising the transmembrane voltage from its resting value ($V = 0$) to a threshold level. Near threshold, a positively charged sodium ion current flows into the axon, further increasing V, which rises rapidly to approximately V_{Na}. At this point, the sodium current falls to zero, and the potassium current begins to carry positive charge out of the axon, causing V to relax slowly back to the resting value. This cycle of activity is termed a space-clamped *action potential* or spike.

To compute these dynamics, Hodgkin and Huxley integrated Equation (11), together with Equations (7) and (8), for a variety of experimental conditions, demonstrating quantitative agreement with measurements of $V(t)$ on space-clamped squid membranes.

Table 1. Parameter values measured by Hodgkin and Huxley (1952) for the giant axon of the squid

Parameter	*Mean*	*Range*	*Standard*	*Units*
C	0.91	(0.8–1.5)	1.0	μF/cm^2
G_{Na}	120	(65–260)	120	mmhos/cm^2
G_K	34	(26–49)	36	mmhos/cm^2
G_L	0.26	(0.13–0.5)	0.3	mmhos/cm^2
V_{Na}	+109	(95–119)	+115	mV
V_K	−11	(9–14)	−12	mV
V_L	+11	(4–22)	+10.5995	mV

NERVE-IMPULSE PROPAGATION

Consider next how this local switching activity propagates along a nerve that is not space clamped, with the following parameters (Figure 1(b)):

- r is the longitudinal resistance per unit length of the fiber, measured in units of ohms per centimeter. For a cylindrical axon of radius a, $r = \rho/\pi a^2$, where ρ is the resistivity of the cytoplasm in ohm-centimeters.
- c is the membrane capacitance per unit length of the fiber, measured in units of farads per centimeter. For a cylindrical fiber of radius a, $c = 2\pi aC$, where C is the capacitance per unit area of the membrane in farads per square centimeter.
- j_{ion} is the ionic current flowing across the membrane (from inside to outside) per unit length of the axon, measured in units of amperes per centimeter. For a cylindrical fiber of radius a, $j_{ion} = 2\pi a J_{ion}$, where J_{ion} is the transmembrane current per unit area given in Equation (7).

Applying Kirchhoff's circuit laws to the differential circuit diagram shown in Figure 1(b) in the limit $\Delta x \to 0$ yields the following *nonlinear diffusion equation*:

$$\frac{\partial^2 V}{\partial x^2} - rc\frac{\partial V}{\partial t} = rj_{ion} \quad (12)$$

from which emerges the nerve impulse. A solution of Equation (12) that represents nerve impulse is a *traveling wave* for which

$$V(x,t) = \widetilde{V}(x - vt) = \widetilde{V}(\xi) \quad (13)$$

with the dependencies on x and t constrained by the variable

$$\xi \equiv x - vt \quad (14)$$

where v is the propagation velocity of the traveling wave.

This assumption implies that the partial derivatives with respect to x and t in Equation (12) are related as $\partial/\partial x = (-1/v)\partial/\partial t = \partial/\partial\xi$. Thus

Equation (12) – a partial differential equation (PDE) – is reduced under the traveling wave assumption to the ordinary differential equation (ODE):

$$\frac{d^2\widetilde{V}}{d\xi^2} + rcv\frac{d\widetilde{V}}{d\xi} = rj_{\text{ion}} \tag{15}$$

Although Equation (15) is easier to solve than Equation (12), it contains less information because the impulse speed v is an undetermined parameter. (*See* **Diffusion Models and Neural Activity**)

In attempting to solve Equation (15), Hodgkin and Huxley were faced with two problems. (1) In order to determine the traveling wave speed v, it was necessary to carry through many tedious integrations without the benefit of an electronic computer. (2) The parameter values for real squid nerves vary over a rather wide range, as indicated in Table 1.

To limit the number of integrations, they selected one axon, with an internal (axoplasmic) resistivity (ρ) of 35.4 ohm-cm, a radius (a) of 0.0238 cm, and the 'standard' membrane values indicated in Table 1, for detailed numerical analysis. For this particular axon, the parameters of Equation (15) are given in Table 2. Since the action potential was measured at 18.5°C, the numerical calculations of the impulse dynamics were also performed for this temperature.

As shown in Figure 2, the shape of the traveling-wave solution calculated for this nerve was found to be in good qualitative agreement with experimental observations, and the calculated impulse velocity was $18.8\,\text{ms}^{-1}$, whereas the measured speed was $21.2\,\text{ms}^{-1}$, again in substantial agreement. Therefore, like a celebrity who is 'famous for being well known', this nerve has become widely recognized and studied as the *standard Hodgkin–Huxley axon*, defined by the parameters listed in Tables 1 and 2.

Although it was impractical for Hodgkin and Huxley to perform the necessary calculations in the early 1950s, there are in fact *two* impulse solutions at two different values for the traveling-wave speed, which are shown in Figure 2. In this figure, the higher-amplitude solution (at $v = 18.8\,\text{ms}^{-1}$) corresponds to the experimentally observed impulse.

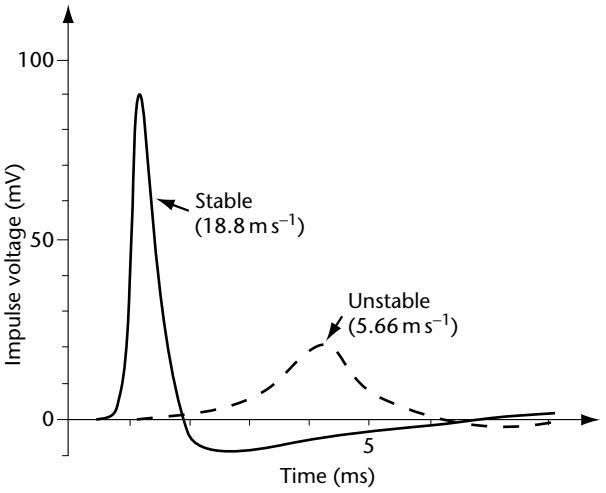

Figure 2. A full-sized impulse (at $v = 18.8\,\text{ms}^{-1}$) and an unstable threshold impulse (at $5.66\,\text{ms}^{-1}$) for the standard Hodgkin–Huxley axon at 18.5°C. (From data in Hodgkin and Huxley (1952) and Huxley (1959)).

The smaller-amplitude traveling-wave solution, with a speed of $5.66\,\text{ms}^{-1}$, was found by Huxley in 1959 using an electronic computer. This solution is unstable in the sense that deviations from it diverge with increasing time. Slightly smaller solutions decay to zero and slightly larger solutions grow to become the fully developed nerve impulse. Thus this unstable solution defines *threshold conditions* for igniting an impulse (Scott, 1973).

Table 2. Standard Hodgkin–Huxley parameters for the giant axon of the squid

Parameter	*Value*	*Units*
ρ	35.4	ohm-cm
a	0.0238	cm
r	2.0×10^4	ohms/cm
c	1.5×10^{-7}	F/cm

DEGRADATION OF A NERVE IMPULSE

In 1966, Cooley and Dodge described the effects of 'narcotizing' a Hodgkin–Huxley fiber by reducing the maximum sodium and potassium conductances by a *narcotization factor*, $\eta < 1$. Thus

$$G_{\text{Na}} \to \eta G_{\text{Na}} \text{ and } G_{\text{K}} \to \eta G_{\text{K}}$$

are the values used in numerical computations.

One qualitative effect of this change is to reduce the speed of the larger-amplitude stable traveling-wave solution as shown in Figure 3. Conversely, the speed of the smaller-amplitude unstable traveling-wave solution is increased. Eventually, a critical point is reached (at $\eta_c = 0.261$) where the two solutions merge together. For yet smaller values of η, no traveling-wave solutions exist. Along the locus shown in Figure 3, a condition of power balance obtains, at which the rate of energy release by the impulse is equal to its dissipation rate.

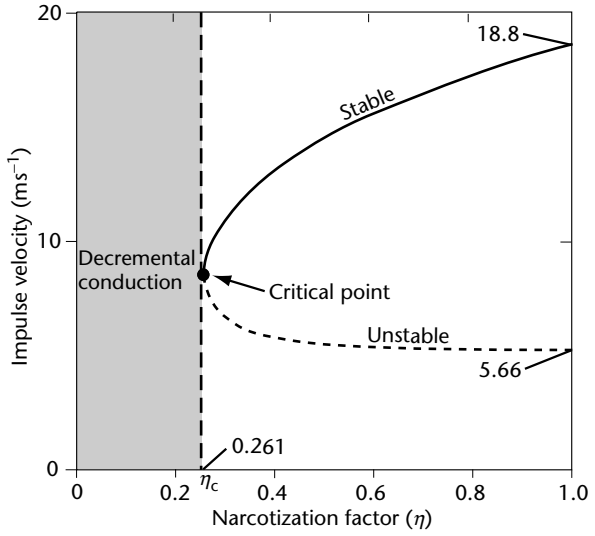

Figure 3. Power balance loci, showing impulse speeds for the Hodgkin–Huxley equations as a function of a 'narcotization factor' (η). (From data in Cooley and Dodge (1966)).

Although Adrian's concept of all-or-nothing propagation holds for $\eta > \eta_c$, its logical basis evaporates for $\eta < \eta_c$. However, in this regime one can find *decremental* propagation of a nerve impulse, where the rate at which energy is generated is only slightly less than the rate of dissipation, so the impulse amplitude relaxes rather slowly to zero. As was emphasized by Lorente de Nó and Condouris in 1959, this phenomenon was long overlooked by electrophysiologists, who had concentrated their attentions on the properties of standard nerves.

The qualitative conclusions stemming from the computations of Cooley and Dodge apply to several other situations in which the ability of a nerve to conduct impulses is degraded, including the following: (1) increasing external concentrations of potassium ions (Adelman and FitzHugh, 1975); (2) higher temperatures, at which the temporal rates of membrane conductance increase according to Equation (10), thereby shortening the potassium turn-on time (Cole, 1968); (3) increasing the leakage conductance (Cole, 1968); (4) abruptly increasing the cross-sectional area, which has implications for information processing at the axonal or dendritic branchings of a neuron (Berkinblit *et al.*, 1970); (5) finally, the propagation of a periodic train of impulses is degraded when the interval between individual pulses becomes less than a certain value, because each impulse then propagates in the *refractory zone* of the preceding impulse.

REFRACTORY AND ENHANCEMENT ZONES

The problems encountered by a nerve impulse that follows too closely on the heels of another have been studied empirically using *double-impulse* measurements (Donati and Kunov, 1976; Scott and Vota-Pinardi, 1982). In such experiments, pairs of impulses are launched on single fibers, and the ratio of impulse speeds is measured as a function of the impulse interval (T).

The lower part of Figure 4 shows measurements of the ratio

$$R(T) \equiv \frac{\text{speed of second impulse}}{\text{speed of first impulse}}$$

for impulses propagating on an axon of the squid (*Lologo vulgaris*). A significant feature of this ratio is the impulse interval $T = T_1$ at which $R(T) = 1$.

In terms of T_1, four regions can be distinguished. (1) *Absolute refractory zone*: for impulse intervals less than $T < 0.4T_1$, it is impossible for the second impulse to propagate; thus $R(T) = 0$. (2) *Relative refractory zone*: for impulse intervals in the range $0.4T_1 < T < T_1$, the second impulse is able to propagate, albeit with diminished speed. (3) *Enhancement zone*: in the range $T_1 < T < 1.8T_1$, the second impulse is observed to travel *faster* than the first impulse. (4) *Uncoupled zone:* if the impulse interval is greater than about $1.8T_1$, both impulses travel at the same speed, with the second impulse uninfluenced by the first. Data from 13 squid axons at temperatures between 14.4°C and 20.4°C give the relationship $T_1 = 58.2 \times 3^{-\text{Temp}/10}$ ms ($\pm 13\%$), in agreement with Equation (10) (Scott and Vota-Pinardi, 1982).

The upper part of Figure 4 is an oscilloscope photograph of the trailing edge of a single squid impulse, into which a second impulse would attempt to propagate. T_0 is the time between the point of maximum slope on the leading edge of $V(t)$ (occurring at about 50 mV, this is off the scale of the figure) and the point on the trailing edge where $V(t)$ crosses over from being hyperpolarizing (more negative than the resting value) to being depolarizing. Both T_0 and T_1 have been measured on the above cohort of 13 axons, showing that $T_0 \approx T_1$ to within experimental errors of about $\pm 15\%$.

The qualitative similarity of these two measurements in the neighborhood of the crossover points indicates that the enhancement zone stems from the depolarizing phase on the trailing edge of the first impulse. From a physical perspective, a depolarizing phase occurs because near its resting level a nerve membrane is oscillatory.

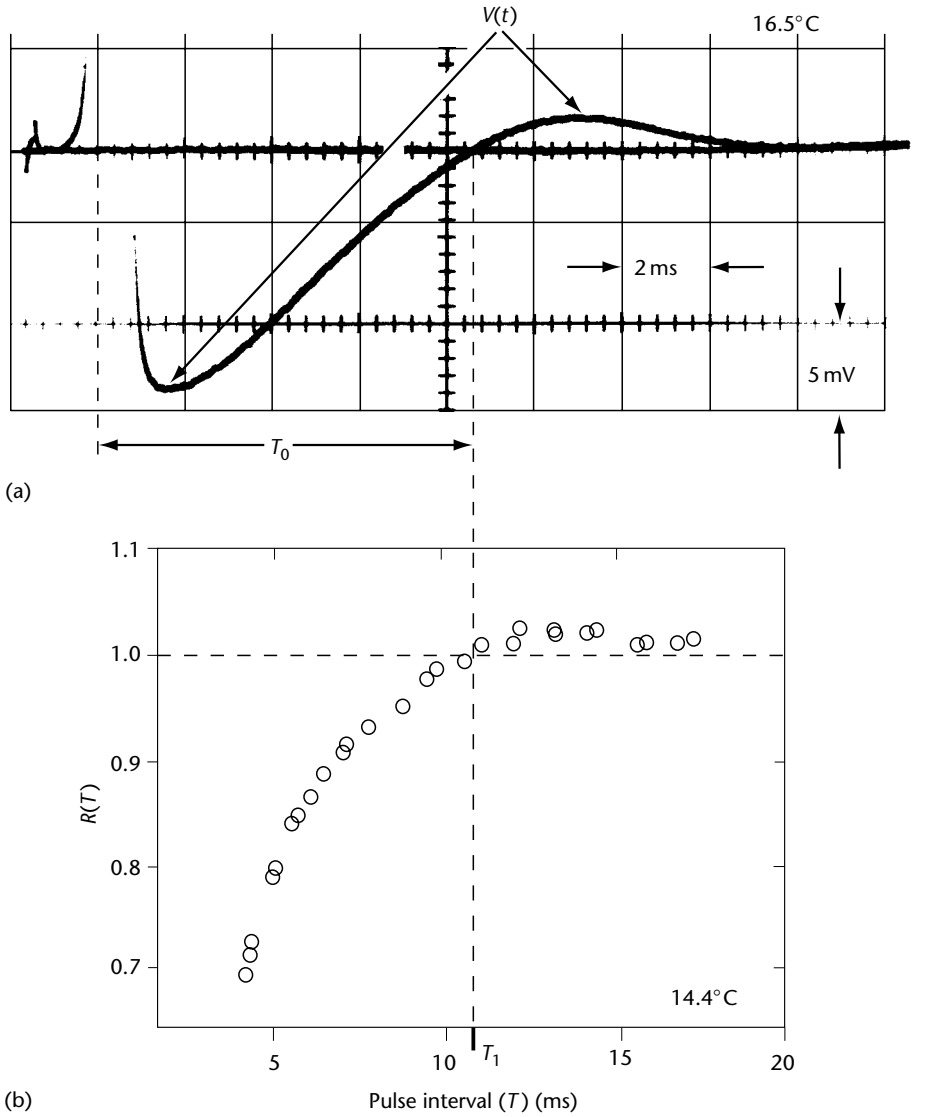

Figure 4. Two data sets related to the refractory zones in the wake of a propagating impulse on a squid axon. (a) An oscilloscope photograph showing the oscillatory tail of a single action potential $V(t)$. (b) Double impulse measurements, where T is the time interval between impulses and $R(T)$ is the ratio of the speeds of the two impulses. (Note that the crossover points in the two data sets are aligned, and the timescales have been adjusted for different temperatures.)

Discovered by Cole and Baker (1941) and noted by Hodgkin and Huxley (1952), subthreshold membrane oscillations of the Hodgkin–Huxley equations were investigated numerically by Sabah and Liebovic (1969), and both experimentally and numerically by Mauro *et al*. (1970). These studies show that a patch of squid membrane near its resting voltage has a damped resonance (Q–3) at around 50–100 Hz, depending on the temperature. (*See* **Neural Oscillations**)

Hormones modulate learning and memory processes by increasing or decreasing the strength with which information is stored.

INTRODUCTION

Memory is often defined as the ability to acquire, store, and retrieve new information. One's memory of one's first teacher at school is represented in the brain by an interconnected network of neurons. If a memory is with you for life, then some permanent change took place in your brain that represents the memory. This usually involves the strengthening of synapses within a specific neural network for a given memory. Hormones do not affect the memory trace directly; instead, they influence modulatory systems that in turn regulate associative strength, thereby making memories stronger or weaker. Hormones are considered to be memory modulators because different doses of a hormone can have opposing effects on memory.

Different forms of memory (declarative, procedural, spatial, etc.) are often divided into two groups: those that depend on the hippocampus, and those that do not. Although the mechanisms for memory storage may differ for different kinds of memory, as a memory modulator, hormones can influence multiple forms of memory by enhancing or impairing learning. Hormones can modulate:

- acquisition – the ability to learn a task,
- consolidation – the transition of information from short-term to long-term memory,
- retention – the ability to remember information,
- extinction – the ability to decrease a behavioral response to conditioning because of a lack of reinforcement,
- retrieval – the ability to recall information.

THE NEUROENDOCRINE SYSTEM

Why are extremely emotional or stressful events remembered so vividly? For instance, who in America will ever forget the events that took place on 11 September 2001? Moments such as these activate our autonomic and neuroendocrine system, resulting in the release of hormones that elicit an increase in heart rate, sweating, nausea, and anxiety. The hormonal release and the ensuing cellular and physiological responses in the brain can have a dramatic influence on the strength with which an event is to be remembered.

Methods of Communication

Endocrine communication occurs when endocrine glands secrete their chemical messengers, hormones such as the glucocorticoids, into the bloodstream. These hormones, in turn, activate target cells throughout the body. Only cells containing the specific receptor will be activated and remain activated until hormone levels decrease. Autocrine and paracrine forms of communication occur when endocrine cells secrete hormones that act on the releasing cell or neighboring cells, respectively. Some chemical messengers, such as noradrenaline (norepinephrine), can act both as a hormone (when released from the adrenal gland) and as a neurotransmitter (when released from neurons in the brain).

Endocrine glands were previously thought to be the only source of hormone secretion into the bloodstream. However, in 1928 Ernst Scharrer discovered that certain neurons in the hypothalamus secrete chemical messengers, termed neurohormones, into the blood, thus establishing the field of neuroendocrinology.

The mechanisms by which the nervous and endocrine systems communicate are displayed in Figure 1. Neurons secrete chemical messengers, known as neurotransmitters, into a specialized region between neighboring neurons called the synapse. Neurotransmitters are modified amino acids that cross the synapse and rapidly activate specific receptors (proteins located on the cell surface), which increase or decrease the activity of the postsynaptic target cell. In addition to neurotransmitters, neurons can also contain and release neuropeptides, such as adrenocorticotrophic hormone (ACTH). Neuropeptides are peptide hormones derived from larger precursor proteins that act as neuromodulators to regulate the activity of neurons. A second method of neuronal communication is neuroendocrine secretion. Specialized neurons, termed neurosecretory cells, release neurohormones into the bloodstream to activate distant target cells; for example, neurosecretory

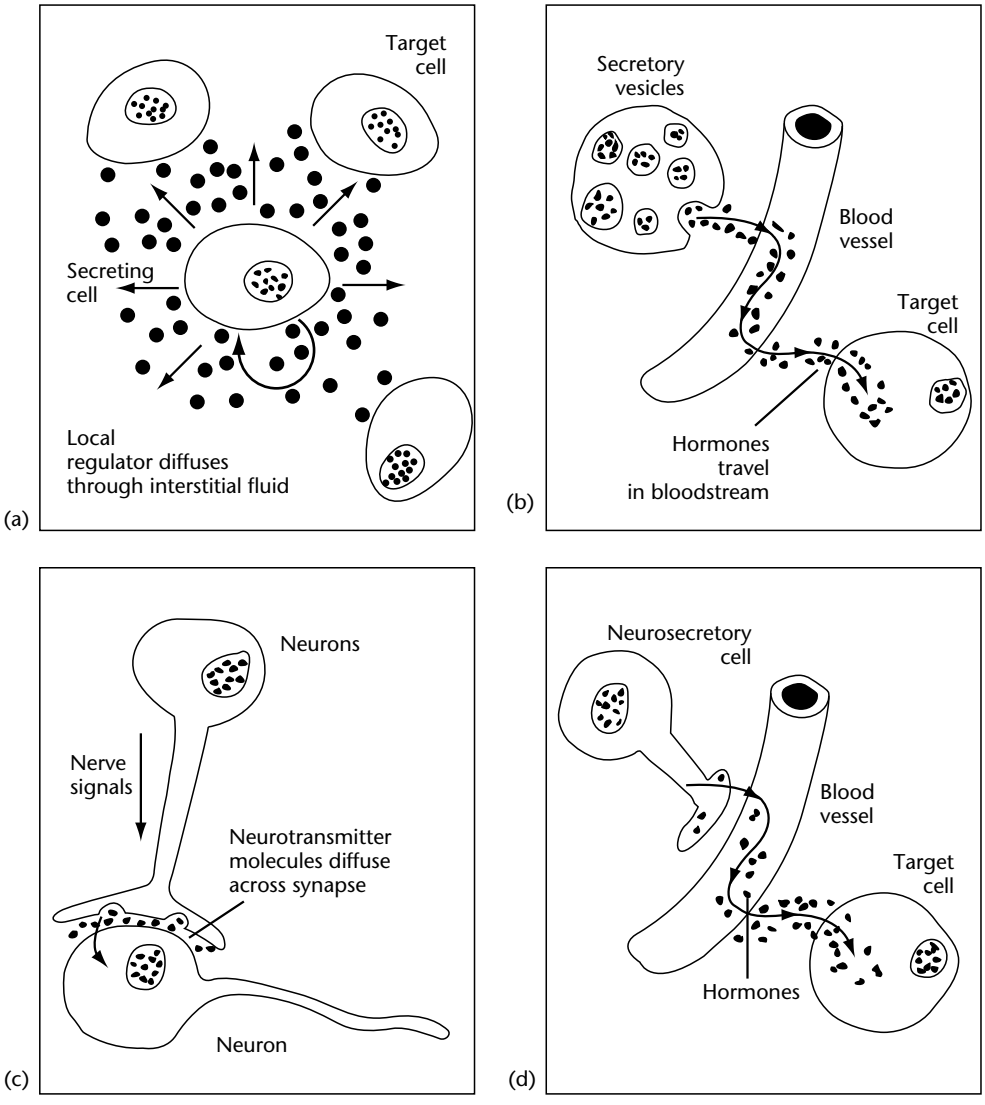

Figure 1. Endocrine and neuronal systems of communication. The endocrine systems of communication include (a) autocrine and paracrine forms in which secretory cells release hormones that act on the releasing cell or adjacent cells, and (b) endocrine forms in which cells release hormones into the bloodstream, activating target cells throughout the body. Neurons communicate by (c), releasing neurotransmitters across the synapse to activate neighboring neurons. Neuroendocrine communication (d) occurs when neurosecretory cells release their hormones into the bloodstream to activate distant target cells. Website of the Center for Bioenvironmental Research at Tulane and Xavier Universities (http://www.som.tulane.edu/ecme/eehome/basics /endosys/hormones.html).

cells of the posterior pituitary secrete vasopressin to activate kidney cells.

The Endocrine Glands

An endocrine gland is a ductless organ that secretes hormones into the bloodstream. The release of hormones from these endocrine glands is monitored and controlled by the pituitary gland, which in turn is controlled by the hypothalamus (Figure 2). The posterior pituitary is not a gland but is actually an extension of the brain that contains nerve terminals which release hormones into the bloodstream.

Let us return to the question of why extremely emotional or stressful events are remembered so vividly. It has been found that during particularly stressful events, the hypothalamic–pituitary–adrenal (HPA) axis is activated, creating behavioral and physiological responses to the stressor that can alter the strength with which memories are stored (Figure 3). Incoming sensory input (sight, sound, and pain) is relayed to higher-order processing centers in the brain, which in turn release neurotransmitters activating hypothalamic neurosecretory cells to release a hormone called corticotrophin releasing hormone (CRH). This hormone travels through the portal blood supply (connecting the hypothalamus with the anterior pituitary) to stimulate cells of the anterior pituitary to release ACTH into the bloodstream. This ACTH activates the adrenal cortex to secrete glucocorticoids such as cortisol, which bind to target cells throughout the periphery and brain. The released glucocorticoids can readily reenter the brain and provide negative feedback to the hypothalamus and pituitary to prevent further release of CRH and ACTH when glucocorticoid levels become too high. Activation of the autonomic nervous system during stressful events additionally stimulates the adrenal medulla to release adrenaline (epinephrine) and noradrenaline (norepinephrine) into the bloodstream. The released glucocorticoids and noradrenaline then interact with memory mechanisms to mark the importance of the event, as described below.

HORMONAL INFLUENCE ON LEARNING AND MEMORY

The influence of hormones on memory often follows a U-shaped curve. For example, when an

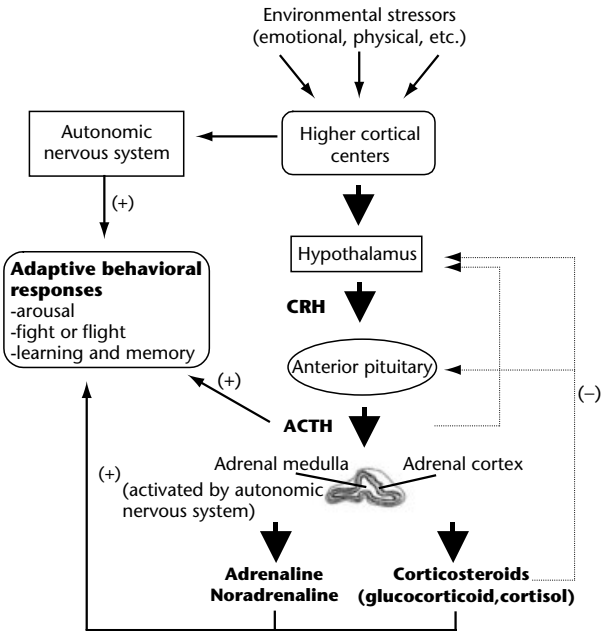

Figure 3. Activation of the hypothalamic–pituitary–adrenal axis during stressful events produces adaptive behavioral responses following the release of corticosteroids and the catecholamines, adrenaline and noradrenaline. Glucocorticoids can provide negative feedback (–) to the hypothalamus and pituitary to prevent further release of hormones. ACTH, adrenocorticotrophic hormone; CRH, corticotrophin releasing hormone.

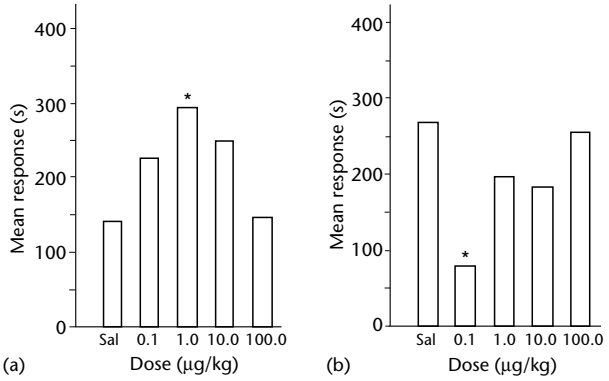

Figure 4. Hormones characteristically produce U-shaped dose–response curves. Some hormones produce either an (a) inverted-U or (b) U-shaped dose–response curve for inhibitory avoidance behavior. Injections of intermediate doses of a hormone are usually the most effective (asterisk) in either (a) enhancing or (b) impairing memory when compared with saline (Sal) control-treated animals.

animal receives a low, intermediate, or high dose of a hormone, only the intermediate dose affects learning and memory (Figure 4). There can also be a biphasic response, where the low and high doses impair memory and the intermediate dose enhances it, or vice versa. These behavioral responses are the hallmark of neuromodulators.

This section will look at three types of behavioral training that require certain limbic structures, such as the hippocampus and amygdala. The first uses food as a motivation to learn a maze task, to study appetitive learning. The second task requires the animal to move actively away from a particular location, or passively 'freeze' when placed in a chamber, to avoid receiving a foot shock, to study active and passive avoidance learning respectively. The final task requires animals to use spatial cues to navigate through a maze either on land or in water, to study spatial learning. The effects of a given hormone will depend on the strength of training (e.g. the intensity of foot shock), the hormone dose, the time of administration (before or after training), and the type of memory being tested.

ACTH

The release of ACTH from the anterior pituitary and subsequent release of glucocorticoids from the adrenal cortex are a critical component of the endocrine and metabolic response to stress. The release of ACTH is also important for behavioral adaptations (learning and memory) to stressful or arousing experience. As early as 1955 it was demonstrated that surgical removal of the pituitary gland – specifically the anterior pituitary – impairs active avoidance learning. However, if these animals were given ACTH, there was no learning impairment. In rodents, systemic injections of ACTH facilitate the acquisition of active and passive avoidance learning and enhance retention of passive avoidance response. This hormone also prolongs extinction of active avoidance behavior and appetitively motivated behavior in a T maze. The amount (or dose) of ACTH injected into the animals will determine whether enhancement, impairment, or no effect is seen. In addition, the same dose of ACTH may either enhance or impair memory, depending on the intensity of the foot shock used to train the animals. Together, these results highlight the modulatory nature of ACTH on learning and memory processes.

It is generally agreed that ACTH cannot cross the blood–brain barrier. So, does ACTH modulate memory directly by activating the central nervous system, or indirectly by activating the adrenal cortex? The answer is likely to be both. The hormone must work through the central nervous system, because ACTH restores performance in

animals that have had their pituitary and adrenal glands removed. Analogues of ACTH that can cross the blood–brain barrier, but do not stimulate adrenal cortex to release glucocorticoids, can mimic the effects of ACTH on conditioning. Furthermore, ACTH receptors are abundant in regions of the limbic system (hippocampus and amygdala) classically associated with learning and emotion. Lesions of these structures block the effects of ACTH analogues on extinction of conditioned avoidance responses.

Evidence suggests that systemic administration of ACTH exerts its effects, at least in part, through peripheral mechanisms. First, it is unknown whether ACTH and its analogues influence learning and memory processes through the same mechanisms. Second, while lesion studies suggest that an intact limbic system is necessary for the effects of ACTH analogues on extinction, this does not prove that these effects are due to the binding of ACTH to receptors within the limbic system. The effects of ACTH on conditioning may be initiated outside the blood–brain barrier, but the limbic system probably is required for the expression of these effects. Finally, glucocorticoids also have modulatory effects on learning and memory processes (discussed below). Together, these findings suggest that the effects of systemically administered ACTH on learning and memory could be initiated at sites in the brain or periphery.

Glucocorticoids

Glucocorticoids (corticosterone in rodents, and cortisol in humans) are steroid hormones, derived from cholesterol, that are secreted by the adrenal cortex into the general circulation. Glucocorticoids often take several minutes to be released in response to a stressor, and several hours for their effects to emerge. This is generally viewed as the second wave of the autonomic response that follows the rapid release of catecholamines, which trigger second-messenger cascades within seconds.

The most common effect of glucocorticoids on memory formation is an impairment following high, sustained doses of glucocorticoids, produced by multiple injections or chronic stress. However, the effects of glucocorticoids on memory consolidation and retention follow an inverted U-shaped dose-dependent relationship. Following training, peripheral or central administration of low doses of glucocorticoids enhances memory, whereas high doses are less effective or may even impair memory. Single injections of moderate doses of corticosterone or the synthetic glucocorticoid dexamethasone enhance memory for passive avoidance response. Similar modulatory effects of corticosterone on learning and memory processes have been observed in contextual-cue fear conditioning and a spatial water-maze task in rats. In addition to the dose, the biphasic effects of glucocorticoids also depend on the time and the relative aversiveness of the task. It has been shown that injections of moderate doses of dexamethasone following training can impair spatial memory in the water-maze task. However, if the training conditions are made less stressful by increasing the water temperature of the maze, such injections can enhance memory. Drug effects are greatest when the hormone is administered immediately after training and are generally ineffective when administered several hours later. This supports the belief that memories of an experience are not fixed or consolidated at the time of the experience, but involve a time-dependent process.

Glucocorticoids readily penetrate the blood–brain barrier and act on receptors in the central nervous system, especially in the hippocampus and amygdala, to influence learning and memory processes. The hippocampus is rich in glucocorticoid receptors, and is the primary neural structure where glucocorticoids exert their actions. In rats, both enhanced secretion and complete removal of corticosterone levels induce loss of hippocampal neurons and atrophy of dendritic structures. This is accompanied by an impairment of spatial memory performance, suggesting that the morphological changes induced by glucocorticoids have an impact on hippocampal function. Glucocorticoids also affect memory storage through influences involving the basolateral nucleus of the amygdala and requiring β-adrenergic activity (i.e. noradrenaline: see below). The amygdala integrates hormonal and neural influences to modulate associative memories in other brain regions, including the hippocampus. For example, lesions of the amygdala or inactivation of β-adrenergic receptors within the basolateral amygdala also block the memory-modulatory effects of intrahippocampal administration of glucocorticoids.

Catecholamines

The catecholamine hormones adrenaline (epinephrine) and noradrenaline (norepinephrine) are secreted by the adrenal medulla in response to the activation of the sympathetic nervous system (see Figure 3). In addition, noradrenaline is the major neurotransmitter released by postganglionic neurons of the sympathetic nervous system.

Together with glucocorticoids, the blood-borne catecholamines help coordinate different parts of the body for adaptation to stressful situations.

Marked elevations in plasma catecholamine levels are detected after a single shock to the foot of an intensity commonly used in avoidance training experiments, suggesting that peripheral catecholamines are responsive to training. Destruction of peripheral sympathetic nerve terminals or removal of the adrenal medulla produces performance deficits in avoidance learning trials, whereas pretraining injections of adrenaline reverse the performance deficit. Administration of adrenaline or noradrenaline following training enhances both active and passive avoidance retentions in rodents. Finally, adrenaline enhances the retention of an appetitive discrimination task in rats and mice, indicating that the modulatory effects of catecholamines are not restricted to aversive training situations. Taken together, these results suggest that catecholamines play a part in modulation of learning and memory processes. Interestingly, the animal may not even have to be conscious for this process to occur, because it has been reported that adrenaline promotes conditioning in anesthetized animals.

Depending on the strength of training, catecholamines may produce either enhancement or impairment of memory formation in a dose- and time-dependent fashion. Moderate shock produces faster learning than mild shock. Adrenaline injections plus mild shock produce learning curves that are nearly identical to those produced by moderate shock. Thus, the levels of endogenous catecholamines achieved in plasma, in response to different footshock intensities, correspond well to the magnitude of retention performance. It has been suggested that the role of catecholamines is to potentiate noxious stimuli, making them especially salient and more likely to be remembered.

Unlike glucocorticoids, catecholamines do not readily enter the brain and the effects of peripheral catecholamines on memory storage processes apparently are mediated at sites outside the blood–brain barrier. Two hypotheses have been developed for how catecholamines affect memory formation. First, activation of peripheral β-adrenergic receptors by catecholamines influences memory through changes in concentration of blood glucose, which readily penetrates the blood–brain barrier and affects neural metabolism, neural activity, and neurotransmitter synthesis. Second, during and after an emotionally stressful event release of catecholamines activates peripheral adrenergic receptors, which indirectly stimulates the amygdala via the vagus nerve and nucleus of the solitary tract. The amygdala, in turn, influences hippocampal memory storage processes. However, because catecholamine receptors are also present in the central nervous system, the effects of systemically administered catecholamines may involve direct actions on central adrenergic receptors. Synthesized primarily in the brainstem, central noradrenaline acts as a general regulator of neurotransmission through extensive projections in the brain. Noradrenaline is directly involved in the general degree of alertness and arousal, as well as in exerting central control over the endocrine and autonomic nervous systems. Evidence shows that the effects of adrenaline on memory consolidation depend on the integrity of the noradrenergic system in the amygdala, and systemic injections of adrenaline induce the release of noradrenaline within the amygdala.

Vasopressin

Vasopressin is a peptide hormone generally known for its antidiuretic and pressor functions. It is predominantly synthesized by two hypothalamic cell types, the magnocellular and parvocellular neurons. Magnocellular neurons send axons into the posterior pituitary, where vasopressin is secreted into the bloodstream to exert its hormonal actions. In contrast, parvocellular neurons send vasopressin-containing projections to both the median eminence (where the hormones are released into the portal vessel system to regulate anterior pituitary function) and the brainstem and spinal cord. Furthermore, extrahypothalamic sources of vasopressin have been identified in the stria terminalis, septum, amygdala, and locus ceruleus. These structures as well as the hippocampus are the major targets of vasopressin-containing projections.

The first report on the involvement of vasopressin in learning and memory appeared in 1965 when de Wied demonstrated that removal of the posterior pituitary prior to training in an active avoidance experiment did not alter acquisition of learning, but markedly accelerated its extinction. This deficit was reversed by the administration of an extract of a portion of the pituitary, later identified as vasopressin. Exogenously administered vasopressin also influences the acquisition, retention, and extinction of learned behavior. In active avoidance experiments in which the conditions were such that the initial tendency to avoid was low, pretraining systemic injections of vasopressin enhanced acquisition of the avoidance response. Pretraining

vasopressin injections are ineffective when the aversive stimulus is stronger, suggesting an interaction between training strength and hormonal treatment, such as we have seen for other hormones. Vasopressin and a variety of fragments and analogues all enhance retention of a shock-motivated passive avoidance response following systemic administration. Avoidance extinction is also delayed by central injections of vasopressin. Moreover, the mutant Brattleboro rat, which lacks the ability to synthesize vasopressin, displayed an impairment in passive avoidance retention and showed more rapid extinction of an active avoidance response compared with control animals. However, injections of vasopressin normalized the learning deficit.

Vasopressin does not readily pass the blood–brain barrier, although there is evidence for active transport of this molecule across the barrier. The memory-modulatory effects of vasopressin in the central nervous system are probably due to vasopressin metabolites, which are endogenous peptides that affect the central nervous system without resulting in endocrine effects on renal function and blood pressure. They are generally more potent than the parent molecule in enhancing passive avoidance retention. Lesion studies and local applications of receptor agonists and antagonists show that vasopressin may modulate retrieval processes through actions in the amygdala and hippocampus, and consolidation processes through actions in the dorsal septum, dorsal raphe and hippocampus.

However, peripheral vasopressin also enhances retention in a variety of tasks through action on receptors outside the blood–brain barrier. Systemic administration of an antagonist that blocks the effects of vasopressin on blood pressure reverses the enhancement of retention and the delay of extinction produced by vasopressin. This effect is most likely due to the peripheral autonomic effects of vasopressin, which alters the state of arousal. Taken together, parallel central and peripheral systems may exist upon which vasopressin acts to influence the strength of memory.

Opioid Peptides

Learning and memory are important aspects of adaptive behavior, which are regulated by opioid peptides in the neocortex, hippocampus, and amygdala. Opioid peptides are derived from the proteolytic cleavage of the precursor proteins preproenkephalin, preprodynorphin and proopiomelanocortin (POMC), producing enkephalins, dynorphins (A and B), and β-endorphins respectively. Two additional opioid-related peptides have been identified, named endomorphin and nociceptin (or orphanin FQ). Binding of opioid peptides to μ, κ, and δ opioid receptors or the nociceptin/orphanin FQ receptor produces a variety of behavioral and physiological responses.

Enkephalins are produced and released from neurons in the brain, and are jointly released with adrenaline from the adrenal medulla in response to stress. Beta-endorphin and ACTH are also released from the anterior pituitary in response to stress. The hormonal and neuromodulatory actions of enkephalins and β-endorphin on learning and memory have been identified in a variety of species and training conditions. The most frequently reported effects of enkephalins and β-endorphins are impairments in the acquisition and retention of learning tasks, although there are some reports of enhancement. For instance, peripheral administration of enkephalins impairs the acquisition and retention of active avoidance performance, and passive avoidance retention in rats and mice, with a U-shaped dose–response curve. Systemic injection of β-endorphin following training generally impairs retention of active and passive avoidance behavior. Thus, enkephalins and endorphins have a modulatory role in learning and memory, because the interaction is dependent on the strength of training and concentration of the drug.

There are several reports on the effects of dynorphins on memory formation. Injection of dynorphin A following training in rats does not affect inhibitory or shuttle avoidance responses, but enhances retention, while it impairs aversive and appetitive learning in chicks. Injection of dynorphins into the hippocampus impairs spatial learning in the water maze, and working memory in the radial arm maze. It is also believed that spatial memory deficits in aged rodents are due, in part, to elevated levels of dynorphin A. The newly identified opioid peptides endomorphin and nociceptin also display a modulatory role in leaning and memory. Injection of endomorphins into the hippocampus impairs spatial memory, working memory, and passive avoidance memory; μ-opioid receptor antagonists block this effect. Nociceptin impairs retention but not acquisition of passive avoidance performance, while intrahippocampal injections induce spatial learning impairments in the water-maze task. Mice containing deletions of the nociceptin gene have enhanced spatial learning ability, greater working memory performance, and enhanced synaptic plasticity such as long-term potentiation.

Evidence thus suggests that opioid peptides can enhance or inhibit memory formation. Memory modulation is dependent on the strength of training and whether the drug is administered centrally or peripherally. Following systemic injections, enkephalins, dynorphins, and β-endorphin apparently act on opioid receptors that lie outside the blood–brain barrier to exert their modulatory actions on learning and memory. It has been suggested that opioids interact with peripheral β-adrenergic systems to regulate the release of noradrenaline in the amygdala. Following central administration opioid peptides appear to act on modulatory systems in the central nervous system to influence learning and memory, which argues for the existence of parallel central and peripheral mechanisms whereby opioid peptides might influence the strength of the memory.

Sex Hormones

The function of gonadal hormones in the nervous system was once considered to be solely the regulation of sexual behavior. Studies implicating estrogen-related effects on verbal memory tests, performance in spatial learning tasks, and reduction in the incidence of Alzheimer disease in postmenopausal women have changed this view. The hypothalamus and anterior pituitary control the cyclic release of estrogen from the ovary throughout the menstrual cycle. One of the first identified nonreproductive actions of estrogen was on the cyclic regulation of synaptogenesis (or synapse formation) in neurons of the hypothalamus and hippocampus. As estrogen levels increase and decrease throughout the cycle, the potential number of modifiable synapses (or spines) used to store information changes. Furthermore, ovariectomized rats having no detectable levels of circulating estrogens have fewer hippocampal spines than rats given two injections of estrogen. Similar increases in spine density have been observed in cultured hippocampal neurons when treated with estrogen.

The structural changes induced by estrogen treatment may alter the ability of the hippocampus to process and store information. When estrogen levels are highest during proestrus in rats, synaptic plasticity such as long-term potentiation (LTP) is enhanced. Estrogen enhances LTP in the CA1 region of the hippocampus but impairs LTP in the dentate gyrus of estrogen-treated ovariectomized rats. In humans, when estrogen levels decline during menopause, there is a decrease in cognitive ability and a greater risk of neuronal cell damage. There have been some studies, although controversial, demonstrating that estrogen replacement therapy may provide some protection against the development of Alzheimer disease, and may improve cognitive function.

The effects of estrogen on learning and memory are varied and somewhat contradictory, with findings indicating enhancement, impairment or no change, depending on the dose of estrogen used. Ovariectomized rats treated with low doses of estrogen have been reported to improve acquisition and choice accuracy in the radial arm maze, while high doses of estrogen impair working memory performance. Prolonged estrogen treatment is reported to improve working memory performance in a radial arm maze, but this does not occur following brief estrogen treatment. Aging female rats with low levels of estrogen during 'estropause' display impaired reference memory in the spatial water-maze task, but improved working memory in the radial arm maze. In women, estrogen treatment impairs performance of spatial tasks, while enhancing verbal memory performance.

Although the mechanism of action for estrogen's effects on learning and memory has yet to be determined, there are some promising models. Estrogens may bind cell surface receptors to rapidly alter neuronal excitability through ion channels and second-messenger systems, and may directly alter gene expression. It is also believed that estrogen interacts with and maintains the basal forebrain cholinergic system by regulating the activity of key enzymes including choline acetyltransferase. Estrogens are therefore considered to have multiple effects on brain structures and behaviors, including learning and memory.

CONCLUSION

It is widely believed that acquisition, storage, and retrieval of information involve the functional modification of synaptic connections between neurons. Hormones have the ability to modulate learning processes by either increasing or decreasing the strength of the memory trace. This can be achieved directly, by altering the structure of neurons, generating greater or fewer numbers of synapses and thereby increasing or decreasing the amount of information that can be stored and affecting the cellular process that results in stronger synapses; or it can be achieved indirectly, by activating the autonomic nervous system and increasing arousal and energy metabolism and hence the efficiency of brain function. The modulatory role of hormones in memory is important because

hormones inform the organism of events that ultimately support survival.

Hunger, Meals, and Obesity

Introductory article

Jan H Strubbe, Department of Animal Physiology, University of Groningen, Haren, Netherlands

CONTENTS

Hunger, meals, and obesity are strongly related topics discussed in this article. Obesity is a severe state of being overweight, which is increasing rapidly in the Western World and is a major health problem. Obesity is often associated with an increased desire for food (hunger) which will be taken as larger bouts of feeding activity (meals). Therfore, to get more insight in the causes of obesity, knowledge of the physiological background of feeding behavior is extremely important. This will be discussed in this article.

INTRODUCTION

In humans and animals, food intake depends on several internal and external variables. They can adapt to changes in the caloric content of the diet so that, over a wide range of content, intake matches energy expenditure and body weight remains essentially unchanged. On a diet with a constant caloric content, an increase in energy expenditure results in increased food intake. One example of this phenomenon is the hyperphagia (overeating) that results from a lower ambient temperature, where the animal has to compensate for its heat loss. In this case, the energy content of the body remains at a constant level, since the subject eats the same amount of calories as it expends. This is one of the arguments for the energy content of the body and therefore the adipose (fat-storing) tissue mass being regulated within narrow limits. Another argument derives from the phenomenon whereby after temporary starvation or overfeeding the disturbed body weight returns towards its normal level through compensatory adjustment of food intake. This indicates that the energy content of the body is subject to homeostatic control (maintenance of internal equilibrium) by the regulation of food intake.

In humans, feeding occurs during bouts of energy intake called meals. Meals are regarded as bouts of behavior that, although necessary for supplying nutrients to the body, result in perturbations of homeostatic controlled parameters. The main strategy is to change average meal size in order to prevent homeostatic disturbances in the body. If conditions dictate that more food be consumed than can be accommodated by means of a small number of large meals, more meals will be eaten. The size of individual meals is the focus of intense research as scientists investigate compounds known as satiety factors that regulate the termination of meals and therefore require animals to consume smaller or larger meals.

This article will discuss the effects of meals on homeostasis, and will propose that the initiation and termination of meals is a well-anticipated and orchestrated behavior intended to maximize the passage of energy into the body, while minimizing homeostatic disruption to the body. Disturbances of this regulation lead to disorders in food intake, such as hyperphagia, and consequently to the development of obesity.

EFFECTS OF MEALS ON HOMEOSTASIS

The meal patterns of humans and animals are strongly related to the light–dark cycle. For example, rats eat 80% of their daily food intake during the dark phase. This means that during each day the energy content of the rat varies considerably, as is also indicated by the alteration in net lipogenesis (fat formation) during the dark phase and net lipolysis (fat reduction) during the light phase. Body weight is constant only over a longer timescale. This rhythmic control of food

intake is governed by oscillators located in the suprachiasmatic nucleus (SCN) in the hypothalamus (a region of the forebrain that exerts profound regulatory influences over physiological and behavioral processes which are essential for survival). These so-called *circadian pacemakers* are synchronized by the light–dark change, and they largely determine the temporal organization of food intake and interact with the short-term regulation of energy intake. A lesion in the SCN will induce arrhythmicity of feeding behavior (i.e. meals are spread equally over the daily cycle).

These rhythmic factors are modulating and not regulatory factors in the sense that they are involved in the regulation of body energy content. Rather, they constitute one of the constraints within which the regulation of food energy intake must operate. There are many constraints of this type, ranging from learned habits in feeding behavior (e.g. adjustment of meal size to expectations of caloric content of the diet, based on gustatory experience), to inhibition of feeding by the demands of other urgent behaviors such as sleeping or social confrontations.

Thus although many non-regulatory factors determine the switching of meals in the 'on' or 'off' direction, there is also a wide variety of regulatory negative feedbacks, or satiety signals, which act in the short term as well as in the long term, reporting to the central nervous system about the current energy content of the body. These signals are released by different compartments where (1) food is ingested (oropharyngeal regions), (2) nutrients are digested and absorbed (stomach and intestines), and (3) fuels are stored (liver and adipose tissues).

The afferent (inward) pathways to the central nervous system may be either nervous or hormonal. In this respect the gut hormones cholecystokinin (CCK), bombesin, and glucagon-like peptide 1 (GLP-1) may play a major role as short-term satiety factors. There is evidence that CCK can act on the afferent pathways of the vagus nerve (which runs from the brain through the thorax to the abdomen), since subdiaphragmatic cutting of the nerve appears to abolish the suppressive effects of CCK on food intake (Figure 1). When the area of entrance of the vagus nerve in the CNS, namely the nucleus tractus solitarius (NTS), is damaged, similar effects are obtained. In conclusion, since CCK-containing neurons and receptors are found in the whole chain from the intestine via the vagus to the NTS, and from there via the parabrachial nucleus to the ventromedial hypothalamus (VMH), it is possible that CCK influences feeding motivation at all of these levels. Since lesioning of the VMH results in strong

hyperphagia and finally in obesity, it has been suggested that this area is the main target for feedback control of satiety signals. However, lesioning of the lateral hypothalamus (LH) caused aphagia (cessation of eating) and a decrease in body weight. On the basis of these findings, the LH is regarded as a feeding or hunger center, whereas the VMH is more likely to be a satiety center.

Among the absorbed fuels, glucose might play a prominent role together with insulin, according to the 'glucostatic theory'. The metabolism of these fuels induces heat production, and the resulting increased body temperature could inhibit feeding activities. Meals are terminated at very similar

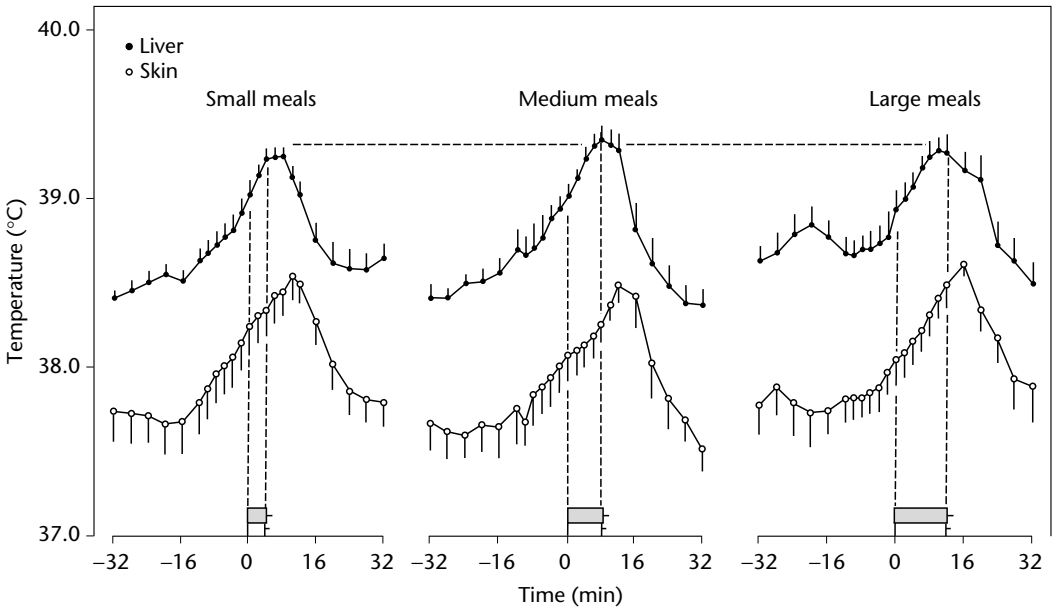

Figure 2. Hepatic and skin temperatures for separate groups of rats consuming small, medium, and large meals. From De Vries J, Strubbe JH, Wildering WC, Gorter J and Prins AJA (1993) Patterns of body temperature during feeding in rats under different ambient temperatures. *Physiology and Behavior* **53**: 229–235.

relatively high liver temperatures, which might provide a signal to stop all feeding activities (Figure 2). This concept has been formulated as the 'thermostatic theory'. The reserve tissues may also inform the central nervous system about their content. Signals may arise in association with the size of adipose tissue ('lipostatic theory'). Among these signals, the hormones insulin and leptin may be important determinants of the regulation of feeding behavior by controlling the size of the adipose tisssue mass. This control holds for the long-term regulation of food intake, setting the motivational background level for feeding behavior in the brain. Other signals may be involved in reporting the size of the glycogen reserves, and would therefore contribute more to the short-term regulation of food intake.

In addition to the negative satiety signals, positive feedbacks from the oropharyngeal regions can also be distinguished. Once a meal has been started, these feedback signals keep the feeding motivation at a relatively high level. Thus they stabilize feeding in the sense that they help to postpone meal termination. These 'positive and negative signals' consist of fluctuating physiological factors (e.g. hormones, blood glucose level, body temperature) which are kept within physiological limits by the animal's decisions to start, continue or stop feeding activities so as to prevent adverse perturbations of homeostasis. Moreover, anticipatory and conditioned processes will help to minimize the perturbations of homeostasis.

EFFECTS OF CONDITIONING ON PREMEAL PHYSIOLOGICAL CHANGES AND HUNGER

The body responds to meals so as to minimize both the magnitude and the duration of homeostatic perturbation. One way in which it does this is by anticipating meals and initiating homeostasis-preserving responses as early in the food-intake process as possible. This meal-anticipating process can also be used whenever the environment dictates that an animal has to eat relatively large meals in order to obtain adequate nutrition. However, the animal does not change its meal pattern simultaneously with the change in environment. Rather, the changes in meal size occur over a period of several days as the animal learns what to expect and what the physiological consequences of a particular meal may be. When rats must eat all of their daily food within a short window of time, there is a maximum meal size possible, and if more food per meal must be eaten, the rat sacrifices weight instead of consuming that much food all at one time. Thus the disruption of other related systems that is caused by increasing the size of a meal may elicit corrective responses (in this case, the

premature cessation of meals) in order to protect other perturbed systems.

A certain flexibility is built into the system so that when large meals must be consumed for survival, and when the environment is completely predictable, anticipatory responses enable a further increase in meal size. Adaptations occur as increases in the autonomic responses to gastrointestinal processing of food and of insulin secretion. Conditioned increases in insulin levels were seen only when rats expected to eat a very large meal (Figure 3). Since this conditioned insulin response was abolished by pharmacological treatment with the muscarinic receptor-antagonist atropin, it can be concluded that the response is caused by the parasympathetic nervous system. These conditioned insulin responses may therefore prevent wider fluctuations in blood glucose levels when the meal is eaten.

When animals expect to eat a large meal, it is also advantageous to keep body temperature low in order to allow a longer period of temperature increase. This indeed occurs in the voluntarily taken meals shown in Figure 2, where the preprandial increases in body temperature are lower when animals expect to eat a larger meal. The thermostatic theory predicts that rats can eat for longer before they reach a 'setpoint' temperature which may terminate the meal. Therefore it is possible that lower body temperatures, as often observed in obese rodents, enable them to eat larger meals.

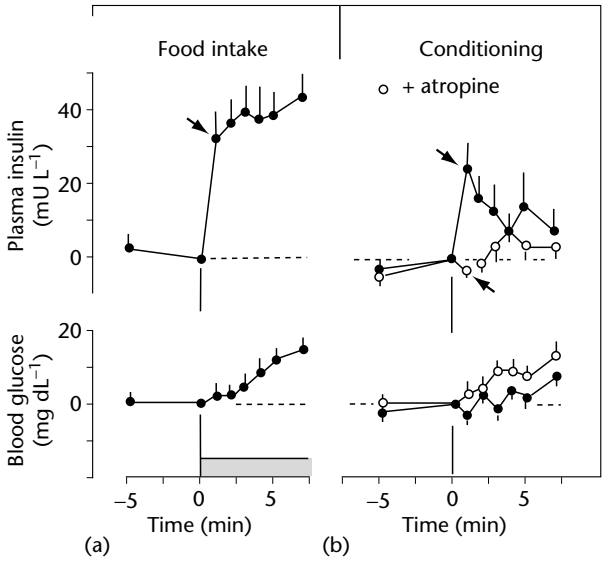

Figure 3. Mean plasma insulin and blood glucose responses (a) during feeding and (b) after opening of doors in front of an empty food hopper, in rats habituated to a feeding schedule of 2 meals per day. In the latter condition, premedication with atropine was also given (open circles). From Strubbe JH (1992) Parasympathetic involvement in rapid meal-associated conditioned insulin secretion in the rat. *American Journal of Physiology* **263**: R615–R618.

INCREASING PREVALENCE OF AND FACTORS CONTRIBUTING TO OBESITY

The prevalence of obesity and overweight type 2 diabetes mellitus is increasing rapidly in the Western world. However, during the last few years major increases in the incidence of overweight have also been seen in other parts of the world. Although obesity in humans can be regarded as a risk factor for many serious diseases, including coronary heart disease and maturity-onset (type 2) diabetes mellitus, the occurrence of gallstones, arthritic problems and varicoses, it is not a disease in its own right except in very severe cases. Even the presence of filled adipose tissues can be of survival value to overcome periods of famine. It is therefore possible that this adaptation has developed more in some regions of the world than in others (e.g. obesity observed in Pima Indians). In a similar way to the situation in hibernation where, for instance, marmots become very fat prior to wintertime, humans in ancient times might have filled their adipose tissues in times of plenty and depleted their stores in times of famine. Under the force of selection pressures this may have led to an adapted 'thrifty' genotype which is able to survive unfavorable external conditions such as fluctuations in the supply of food due to dryness or low ambient temperatures.

Although the range over which body fat stores are filled under normal conditions may vary widely between individuals, each individual or group of individuals has its own genetically determined setpoint of adipose tissue size which is dependent on age and external conditions. There is evidence that the body mass index (BMI) (i.e. body weight in kilograms divided by the square of the height in meters) of children correlates strongly with those of their biological parents and not with those of their adoptive parents. Moreover, if both parents are obese, there is a greater likelihood that their children will also become obese.

These phenomena provide evidence for a genetic background of human obesity. However, we should also take into account the behavioral component, which again is very similar between

parents and children, as the behavior and genetic background may act in the same direction.

NEW PERSPECTIVES ON HUNGER, MEALS, AND OBESITY

The mechanism of the setpoint control (i.e. the regulation of food intake) has been the subject of recent research. Genetically determined disturbances in this regulation may lead to an imbalance between intake and subsequent storage and expenditure. It is the goal of obesity research to determine the nature of the genetic background of obesity and the point of action on behavior and physiology. The many genetic obese animal models may help to establish the origin of such defects, although it is very difficult to distinguish between primary and secondary effects.

It is known that in many genetically obese rodents, such as the ob/ob mouse, the rate of thermogenesis (heat production) is decreased. The thermogenic effect of food in obese humans is also often reduced. It has been suggested that they eat more in order to increase heat levels in the body and to prevent heat loss by means of insulation with extra adipose tissue. Thus a lower preprandial temperature or decreased prandial slope may be one of the major causes of eating larger meals, which may result in obesity. Indeed, obese rodents such as the obese Zucker rat eat larger and less frequent meals. Therefore the deviating factor in food-intake regulation of obesity may occur not in the initiation of meals but in their termination. In fact the strategy is quite similar to those in lactating and diabetic rats, and in rats kept at low ambient temperatures, although there may be different mechanisms underlying the control.

Although decreased thermogenesis may be one of the final physiological processes that regulates the behavior of obese rodents, there may be several physiological processes involved in this defect, including decreased feedback control in the short term (CCK and GLP-1) or in the long term (insulin and leptin). In recent years the discovery of leptin, a hormone that is secreted by adipocytes and which is thought to act as a signal for fat stores, has provided new insights into the interrelationships between obesity and energy regulation. Studies have shown that mice strains which lack either the gene that is responsible for the production of leptin (e.g. ob/ob mice) or its receptor (e.g. db/db/mice) become obese, while administration of recombinant leptin results in direct weight loss in the ob/ob mice. However, the ineffectiveness of leptin in humans suggests that there is marked resistance, in contrast to the situation in non-obese rodents. The targets of leptin include pro-opiomelanocortin (POMC) neurons in the arcuate nucleus which is located close to the VMH. Leptin receptors are located on the POMC neurons that synthesize melanocortins. Studies in humans have shown that polymorphisms of the melanocortin (MC-4) receptor may be associated with obesity. Future research on agonists of this MC-4 receptor will reveal the many physiological processes that are governed by this receptor, including the stimulation of thermogenesis, which may be a final causal factor allowing humans and animals to reduce their food intake. Thus the development of selective agonists will be a useful approach in the treatment of obesity.

CONCLUSION

In humans and animals, body weight is often maintained within narrow limits on a variety of diets and under different external conditions by homeostatic control involving the regulation of food intake. The tendency to display feeding behavior (hunger) or to stop meals (satiety) at any particular point in time will depend on (1) constraints such as day–night rhythms, and all kinds of learned habits and behavioral interactions, (2) the current level of energy expenditure, (3) possible shifts in the desired level of body energy content, and (4) the combined result of all of the above-mentioned satiety signals pooled in the central nervous system. These 'positive and negative signals' consist of fluctuating physiological factors (e.g. hormones, blood glucose levels, body temperature) which are kept within physiological limits by the animal's decisions to start, continue, or stop feeding activities in order to prevent adverse perturbations of homeostasis of body weight and physiological variables. Moreover, anticipatory and conditioned processes will help to minimize such perturbations of homeostasis.

Huntington Disease

Introductory article

James F Gusella, Massachusetts General Hospital/Harvard Medical School, Charlestown, Massachusetts, USA

CONTENTS

Huntington disease (HD) is a neurodegenerative disorder that involves the loss of neurons in the basal ganglia (particularly the caudate nucleus and the putamen) and in the cerebral cortex. It is characterized by a peculiar writhing movement disturbance, but also has intellectual and psychiatric manifestations. All cases of HD are genetically caused, resulting from an expanded CAG trinucleotide tract that encodes an elongated stretch of consecutive glutamine residues in huntingtin, a large protein of unknown function.

SYMPTOMS OF HUNTINGTON DISEASE

Huntington disease (HD) is named after George Huntington, a nineteenth-century family physician on Long Island, New York, who first described the symptoms of the disorder and recognized its inherited nature. The characteristic feature of HD is a peculiar motor disturbance that begins subtly with manifestations such as clumsiness, slight adventitious movements, awkward gait or lack of smooth eye pursuit. However, the movement disorder inexorably progresses to blatant chorea that consumes all parts of the body and is only absent during sleep. Indeed, HD was originally termed Huntington chorea because of the distinctiveness and exaggerated nature of its hallmark symptom. However, a century later the name was changed to HD in recognition of the presence of other disease manifestations, including intellectual decline and psychiatric disturbances. Psychiatric symptoms, which include chronic depression, impulsive behavior, personality changes and occasionally frank psychosis, are variably present and may in some cases precede the motor disturbance by many years. However, age at onset of HD is usually judged on the basis of the first detected neurological symptoms, which are more reliably detected.

The age at neurological onset of HD varies from the juvenile years to late in life, but most cases manifest in middle age, usually after more than half a lifetime without any detectable abnormality. As the disorder progresses, the HD patient suffers increasing lack of motor control in combination with decreasing intellectual capacity, until the capacity for independent functioning and eventually communication is lost. The HD patient requires constant care and protection from self-injury. Late in the course of the disorder, which extends for 10–20 years after onset, the patient will typically have exhibited dramatic weight loss and the chorea may have given way to rigidity, particularly in juvenile-onset cases. Death then ensues, often due to heart disease resulting from the constant motions and dramatic weight loss, or to aspiration pneumonia, resulting from difficulties in taking food.

BRAIN DAMAGE ASSOCIATED WITH HUNTINGTON DISEASE

Post-mortem examination of brains from HD patients has revealed a characteristic pattern of neuronal loss that produces the disorder's clinical symptoms. The region that is affected earliest and most severely is the caudate nucleus, whose architecture is eventually completely destroyed by the effects of the mutation. Neuronal cell loss shows a gradient of progression across the caudate that eventually encompasses the adjacent putamen. Medium-sized spiny neurons that use the neurotransmitter γ-aminobutyric acid (GABA) and send axons out of the caudate are most vulnerable to the disease, while other neuronal types are relatively spared. As the GABA neurons are lost, the inhibition that they would normally cause in downstream target neurons is released, presumably leading to the characteristic uncontrolled movements. In late-stage HD and in juvenile-onset

cases, the patient may display rigidity rather than uncontrolled movements, as a result of the spread of neuropathology beyond the caudate to other regions. In late-stage HD brains, the caudate and putamen are completely destroyed, and it is evident that neuronal cell loss also affects other regions, particularly layers III, V and VI of the cerebral cortex. Overall brain weight may be reduced by 35% or more, but the specific neuronal populations that contribute to all of this loss have not been clearly delineated.

GENETIC BASIS OF HUNTINGTON DISEASE

HD has been detected in all races, but is most frequent in Caucasians, with a prevalence of *c*. 1 in 10 000. The disorder is due to a dominant genetic defect in a gene on chromosome 4 that has a segment of consecutive CAG codons in the 5′ coding sequence. On normal chromosomes, the CAG trinucleotide repeat is polymorphic with alleles consisting of 10–34 CAGs that are inherited in a stable mendelian fashion. The trinucleotide stretch is expanded to more than 35 CAGs on HD chromosomes, and shows a high mutation rate through meiotic transmission. Most HD chromosomes contain 40–50 CAG units, but they may have as many as 250 units. When transmitted to the succeeding generation, most of them undergo modest size changes of a few CAGs, with a bias towards length increases. Occasionally, transmissions from a male parent involve much larger length increases, up to a doubling or more in the number of CAG units, due to particular instability during spermatogenesis.

The CAG expansion mutation is the only aberration that has been found in patients with the disorder, and its length is the major factor determining age at onset of neurological symptoms. Most HD patients display midlife onset due to 40–50 CAGs. Individuals with 35–39 CAGs typically show HD onset late in life or not at all. By contrast, those with the longest CAG arrays show juvenile onset. After considering the effect of CAG tract length, the remaining variation in onset age may be due to other genetic, environmental or stochastic factors. Only one genetic modifier of relatively modest effect, namely a subunit of the glutamate receptor, has been identified to date. Interestingly, individuals with two doses of the HD defect and no normal HD gene copy do not show significantly accelerated onset. It is also noteworthy that progression to death, which typically occurs around 15 years after onset, does not show any correlation with CAG tract length. This suggests that once the mechanism of pathogenesis has been fully triggered, factors other than the genetic defect become paramount.

TEST FOR THE HUNTINGTON GENE

Prior to the discovery of a linked genetic marker for HD in 1983, there was no reliable method for determining whether asymptomatic 'at-risk' individuals had inherited the disease gene. As a result of mapping HD to chromosome 4, a linkage test became available which was applicable to prenatal and predictive testing in families with sufficient living members to identify the disease chromosome reliably via the alleles at linked polymorphic DNA markers. With the cloning of the HD gene and the discovery of the nature of the mutation, a direct DNA test based on polymerase chain reaction (PCR) amplification across the CAG repeat became possible. The direct test does not require DNA from other family members, and it is 100% diagnostic of HD. It can be used for prenatal determinations, predictive testing in 'at-risk' individuals, and for HD confirmation or differential diagnosis in those with extant movement disorders. The decision to undergo predictive testing is an intensely personal one that cannot be predicted on the basis of such factors as education, socioeconomic status or religious beliefs. For some individuals, the 'need to know' derives from a strong desire to eliminate the uncertainty of being 'at risk', for peace of mind, life planning or reproductive decisions. However, as there is currently no treatment for preventing onset or slowing the progression of HD, many 'at-risk' individuals choose not to undergo predictive testing, as they have learned to cope with the uncertainty. For some, this decision is made after the potential consequences of predictive testing have been explained through intensive genetic counseling. The provision of such counseling before proceeding with actual testing has, since the advent of the linkage test, been considered essential for a disorder such as HD, which has inherent psychiatric effects and a suicide rate far above normal.

EFFORTS TO PREVENT HUNTINGTON DISEASE

Prenatal testing clearly provides one means of reducing the impact of the HD defect in future generations. However, for individuals who are born with the HD defect, any hope of developing a treatment is focused on understanding the mechanism of pathogenesis and thereby developing a rationale

for therapy. Current evidence favors the HD mutation acting through the polyglutamine tract of huntingtin, via a 'gain of function' rather than through a simple loss of the protein's inherent activity. Notably, at least seven other neurodegenerative disorders, spinal and bulbar muscular atrophy, dentatorubropallidoluysian atrophy and spinocerebellar ataxias 1, 2, 3, 6 and 7, are all due to similar CAG expansion mutations extending the length of polyglutamine tracts in various regions of other proteins. This suggests that a similar 'gain of function' in each of these proteins results in neuronal toxicity, but the different pattern of neuronal loss in each disorder indicates that the specificity of neuronal toxicity is conferred by the function, structure or localization of the particular protein that is hosting the polyglutamine segment.

Huntingtin's primary structure and pattern of expression do not provide any direct clues about the specificity of neuronal loss in HD. Huntingtin shows no significant similarity to other proteins, and its normal function is still unknown, although roles in a wide range of cellular activities, including transcription, RNA splicing, cytoskeletal function, intracellular signaling and protein trafficking have been suggested. The protein is present in many different cell types (neuronal and non-neuronal), and is essential for normal development. However, the normal polyglutamine tract varies widely in length in other species, and is entirely absent from fruitfly huntingtin, which suggests that it is not necessary for huntingtin's normal function. The expanded glutamine tract probably alters the conformation or folding of the mutant huntingtin protein, conferring a new physical property that acts in a dominant manner to trigger pathogenesis.

The relationship between the genotype (number of CAGs) and phenotype (expression of HD) of HD patients has provided a series of criteria for studying the mechanism that triggers pathogenesis. These suggest that the polyglutamine tract must exceed a critical threshold length in order to trigger the disorder within a normal lifespan. Once the threshold (> 35 CAGs in humans) is exceeded, the mechanism is progressive with increasing numbers of consecutive CAGs, is dominant over the normal HD gene copy, and is more dependent on polyglutamine length than on the presence of two copies of the mutant gene. One property that matches these criteria is the capacity of a small amino-terminal fragment of huntingtin to self-aggregate in a test tube, converting from a soluble to an insoluble form. Production of similar fragments inside cells promotes the formation of various soluble and insoluble cellular inclusions, which in some cases are similar to inclusions observed in surviving neurons in post-mortem HD brain. It is not clear whether the intracellular inclusions in HD brain are crucial mediators of pathogenesis, or whether they are secondary consequences of huntingtin being degraded in cells that have been damaged by the effects of the mutation.

Although the simplicity of the former possibility is attractive, the lack of specific and consistent cell death as a result of inclusion formation in cell-culture and mouse models casts doubt on it. Instead, the novel conformational property of mutant huntingtin may actually trigger the disorder in patients by acting within the full-length protein, where its effect may be to alter protein–protein interactions rather than to produce insoluble inclusions. This alternative possibility has been supported by studies in 'knock-in' mice, in which the HD mutation has been introduced into the mouse equivalent gene, resulting in faithful expression of the full-length mutant huntingtin protein. These mice display altered behavior of the full-length protein many months before the formation of intraneuronal inclusions. The alterations in mutant huntingtin are seen specifically in striatal neurons and fulfill the genetic criteria outlined above, perhaps indicating an early event in the pathogenetic pathway.

Whether the trigger for pathogenesis acts at the level of full-length huntingtin or via a truncated fragment, assays using amino-terminal fragments still offer an effective method for monitoring the novel conformational property conferred by the HD mutation. Therefore they may be useful for identifying small molecules that interfere with or promote this process. Screening of compound libraries has already identified a few such compounds. It is expected that the continued pursuit of this strategy, followed by testing of the compounds in cell-culture, lower-organism and mouse models, offers the best current hope for identifying a drug to prevent the onset of HD. Such a therapy might also be expected to be effective in each of the other polyglutamine disorders, since it would be aimed at the fundamental pathogenetic property produced by the CAG expansion mutation.

An alternative route to a specific therapy for HD would be to delineate further the pathway of pathogenesis, which presumably consists of an initial impact of the mutant protein in susceptible neurons, followed by a cascade of changes that eventually lead to cell death. It has been postulated that the first effect of the expanded glutamine tract is to produce an altered protein–protein interaction that is particularly deleterious to vulnerable neurons.

Huntingtin has been shown to interact with more than 30 other proteins, but none of these has yet been established as a partner that participates in a mechanism that initiates pathogenesis. Identification of such a partner would provide an additional target for therapeutic drug screens. Once the pathogenetic pathway is triggered, each of the changes that eventually lead to cell death might also provide a later target for development of neuroprotective therapeutics. Various potential targets, such as the processes of energy metabolism, caspase proteases involved in cleaving huntingtin, and other proteins that participate in apoptotic cell death pathways have been suggested and are currently being tested in model systems. However, no intervention has yet been shown to be effective in HD patients. Indeed, at neurological onset an HD patient may already have lost 30–40% of vulnerable caudate neurons, and many of the remainder may be dysfunctional. Efforts to rescue the latter might be expected at best to halt the progression of disease symptoms. Finally, the decimation of the striatum in severely affected individuals suggests that neuronal implants may be the only available possibility for treatment in these cases. This approach is being attempted, but has not yet shown unequivocal success.

CONCLUSION

HD differs from more common neurodegenerative disorders in having an exclusively genetic cause. Delineation of the precise genetic alteration that causes specific neurodegeneration in HD has provided the unequivocal starting point and initial clues to the subsequent steps in the process of pathogenesis. Continued analysis of this pathway using genetic and biochemical approaches to define potential targets for therapeutic intervention offers the best hope for complementing effective prenatal and presymptomatic diagnosis with effective treatments to prevent the onset and progression of this devastating disorder.

Hypothalamus

Introductory article

Charles W Malsbury, Memorial University of Newfoundland, St John's, Newfoundland, Canada

CONTENTS

The hypothalamus is a collection of cell groups (nuclei) at the base of the brain that influences nearly every aspect of physiology and behavior. Hypothalamic neurons participate in neural networks that integrate endocrine, autonomic and behavioral responses that must occur together for an animal to interact successfully with its environment.

INTRODUCTION

The hypothalamus is an aggregation of discrete cell groups, or nuclei, that form the ventral part of the forebrain. This small part of the brain is critically important for the homeostatic regulation of most aspects of physiology, including the regulation of the endocrine system. Hypothalamic neurons also participate in neural networks that regulate eating and drinking, and defensive and reproductive behaviors. Thus the functions in which the hypothalamus participates are vital for both individual and species survival.

A central idea is that the hypothalamus has an integrative role in regulating physiology and behavior. It participates in the coordination of three types of responses – endocrine, autonomic and behavioral – that must occur together for an animal to interact successfully with its environment. For example, when an animal confronts a threat, the hypothalamus is required for the coordinated release of stress hormones, activation of the sympathetic nervous system, and activation of the appropriate behavior (fight or flight).

ANATOMY

The hypothalamus extends from the region of the optic chiasm to the posterior border of the mamillary bodies at the base of the brain (Figure 1). The thalamus forms its dorsal boundary. The hypothalamus has a medial division that contains discrete cell groups (nuclei) and a lateral division, the lateral hypothalamus (LH), in which the neurons are distributed diffusely.

Because of the variety of responses in which it participates, the hypothalamus must communicate with many regions of the brain and with the pituitary gland. Some of these connections carry sensory information to the hypothalamus. Although visual and auditory stimuli can influence hypothalamic activity, the hypothalamus is not involved in visual or auditory perception. For example, the visual input to the hypothalamus conveys information about light and dark, not visual patterns. A direct projection from the retina allows the light/dark cycle to 'set' the 24 h (circadian) clock mechanism within the suprachiasmatic nucleus. Taste, and sensory information from visceral organs such as the stomach, liver and heart, are also relayed to the medial and lateral hypothalamus directly from neurons within the posterior brainstem (medulla). Olfactory stimuli are extremely important in guiding the social behavior of rodents. Olfactory information reaches the hypothalamus after it is processed in limbic system structures such as the amygdala. The hypothalamus has extensive reciprocal connections with the limbic system. The limbic system can be loosely defined as the network of interconnected forebrain structures that is particularly important for emotion. It includes the hippocampus (important for memory) and the amygdala, itself a collection of cell groups with different functions. The hypothalamus is often included within definitions of the limbic system.

Some of the pathways that carry connections to and from the hypothalamus are organized into discrete and conspicuous bundles like the fornix and the stria terminalis, while others are diffuse and difficult to trace. Important fibre systems of the latter type include the medial forebrain bundle and the ventral amygdalofugal pathway. Despite the word 'medial', the medial forebrain

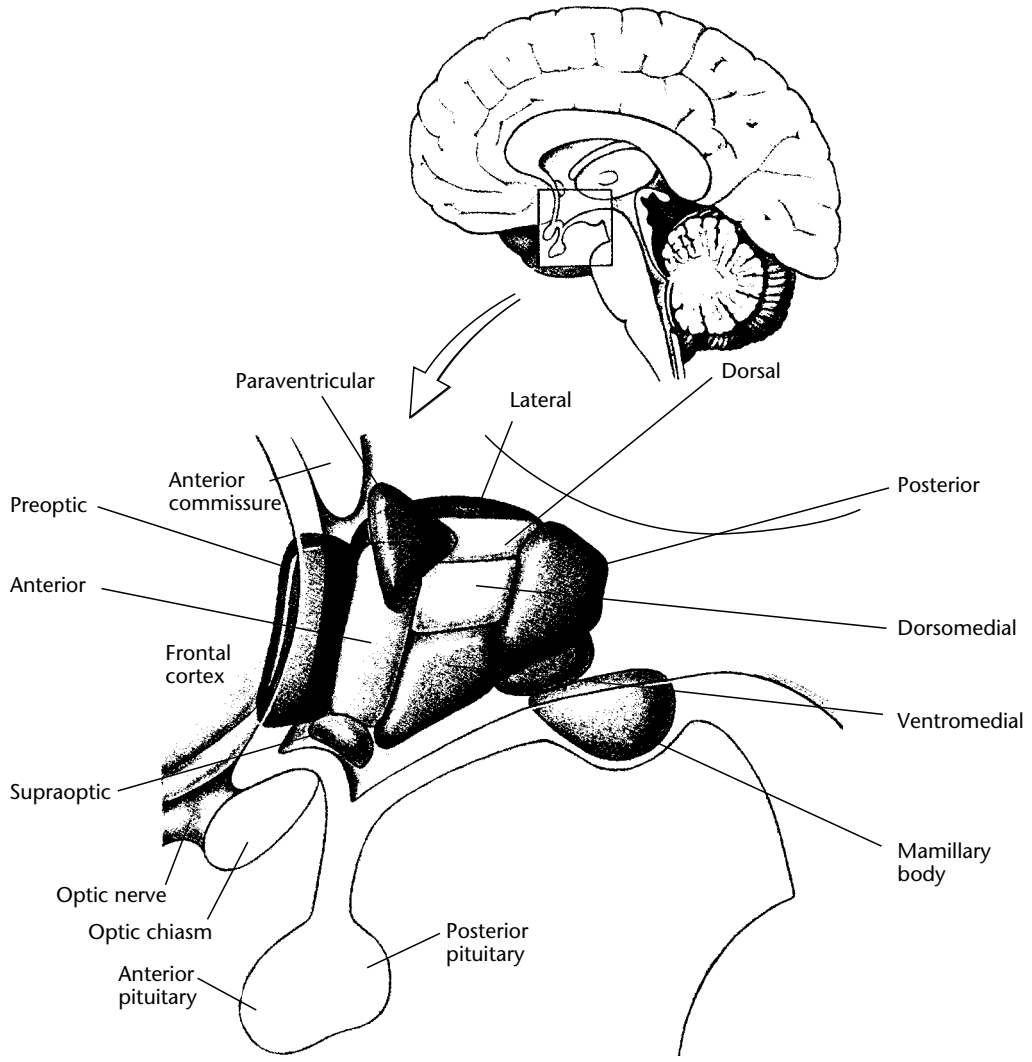

Figure 1. The nuclei of the human hypothalamus are shown in midline views of the right hemisphere.

bundle (MFB) is located within the LH, and despite the word 'bundle', these axons are not arranged into a discrete bundle, but are spread out over the whole lateral hypothalamic area. The MFB contains numerous ascending and descending components. Many of these form synapses with neuronal cell bodies within the LH and also send branches into the medial hypothalamus. However, some MFB axons only pass through the hypothalamus. An important example is the nigrostriatal pathway: this ascending pathway originates in the substantia nigra of the ventral midbrain and supplies the monoamine, dopamine, to the basal ganglia of the forebrain. Degeneration of the nigrostriatal pathway is the cause of the movement disorder known as Parkinson disease. Axons from other monoamine cell groups, i.e. those producing serotonin and noradrenaline (norepinephrine), ascend from the posterior brainstem, enter the MFB and terminate within the hypothalamus. The MFB also carries certain outputs of the medial hypothalamus. For example, neurons within the medial preoptic area are critically important for male sex behavior. The axonal projections of the preoptic area that facilitate sexual arousal descend to the midbrain within the MFB.

The amygdala is a major source of input to the medial hypothalamus. Input from this part of the temporal lobe arrives via two pathways: the stria terminalis, and the ventral amygdalofugal pathway. These provide a route for cortical and limbic influences on hypothalamic activity. This is one way in which a variety of sensory information, for example olfactory stimuli, reaches the hypothalamus. It is

also through these pathways from the amygdala that psychological stress and emotions such as fear and anger influence hypothalamic activity.

RELATION OF THE HYPOTHALAMUS TO THE ENDOCRINE SYSTEM

The hypothalamus is the final common pathway in the neural control of the endocrine system. The glands that secrete hormones into the bloodstream (e.g. the gonads, thyroid and adrenal glands) are each ultimately controlled by a particular set of hypothalamic neurons. These neurons are different from others in one respect. When excited, instead of releasing neurotransmitters that act at synapses, they release hormones near small blood vessels at the ventral surface of the hypothalamus (the median eminence). These capillary loops within the median eminence carry hypothalamic hormones down the pituitary stalk and into the anterior pituitary gland. The neurons that produce hypothalamic hormones are distributed throughout the medial hypothalamus, more or less concentrated within particular nuclei (Figure 2).

The hypothalamus participates in homeostatic regulation of hormone secretion through negative feedback. For example, the hypothalamus controls the blood level of the adrenal steroid hormone, cortisol, by secreting adrenocorticotrophic hormone (corticotrophin) releasing hormone (CRH). When one experiences stress or fear, input from the limbic system activates the hypothalamic neurons that release CRH, which in turn stimulates cells in the anterior pituitary to release adrenocorticotrophic hormone (ACTH). The release of ACTH stimulates the adrenal cortex to secrete cortisol into the bloodstream. Cortisol feeds back onto both the hypothalamus (neurons of the paraventricular nucleus which produce CRH) and the anterior pituitary (ACTH-producing cells) to limit

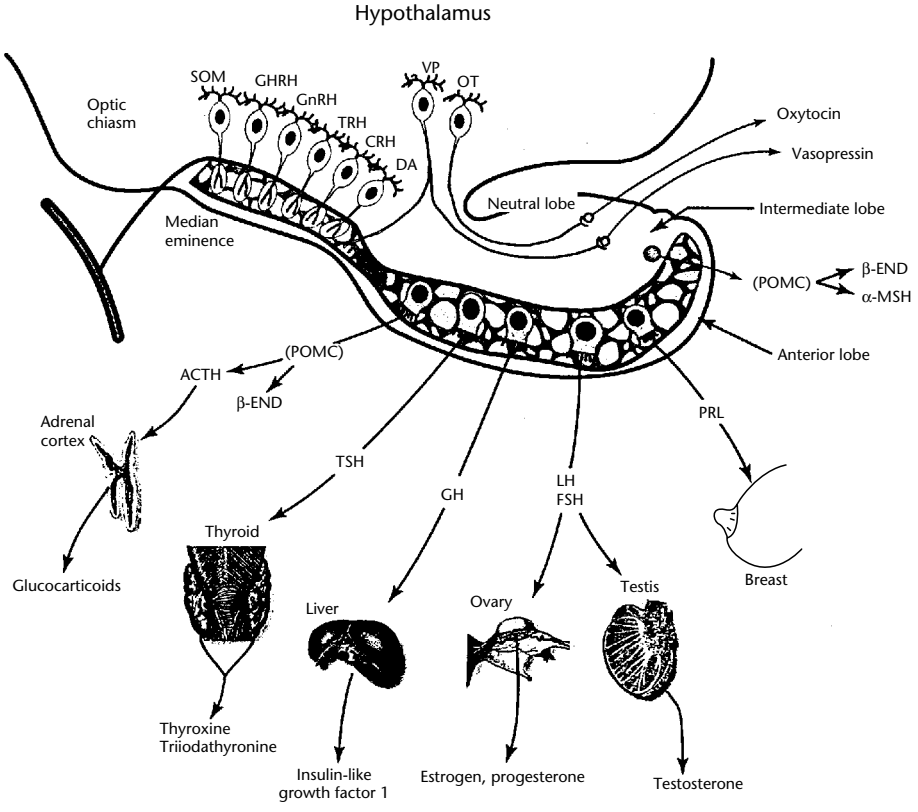

Figure 2. Organization of the hypothalamic control of the endocrine system. Hypothalamic release and release-inhibiting hormones: CRH, corticotropin (ACTH) releasing hormone; DA, dopamine, the prolactin release-inhibiting hormone; GnRH, gonadotropin releasing hormone; GHRH, growth hormone releasing hormone; TRH, thyrotropin releasing hormone; SOM, somatostatin (growth hormone release-inhibiting hormone). Anterior pituitary hormones: ACTH, adrenocorticotropic hormone; β-END, beta-endorphin; FSH, follicle stimulating hormone; GH, growth hormone; LH, luteinizing hormone; PRL, prolactin; TSH, thyroid stimulating hormone. Posterior pituitary hormones: VP, vasopressin; OT, oxytocin. POMC, proopiomelanocortin; MSH, melanocyte stimulating hormone.

further increases in cortisol secretion. Negative feedback is mediated by receptors for the various endocrine hormones within the hypothalamus, for example cortisol feeds back directly to CRH neurons via cortisol (glucocorticoid) receptors within those neurons. Hypothalamic hormone receptors do more than mediate negative feedback. For example, receptors for the gonadal steroid hormones, androgen and oestrogen, not only participate in negative feedback regulation of androgen and oestrogen secretion, but also mediate the stimulatory effects of these hormones on social and reproductive behaviors. During early development, gonadal steroid hormones act on these receptors to guide the sexual differentiation of the hypothalamus.

The posterior pituitary hormones, vasopressin and oxytocin, are produced by other, larger (magnocellular) neurons within the paraventricular and supraoptic nuclei. These hormones are transported down the pituitary stalk within the axons of the hypothalamic neurons that make them and stored in axon terminals within the posterior pituitary. When the hypothalamic neurons are excited by the appropriate neural inputs, oxytocin and vasopressin are released from the posterior pituitary into the blood. For example, nursing, through stimulation of the nipples, excites hypothalamic neurons that release oxytocin into the bloodstream. Oxytocin acts on the breasts to produce milk ejection. This is an example of how some hypothalamic neurons act as neuroendocrine transducers. The brain responds to nipple stimulation and relays this somatosensory information to the hypothalamus via neural (synaptic) signals. Oxytocin neurons respond to these neural signals and produce a hormonal output.

FUNCTIONS OF HYPOTHALAMIC NUCLEI

Examples of the many aspects of physiology and behavior in which hypothalamic nuclei participate are shown in Table 1. It is important to note that more than one nucleus may be involved in a particular function. This is illustrated in the following discussion of the hypothalamic control of eating behavior.

The neural mechanisms for chewing, swallowing, and even reacting to the taste of food, are located posterior to the hypothalamus. Early animal research suggested that the hypothalamus is important for the motivation to eat (appetite), but this idea has been disputed. The idea that neurons within the medial and lateral hypothalamus interact to regulate appetite was first proposed in the 1950s, based on the dramatic effects of hypothalamic lesions on eating and body weight in animals. Lesions of the medial hypothalamus produce overeating and obesity, while lesions of the LH reduce appetite and body weight. This led to the 'dual center' model: the idea that the LH was the location of a 'hunger center', while the medial hypothalamus was the location of a 'satiety center'. Satiety refers to the natural state that follows eating when appetite is inhibited. Increasing activity of the medial hypothalamic satiety center during and following eating was thought to inhibit activity in the lateral hypothalamic hunger center and thus terminate a meal. This model was eventually rejected because of the following findings. First, damage to the LH does not selectively reduce appetite. Animals with extensive bilateral damage to the LH initiate little or no eating or drinking; in fact, they initiate very little behavior of any kind. Second, destruction of axons that merely passed through the LH could duplicate the effects of LH lesions. As mentioned above, the nigrostriatal dopamine pathway passes through the LH on its way to innervate the basal ganglia. The finding that selective destruction of dopamine neurons at any point along the nigrostriatal pathway produced the same deficits as nonselective damage to the LH cast doubt on the idea that cell bodies intrinsic to the LH play a role in eating behavior. Finally, the idea of a medial hypothalamic satiety center was rejected when it was found that the overeating and obesity that follow bilateral damage to the medial hypothalamus could be explained by a metabolic change produced by the lesions. Bilateral lesions of the medial hypothalamus that include the ventromedial or paraventricular nuclei produce chronic hyperinsulinemia, the continuous oversecretion of insulin. Damage to the medial hypothalamus disrupts the neural regulation of insulin secretion by removing an inhibitory influence on the parasympathetic innervation of the pancreas. The resulting abnormally high blood insulin levels cause much of the glucose that is absorbed after a meal to be immediately put into storage in the form of fat. Thus it is possible that animals with medial hypothalamic lesions overeat not because of a lack of satiety, but because they must keep eating to ensure that they have enough glucose and other nutrients in their blood to meet their immediate energy requirements. However, recent discoveries have renewed interest in the idea that the hypothalamus regulates appetite, the motivation to eat, not merely the autonomic regulation of insulin secretion.

Table 1. Hypothalamic nuclei and some of the functions in which they participate. Nuclei are listed according to their longitudinal position, i.e. anterior nuclei are at the top of this list, posterior nuclei at the bottom

Preoptic	Fertility: neurons scattered through the preoptic area produce GnRH, essential for fertility in male and female. In humans and other primates GnRH neurons are found throughout the longitudinal extent of the hypothalamus
Medial	Gonadal hormones act here to promote male sexual behavior and parental behavior. The medial preoptic area contains the sexually dimorphic nucleus, which is larger in male rats. The human hypothalamus also contains a sexually dimorphic nucleus, the INAH-3, in a similar location Temperature-sensitive neurons regulate body temperature by autonomic responses (dilation of blood vessels) and behavioral responses (seeking or avoiding warmth)
Ventrolateral	Neurons here induce sleep through inhibition of histamine neurons in the posterior hypothalamus
Suprachiasmatic	Neurons generate 24 h (circadian) rhythms of endocrine and behavioral responses
Supraoptic	Source of blood-borne oxytocin and vasopressin
Anterior	Neurons facilitate defensive and aggressive behavior
Paraventricular	
Magnocellular	Source of blood-borne oxytocin and vasopressin
Parvocellular	Regulates thyroid via production of thyrotropin releasing hormone (TRH) Integrates responses to stress: • produces CRH • projections to medulla and spinal cord increase behavioral arousal and activate sympathetic nervous system to increase heart rate and blood pressure Regulation of eating and body weight: • a site where peptides act to stimulate or inhibit appetite • projections to medulla regulate parasympathetic innervation of gastrointestinal tract and pancreas
Ventromedial	In rats, estrogen and progesterone act here to induce female sexual receptivity
Arcuate	Produces growth hormone releasing hormone (GHRH) Neurons here release dopamine into the median eminence to inhibit pituitary prolactin secretion Leptin acts here to inhibit appetite
Lateral hypothalamus	Activity here increases arousal, appetite and thirst

CRH, corticotropin releasing hormone; GnRH, gonadotropin releasing hormone; INAH, interstitial nucleus of the anterior hypothalamus.

The discovery of leptin in 1994 provided new insight into the regulation of appetite and body weight. Leptin is a hormone made by fat cells. The blood level of leptin informs the brain of the amount of fat the body is carrying. The more fat, the more leptin in the blood. Leptin inhibits appetite and thus serves as a negative feedback signal to help regulate eating and body weight. Leptin receptors are present in the hypothalamus, including the medial hypothalamus, and injections of leptin into the cerebral ventricles inhibit eating in animals. Together these findings suggest that leptin acts on neurons within the medial hypothalamus to inhibit appetite.

The discovery of leptin, along with the discovery of several hypothalamic peptides that stimulate appetite, has led to a new model of how neurons within the medial and lateral hypothalamus interact to regulate appetite (Figure 3). Neuropeptide Y, orexin A and melanin-concentrating hormone all stimulate eating when injected into the rat brain. Neuropeptide Y is made by neurons of the arcuate nucleus, part of the medial hypothalamus, while the other two peptides are made by separate populations of LH neurons. The demonstration that LH peptides stimulate eating has revived the idea that neuronal cell bodies within the LH have a role in regulating appetite. So although the LH is no longer thought of as the 'hunger center', LH neurons are part of the neural network that gives rise to hunger.

CONCLUSION

The hypothalamus is a critical interface between the brain and the rest of the body. It influences nearly every aspect of physiology and behavior. It integrates endocrine, autonomic and behavioral responses that must occur together for an animal to interact successfully with its environment. Although its role in initiating goal-directed behavior (motivation) has been controversial, evidence

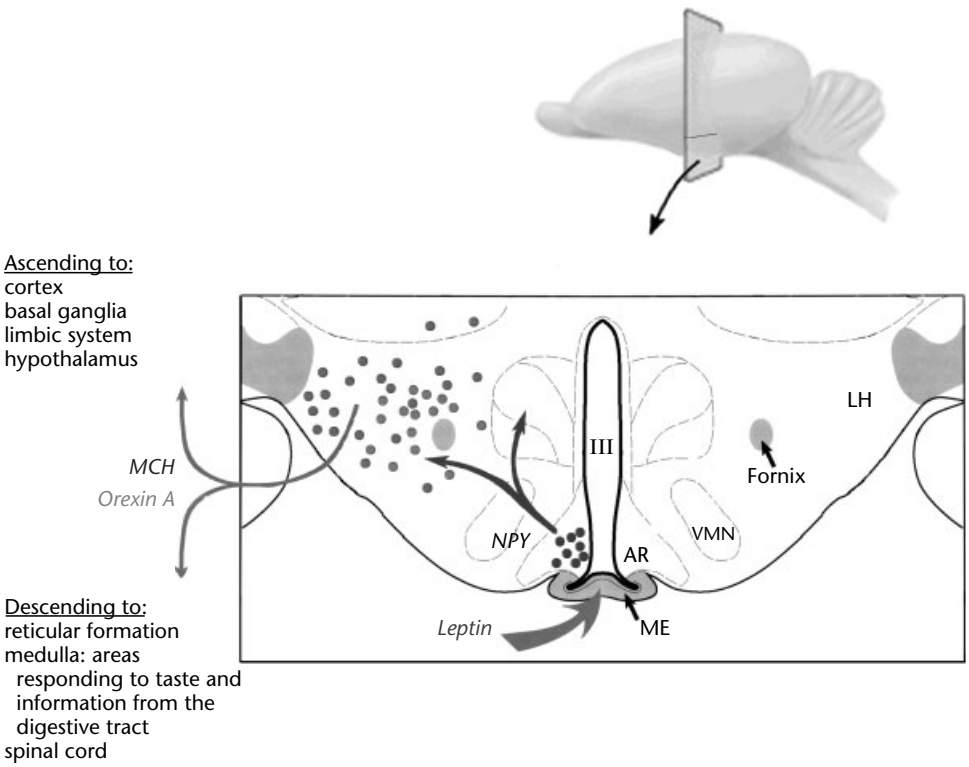

Figure 3. A section through the rat hypothalamus depicting how interactions between the hormone leptin and neurons of the medial and lateral hypothalamus (LH) regulate appetite. Anatomical structures are labeled on the right half of the section, and peptide-containing neurons are shown on the left half. Neuropeptide Y (NPY), orexin A and melanin-concentrating hormone (MCH) are appetite-stimulating peptides. Neurons in the arcuate nucleus (AR) release NPY that excites orexin A and MCH neurons in the LH. Orexin A and MCH neurons have similar widespread projections to other brain regions including those concerned with behavioral activation and arousal which accompany food deprivation and food-seeking. In this model leptin inhibits appetite by directly inhibiting NPY neurons in the medial hypothalamus. This reduces the excitatory influence of NPY neurons on the MCH and orexin neurons in the LH. It should be noted that the MCH and orexin neurons influence other behaviors as well as eating. For example, it has recently been discovered that the sleep disorder, narcolepsy, is caused by the loss of hypothalamic orexin neurons. ME, median eminence; VMN, ventromedial nucleus; III, third ventricle.

suggests that it does have this role in regulating eating behavior. That is, hypothalamic neurons are part of the network of neurons that mediates the motivation to eat (hunger or appetite).

Kindling

Introductory article

Deborah M Saucier, University of Saskatchewan, Saskatoon, Canada
Michael E Corcoran, University of Saskatchewan, Saskatoon, Canada

CONTENTS

Kindling is a model of complex partial epilepsy and neuroplastic change within the nervous system.

INTRODUCTION

The first description of a kindling-like effect was the observation made by Watanabe in 1936, who electrically stimulated the cerebral cortex of freely moving dogs and found that convulsive seizures developed progressively, eventually resulting in the occurrence of spontaneous convulsions. Studies from Jose Delgado's laboratory at Yale in the late 1950s and early 1960s found that behavioral seizures developed during ictal electroencephalic (EEG) discharge and that ictal EEG grew as the number of stimulations progressed. However, these observations were largely left unnoticed by the general scientific community until the seminal paper by Graham Goddard in 1967.

Intriguingly, research on intracranial self-stimulation (ICSS) had previously documented the development of seizures (both electrographic and behavioral manifestations) as a side effect of the ICSS procedure, which is a means of investigating the neural basis of reinforcement. However, the seizures that sometimes accompanied ICSS were viewed primarily as an artifact and a potential confound for those studying the neural basis of reinforcement, rather than as a phenomenon interesting in itself.

The discovery of kindling arose primarily from a serendipitous error that occurred during Graham Goddard's doctoral research, which was to study the effects of electrical stimulation of the amygdala on conditioning in rats. Owing to an equipment malfunction he accidentally delivered repeated trains of fairly high-intensity stimulation to the amygdala of some rats, one of which developed seizures after a few repetitions. The rat continued to display seizures even after the equipment had been repaired, and Goddard observed that similar stimulation given to naive rats did not cause seizures. In other words, it was the repeated application of stimulation that led to seizure, rather than the stimulation itself. Goddard's additional insight was that the brain itself might have been changing in response to the repeated application of stimulation, and that this phenomenon might model neural mechanisms of learning.

Goddard's subsequent research not only established the parameters of kindling, but also demonstrated a number of the fundamental characteristics associated with this phenomenon. He and his colleagues found that repeated application of brief trains of electrical stimulation leads to the development of generalized convulsions in rats and that this state of induced susceptibility to convulsion is seemingly permanent. They demonstrated that kindling depends on the distributed application of high-frequency stimulation and that it is unlikely to be due to pathological effects of electrical stimulation such as tissue damage, poison, edema, or gliosis. Finally, they confirmed that kindling occurs when similar treatments are applied to the cat and the monkey; it is not unique to the rat's central nervous system.

Although Ronald Racine may not have been the first to recognize kindling as an important phenomenon, the field of kindling has been (and continues to be) profoundly influenced by his research, beginning in 1969, and especially by two papers published in 1972. Racine was the first to recognize that the EEG events accompanying kindling must be recorded, allowing the subtle neural changes (which are not evident in the convulsions) to be studied. Racine's research was the first to characterize the EEG changes occurring in response to the repeated application of electrical stimulation. Racine developed a rating scale for classifying behavioral seizure development that is now used

almost universally in kindling research. He also clarified the relations between repeated stimulation, ictal discharge, and kindling. Finally, he imagined that the neural changes underlying the kindled state might be widespread throughout the brain and he developed procedures to test this hypothesis. Using these techniques, Racine demonstrated that kindling involves widespread transsynaptic changes. Together with Goddard's initial experiments, Racine's research defined the kindling phenomenon.

Although other people made significant contributions during the early days of kindling research, the final person that we shall focus on here is Juhn Wada, a clinical neurologist. Wada performed seminal experiments in cats in which he discovered that establishment of a cortical focus with ethyl chloride and aluminum hydroxide led to the development of independent foci in other cortical and subcortical sites and to the evolution of behavioral seizures. In the early 1970s Wada began to investigate the susceptibility of Senegalese baboons (*Papio papio*) to kindling. Further research resulted in the study of the characteristics and mechanisms of kindling in rats, cats, monkeys, and baboons. This work produced, among other things, the first systematic and extensive descriptions of kindling in cats, baboons, and monkeys. Importantly, Wada was among the first to describe the occurrence of spontaneous seizures during kindling. Less tangibly but no less importantly, the endorsement of kindling by a prominent neurologist such as Wada, in his research papers, in presentations at meetings, and in the series of books he edited, eased its acceptance by the neurology community as a legitimate and important preparation in experimental epilepsy.

MAIN FEATURES OF KINDLING

Kindling involves the progressive development of seizures and an enduring increase in seizure susceptibility in response to repeated electrical stimulation in the brain. Convulsions can be triggered when low-intensity current of brief duration is repeatedly passed through the uninsulated tip of chronically implanted electrodes within certain areas of the brain. Initial simulations result in epileptiform afterdischarges of short duration. Stimulation intensity is usually at the afterdischarge threshold, which is arbitrarily defined as the lowest intensity of stimulation that evokes an afterdischarge at the stimulation site. The initial seizure activity consists of low-amplitude afterdischarge spikes, and there is a limited propagation to other sites in the brain. Repetition of the stimulation at a fixed interval (usually 24 h) and intensity will lead to an increase in seizure activity manifested by typical behavioral responses and EEG patterns. Typically kindling stimulations are a 1 s train of constant current biphasic square wave pulses, each pulse with a duration of 1.0 ms. Biphasic pulse pairs are delivered at a rate of $60\,s^{-1}$.

Kindling is persistent. In limbic sites there is typically no remission of the phenomenon observed. Kindled animals can display spontaneous seizures, typically after many repeated stimulations. Kindling does not appear to result from focal tissue damage. Lesioning of a kindled site does not affect subsequent kindling from other sites, which indicates that lesion-induced damage does not itself kindle seizures or facilitate electrical kindling. Further, lesions at the tip of the implanted electrode interfere with kindling from the stimulated site. This suggests that intentional gross damage to the stimulated site does not facilitate kindling; rather, it interferes with it. Additionally, homotopic contralateral unstimulated sites will show a saving in the number of stimulations required to produce a generalized convulsion, indicating that kindling is a trans-synaptic plastic change that occurs throughout much of the brain of the kindled animal.

Kindling occurs in response to chemical as well as electrical stimulation. Carbachol, a cholinergic agonist, effectively kindles seizures. When carbachol is infused into the brain at doses that are initially subconvulsive, there is a progressive increase in seizure activity and severity of convulsions. Picrotoxin, a γ-aminobutyric acid (GABA) antagonist, kindles seizures when injected either into the amygdala or intraperitoneally at subconvulsive doses. Morphine or opioid peptides also kindle seizures when repeatedly injected intracerebrally at initially subconvulsive doses.

Chemically induced kindling is fully transferable to electrically induced kindling. The strength of transhemispheric transfer between chemical and electrical kindling is as strong as transhemispheric transfer between electrical and electrical kindling. The transfer data provide strong evidence that the mechanisms underlying chemically induced kindling are the same as those underlying electrically induced kindling. In general, any procedure that evokes sustained and rapid burst firing of neurons has the potential to kindle convulsions. Thus, the most important requirement of kindling is not the form that the stimulus takes, but whether it evokes burst firing of neurons, as do carbachol and specific forms of electrical stimulation.

The developing brain appears to be more seizure-prone than the adult brain. Rats given a

single subconvulsive exposure neonatally to a proconvulsant treatment (e.g. kindling simulation, exposure to heat) and examined as adults displayed decreased thresholds for kindling and an increased rate of kindling. However, the rate of kindling in immature rats is more rapid than that observed in adults, suggesting that the immature brain is more hyperreactive than the mature brain. Given the results from early exposure to epileptogenic experiences and their ability to permanently affect future plasticity, we have good evidence that the immature brain has a predisposition toward hyperexcitability.

The immature brain is not completely homologous with the adult brain. For instance, the immature brain is hypersensitive to the glutamate agonist, *N*-methyl-D-aspartate (NMDA), injections of which result in intense seizures and hippocampal damage, whereas injections of kainic acid produce intense seizures with relatively little damage. In the adult brain, this pattern is reversed: NMDA injections produce much less severe seizures, whereas kainic acid injections are much more toxic and produce widespread damage. Further discrepancies between the immature and the mature nervous systems can be observed in the response to infusions of muscimol (a $GABA_A$ receptor agonist). In the developing nervous system, muscimol is proconvulsive, whereas in adult rats it is an anticonvulsant. These results suggest that the immature brain is differently disposed to hyperexcitability, although regardless of the treatment, epileptiform activity in the infant enhances future seizure susceptibility.

KINDLING AS A MODEL: EPILEPSY AND NEUROPLASTICITY

Kindling as a Model of Epilepsy

Epilepsy is a disorder characterized by recurrent and unpredictable episodes of seizure activity. The hallmark for diagnosis is two or more unprovoked seizures combined with epileptic spikes occurring while an EEG is recorded. The prevalence of a second seizure is approximately 40% in those who have had a single unprovoked seizure. Treatment of epilepsy typically aims to prevent or suppress seizures through the use of antiepileptic drugs.

Many types of epileptic seizures occur and the frequency and form of seizures is variable. However, two major types of seizures are typical and are usually described as either partial or generalized. Partial seizures are ones in which seizure activity is limited to one area of the brain. Complex partial seizures (also referred to as temporal lobe epilepsy) may involve complicated motor acts and impairments of consciousness during the motor component of the convulsion. Generalized seizures refer to the involvement of the whole brain and typically involve two-phase generalized convulsions: the tonic phase, which involves the loss of consciousness and falling with body rigidity; and the clonic phase, during which the body extremities jerk and twitch.

Many facets of kindling make it a good model of complex partial epilepsy in humans. First and foremost, kindling is the progressive development of seizures, which makes it very similar to post-traumatic epilepsy, and it can result in the development of repeated spontaneous seizures, a hallmark of epilepsy. However, kindling also exhibits many other features that make it a good model of complex partial epilepsy.

Although complex partial seizures can occur throughout the brain, in humans they typically occur in the temporal lobe. In nonhuman animals, parallel limbic areas (including the amygdala, hippocampus, and septum) kindle readily. In humans, partial seizures are initially limited to one site in the brain, which is what is observed during the initial stages of kindling in limbic sites. The afterdischarge and subsequent EEG that are observed following a kindling stimulation in animals are very similar to those of a human undergoing an epileptic seizure. The form of the convulsions resulting from early kindling in the amygdala is very similar to that observed in humans with complex partial epilepsy. Kindling, like epilepsy, may progress from complex partial seizures to become more severe and generalized. Like generalized convulsions in humans, kindled generalized seizures in nonhuman animals are marked by tonic–clonic convulsions, including falling with body rigidity, and body extremity jerking. Thus, kindling shares anatomical, EEG, and convulsive features with epilepsy.

Importantly, drugs that are effective in treating epilepsy have similar effects on kindling. Treatments with barbiturates, GABA agonists or benzodiazepines are all effective in retarding kindling. Kindling therefore enables researchers to test new treatments for epilepsy on brains that are truly epileptic. This is not the case with seizures that are triggered once only, as is the case with electroconvulsive shock or PTZ seizures. However, for those studying the causes or treatment of epilepsy the most valuable feature of kindling as a model of complex partial epilepsy is its predictable development. In the limbic system the reliable rate of

kindling provides researchers with excellent parametric control over the seizures.

There is one major difficulty in firmly asserting that kindling thoroughly models complex partial or generalized seizures. The definition of both complex partial and generalized seizures requires the impairment or loss of consciousness during the seizure. Although nonhuman animals may exhibit a number of features that are suggestive of the loss of consciousness, nonhuman animals are essentially nonverbal. As our window onto consciousness is primarily verbal, we cannot definitively state that kindling results in an impairment or loss of consciousness in nonhuman animals.

Kindling as a Model of Neuroplasticity

In 1948 Jerzy Konorski coined the phrase 'synaptic plasticity', conceiving it as a long-lasting change in neural activity. Although Konorski may have coined the term, it was Donald Hebb in 1949, with the publication of *The Organization of Behavior*, who has had the greatest impact on our thinking about plasticity phenomena. Hebb suggested that it was the plastic nature of neurons and their ability to change their responses that was the basis of learning in the nervous system. In 1949 Hebb stated, 'any two cells or systems of cells that are repeatedly active at the same time will tend to become associated, so that activity in one facilitates activity in the other.' This definition still describes what is understood as neuroplasticity today.

Kindling involves an increase in the responsiveness of neurons to previously weak or ineffective stimuli. This change is persistent, and may even be permanent – certainly it is a long-lasting change in neural activity. We now know that neuroplasticity can result from the growth of new synapses, the activation of previously inactive synapses, and changes in efficacy of synapses, among other things. Importantly, the changes associated with kindling are widespread and trans-synaptic, suggesting that the entire nervous system is responding to the kindling stimulations. Kindling may modify the efficacy of synapses, and it has been suggested that kindling may result from the activation of previously dormant synapses. Further, research suggests that in adult rats, markers for synaptic growth appear following the application of initial kindling stimulation, leading to speculation that kindling results in the production of new synapses. Thus, at a basic level, kindling results in plastic change of the nervous system that is specific to kindling itself.

Recall, however, that when Goddard first observed the kindling phenomenon he thought that perhaps kindling was a model for learning. Today kindling is not thought of as a model for learning; rather it is a model of pathological neuroplastic change. In fact, kindling in the limbic system has been shown to interfere with a number of forms of learning. Moreover, the learning impairments are relatively specific to the site that was kindled: it has been demonstrated that hippocampal kindling, but not kindling of the amygdala, interferes with tasks that are thought to be mediated by the hippocampus.

Kindling does share superficial similarity with another model of neuroplasticity, long-term potentiation (LTP). The latter is marked by a long-lasting increase in the responsiveness of neurons that have been exposed to a brief electrical stimulation. Similar potentiation can occur following kindling stimulation, and is known as kindling-induced potentiation (KIP). The fact that potentiation occurs with kindling, and the similarities between the techniques for the induction of LTP and kindling, have resulted in many discussions of whether common mechanisms underlie these two phenomena. Although some similarities are observed at the molecular layer (for example, the participation of various protein kinases in the production of both KIP and LTP), there are some significant differences between KIP and LTP. Most importantly, unlike kindling, LTP does not require the production of afterdischarge, and repeating the stimuli required to produce LTP does not result in afterdischarge or kindling. Unlike kindling and KIP which are extremely persistent, LTP typically decays to baseline within several days or weeks. Another difference is that various brain structures often show very different propensities to kindle and undergo LTP.

There are large distinctions in the neural activity that produce LTP and KIP. Kindling-induced potentiation results from the summation of activity in the many pathways (excitatory and inhibitory) that are activated by the kindling stimulation. The widespread trans-synaptic activation observed in kindling and KIP does not typically occur in LTP paradigms. Typically, LTP results from local activation of relatively few neural circuits. As such, it may be that the difficulties in comparisons between LTP and kindling or KIP result from the fundamental difference between these phenomena in evoking widespread trans-synaptic change, rather than in any meaningful difference between the mechanisms underlying the production of these phenomena.

PUTATIVE MECHANISMS OF KINDLING

The form of the stimulation required to elicit the kindled state can vary; the only requirement is that it must trigger an afterdischarge. Stimuli that do not produce an afterdischarge do not result in kindling. Unlike the parameters and features of kindling, the mechanisms underlying kindling are little known and frequently contentious. We will focus on the anatomical explanations of kindling as well as the intriguing results provided by fast- and slow-kindling strains of inbred rats.

Neuroanatomical Correlates of Kindling

Brain sites vary in the number of stimulations required to produce behavioral seizures. In order of decreasing sensitivity to kindling, the following pattern was found: amygdala, globus pallidus, piriform cortex, olfactory bulb, septal area, preoptic area, caudate putamen, and hippocampus.

Although the piriform and perirhinal cortices produce generalized convulsions rapidly, they may have a critical role in the development of kindling. Limbic sites such as the amygdala are unable to directly support convulsive motor responses, although kindling of the amygdala results in eventual development of convulsive motor responses. It appears that the recruitment of perirhinal cortex may be essential for triggering convulsions, and participation by the piriform cortex may be required for additional amplification of convulsions. The perirhinal cortex has numerous close and reciprocal connections with the frontal motor cortices. Depressing activity within the frontal motor cortex of the rat retarded the development of kindling – reducing the duration of both afterdischarges and convulsions.

Examinations of kindling in the claustrum have demonstrated that this structure is extremely sensitive to kindling, rapidly producing intense and prolonged seizures. Furthermore, unlike many other forebrain structures, convulsive motor responses are produced during the stimulation itself. Conversely, lesions of the claustrum significantly retard the kindling of seizures with stimulation occurring elsewhere in the brain. These results suggest that the claustrum also plays a part in the production of the convulsive motor responses that are characteristic of kindled seizures. Taken together, these results suggest that the claustrum along with the piriform, perirhinal, and frontal motor cortices has a major role in the production of convulsions and thus in the progression of kindling from complex partial seizures to generalized seizures. Moreover, destruction of any one of these structures does not result in the complete cessation of kindling, although kindling is significantly retarded. It therefore appears that there are multiple pathways by which kindling can proceed and develop.

Hippocampal degeneration is often observed in people who have temporal lobe epilepsy. It has been suggested that it is the loss of cells critical for the regulation of normal inhibition within the hippocampus that underlies kindling. Although it does appear that cell loss occurs following status epilepticus (typically induced by kainic acid), the evidence for cell loss following kindling is much less compelling. Some researchers have observed that there is cell loss in the hilus of the hippocampus following kindling; however, others have observed that the volume of the hilus is changed following kindling, confounding calculations of cell density. Furthermore, kindling does not result in increased numbers of microglia, or increases in the numbers of apoptotic cells. Although kindling does appear to increase the number of reactive astrocytes, these increases have also been observed in rats that were not fully kindled, suggesting that astrocytic activation may have been related to neuronal activity rather than to kindling itself. Thus, it does not appear that kindling is strongly associated with cell loss within the hippocampus. The evidence from kindling studies suggests that the hippocampal degeneration observed in patients with chronic epilepsy may be the result of episodes of status epilepticus, not the cause of the epilepsy.

Another area of intense focus within the hippocampus has been the observation that patients with temporal lobe epilepsy also exhibit abnormal sprouting in the excitatory pathways of the hippocampus (the mossy fibers). The mossy fibers are axons of the granule cells of the dentate gyrus and project to pyramidal cells of the area CA3 of the hippocampus. Many people who have epilepsy may have experienced some type of traumatic incident (fever, head injury) prior to the development of epilepsy. It has been suggested that the time course for the development of these abnormal mossy fibers parallels observed time courses between initial trauma and subsequent seizure syndromes. Thus, mossy fiber sprouting (MFS) has been suggested as a putative mechanism of enhanced seizure susceptibility.

Both kindling and status epilepticus can result in the induction of MFS. However, a number of researchers using a variety of species and techniques have demonstrated that MFS can be dissociated from the progressive development of seizures.

These demonstrations include observations that the amount of MFS is not related to the intensity of kindled seizures, and the protein synthesis inhibitor, cyclohexamide, blocks status epilepticus-induced MFS without affecting the expression of status epilepticus itself. Researchers have reported that MFS targeted inhibitory cells and may actually restore inhibitory responses within the hippocampus. Furthermore, MFS has been shown to occur with stimulations that produce LTP and that do not result in kindling. Thus, MFS may actually reflect neural activation, something that undoubtedly occurs during kindling, rather than synaptic modifications that result in enhanced ability of the hippocampus to produce seizures.

Fast- and Slow-kindling Rats

Ronald Racine developed two strains of rats that were highly inbred based on their rate of kindling. The fast strain kindled 40–50% more quickly than normal rats, whereas the slow strain kindled 200–300% more slowly than normal rats. These differences are observed primarily within the amygdala, as both fast and slow strains tend to kindle at normal rates when stimulation occurs in the hippocampus. The fast strain is more susceptible to picrotoxin or bicuculine, which are GABA antagonists, whereas the slow strain require smaller doses of barbiturates (GABA agonists) to produce anesthesia. Thus, GABA-mediated inhibition may have a role in the observed differences between the fast and slow strains.

The fast and slow strains exhibit profound differences in the expression profile of the α subunit of the $GABA_A$ receptors. The fast strain express approximately 50% fewer of the adult inhibitory form of the subunit, $\alpha 1$, whereas they overexpress the neonatal excitatory forms of the GABA α subunits. The slow strain underexpresses neonatal excitatory subunits and expresses approximately 200% more of the inhibitory, $\alpha 1$ subunits. These results are consistent with the fast strains demonstrating an arrested development of the $GABA_A$ receptor system, suggesting that the molecular correlate of the fast kindling phenotype is related to differences in GABA-mediated inhibition. Other researchers have found that hippocampal commissure kindling results in the conversion of $GABA_A$ receptor subunits to include a greater prevalence of neonatal, excitatory forms in otherwise normal adult rats. Additionally, following status epilepticus in adult rats, researchers have observed an upregulation of the messenger RNA for the excitatory, neonatal forms of $GABA_A$ simultaneous with downregulation of the inhibitory, adult-form mRNA in otherwise normal adult rats. There have been numerous demonstrations that changes in $GABA_A$ inhibition occur following seizures and kindling. It seems likely that the mechanisms that underlie kindling are related to the results obtained by examining these fast and slow strains.

CONCLUSION

Kindling is the predominant model of clinical epilepsy. Kindling can occur following electrical stimulation or the injection of proconvulsant chemicals as long as the stimulation produces afterdischarges. Studies of the mechanisms of kindling will continue to provide important insights into the causes and treatment of epilepsy.

Levels of Analysis in Neural Modeling

Introductory article

Peter Dayan, University College London, London, UK

CONTENTS

Neural systems are analyzed by building multiple levels of descriptive and explanatory mathematical models. Parallel to these are interpretive computational models, showing how information is represented and manipulated.

LEVELS OF ORGANIZATION IN THE BRAIN

The construction and refinement of qualitative and quantitative models for observed phenomena is the standard practice in neuroscience, just as it is in all other scientific disciplines. What particularly distinguishes neural modeling, apart from the sheer complexity of the phenomena, is that brains are computational devices, transducing, representing, manipulating and storing information, and using this information to control actions. The most comprehensive neural models must therefore play the dual role of accounting for experimental data and interpreting it in terms of underlying computations. Understanding what neural models are, what their connections to experimental data are, and how to build and use them in practice, is tricky because of the complexity and the multiple goals for modeling.

One key idea for structuring the enterprise of modeling that has many, and confusingly different, manifestations is that of different levels of organization. The confusion comes because there are at least four different, though partially overlapping, threads to this idea. Understanding these threads of levels of organization is fundamental to understanding the construction and critique of neural models.

The first thread is the standard one of scientific reduction, describing observable phenomena in qualitative and quantitative detail, and explaining them in terms of descriptions of their underlying substrates at lower and less abstract levels.

The second thread is that of the construction or synthesis of systems to execute some particular task. Here, the use of different levels is a conventional divide-and-conquer strategy in the face of design complexity. For instance, programmers building large computer systems decompose complicated functions (at higher levels) using simpler subroutines and procedures (at lower levels). Modern object-oriented programming methods take this one stage farther.

The third thread, originally suggested by David Marr, is associated specifically with computational modeling. It involves a computational level, which is an abstract description of the goal of the task, and the logic of the strategy by which it is to be satisfied; an algorithmic level, which is a description of the way that information should be represented and algorithmically manipulated in the service of carrying out the task; together with an implementational level, which is a description of the way that these representations and manipulations are instantiated in neural hardware. To avoid confusion, we will reserve the word 'planes' for these three computational levels.

The fourth and final thread is that of levels of processing as a strategy for manipulating and extracting information from input. This is well exemplified by the visual system of primates. In some primates, tens of different structurally and functionally defined areas of the brain are devoted wholly or partially to analyzing visual information. On the basis of various sources of evidence, including characteristic layers of termination of connections, these areas appear to be organized in a somewhat loose hierarchy. This hierarchy starts from the lowest level in primary visual cortex, where cells tend to have comparatively small receptive fields (i.e. are directly responsive only to a small area of visual space) and simple response properties (for instance, responding to small bars of light at particular orientations). The hierarchy extends all the way up to much higher levels involving areas such as the inferotemporal cortex,

where cells have large receptive fields and complex response properties (for instance, responding to pictures of particular classes of faces, but not to other apparently similar objects). Similarly, when building machines to process images for such tasks as object recognition, one can build a processing hierarchy, in which the visual input is subjected to sequences of manipulations leading to the answer.

The idea in the fourth thread that visual and other inputs might be processed hierarchically is quite distinct from the idea in the other three threads about the hierarchical organization of the analysis of a complex system such as a brain. The latter, which is the main focus of this article, applies whatever form neural computations happen to take – it is about describing and explaining the behavior of systems of any sort.

TYPES OF NEURAL MODEL

Conventional Reductive Models

The first thread to the idea of levels concerns standard reductive modeling. For the practical (as opposed to the philosophical) aspects of this, models are useful in at least two ways: describing neural phenomena, and providing a means for reductionist explanations of the phenomena, by appealing to the mechanisms that might actually be responsible for generating the phenomena in the first place. These mechanisms themselves are usually understood in terms of models. Thus, the modeling process is recursive in the sense that explanatory models at one level are built from descriptive or explanatory models at a lower level; explanatory models at the lower level are built from descriptive or explanatory models at a yet lower level. Although models need not be expressed as a set of mathematical equations, quantifying them in some way is essential to be able to check whether the mechanisms postulated (or rather the models of the mechanisms postulated) are really capable of capturing the phenomena to the desired degree of accuracy.

One example of this reduction is the phenomenon of the behavior of an interconnected network of neurons. This can be described in terms of a (relatively complicated) dynamic state description, but it might also be explained in terms of descriptions of the properties of the individual neurons and their connections. In turn, the descriptions of the individual neurons can be explained in terms of their detailed geometry and the membrane-bound channels they contain.

Another example is modeling the shape over time of the voltage inside an axon (relative to extracellular space) during the passage of an action potential or spike. The data can be characterized at some level of detail, such as the time course of the voltage averaged over a large number of spikes. The data can be summarized, at least within the approximation of experimental error, by any number of different descriptive quantitative models. For instance, one could tune the parameters of various high-order polynomials or piecewise linear functions to replicate the shape of the spike accurately. In contrast to these nonmechanistic descriptions, Alan Hodgkin and Andrew Huxley, in their classic study, were interested in explaining how action potentials arise, and therefore constructed a model on the basis of what they expected about the way that cells might manipulate the potential difference between inside and outside. They had evidence that the basic mechanism was some way for the axon to change its permeability to particular ions, so they postulated as a mechanism a form of channel or gate in the cell's membrane. They built a quantitative explanatory model of the action potential from a quantitative descriptive model of the gate, fitting the parameters of the model to make correct the form of the overall action potential it produced.

Following the advent of more powerful experimental techniques, we can now understand Hodgkin and Huxley's deterministic phenomenological channel model in terms of a large number of tiny individual channels in the membrane which open and close in a stochastic manner. The summed effect of all these individual channels matches Hodgkin and Huxley's model very closely. So we can now build an explanatory model of the action potential using descriptive models of these gates. Based on even more recent experimental evidence, we could go further, and try to build explanatory models of these gates from our knowledge of their molecular structure.

The general conclusions from such examples are that there are different levels of model, corresponding to different levels of reduction of a phenomenon, and, often in neuroscience, different levels of anatomical detail. At a level, there are descriptive models which capture the behavior without much regard to the substrate, and explanatory models, which capture the behavior by reducing it to models at lower levels. Quantitative models tie together the different levels because they allow proof, or at least numerical demonstration, that the behavior assumed at one level can truly account for the behavior that it is intended to explain.

Almost always, the models at a given level are only approximate, with models at lower levels being faithful to more intricate details of the experimental observations.

One can think of the models at different levels as constraining each other – the model of the stochastic channel has to behave correctly to produce the overall spike, if such gates are really to be responsible for generating action potentials. Similarly, explanatory models of the action potential are constrained by what is possible at lower levels. One can also think of the different levels as liberating each other – there are many different gating mechanisms that have the same qualitative behavior – so if one is only interested in the effect of gating and not its cause, then one need not be concerned with the explanatory details of the model. In practice, there is not really such a strong separation between explanatory and descriptive models. For instance, Hodgkin and Huxley did not just build any descriptive model of their phenomenological gate. Indeed, so close was their descriptive model to the true underlying mechanism, that we can now interpret in terms of the latter some of the parameter values that they found by their fitting process.

Computational Interpretive Models

Computational models start from the premise that many of the tasks for brains are best characterized as involving computations. That is, brains solve computational problems, and it is a matter only of taste whether they are referred to as electrochemical computers. For example, for a bee to forage optimally in a field containing two types of flowers with different characteristics of provision of nectar, it must continually compute the choice between sorts of flower to land on. Equally, to catch a flying ball in the hand, the brain has to transform the visual input about where the ball is and how it is moving into a sequence of motor commands to move the hand to an appropriate place at an appropriate time, with the fingers arranged correctly. This transformation happens in various parts of the visual and motor systems of the brain.

Computational modeling is about imputing a computational task and interpreting the collective behavior of the neural components of the system in terms of this task. In these cases, the tasks involve generating the appropriate output, such as the choice of the better flower or the sequence of actions to catch the ball, from the input, such as the past qualities of the flowers or the visual impression of the ball over time.

More concretely, computational modeling involves understanding (i.e. interpreting) how neural machinery can represent and store information about aspects of the outside world, and how it can transform information from one form to another in the performance of tasks. Typically, representation involves the simultaneous spiking activities of large, distributed populations of neurons; storage involves both the persistent activity of neuronal populations and changes in the efficacies or strengths of synaptic connections between neurons; and transformations are occasioned by the propagation of activity within and between populations of neurons. As in a standard computer, the semantics of the computation, that is, its computational meaning, are implemented by the syntax of the physical substrate, for example the biophysical rules according to which activity propagates and synapses change their strengths.

Computational models can themselves be decomposed into the three planes of Marr described above, from an abstract description of the underlying task, through a more concrete description of the representations and algorithms adopted to satisfy the task, to a description of how these representations and algorithms are actually implemented. There is not necessarily a single description in the computational and algorithmic planes – there can be many different algorithmic ways of expressing the same transformation. For instance, to work out the product $a \times b$ of two positive integers, one can add a to itself b times, or b to itself a times, or use the standard long-multiplication method most of us learned at school, or add together the natural logarithms of a and b, and exponentiate the result. These different algorithms share the same description on the computational plane.

Computational models satisfy many of the same properties as conventional models. First, in the same way that there are different levels of conventional models, there are different levels of computational models, paralleling a decomposition of the underlying computation. Second, there are both descriptive and explanatory computational models. For example, take the case of a single, spiking, neuron. One can build a descriptive model of what the output of a neuron represents by presenting all possible classes of input to the animal and recording what spikes it produces. However, one can also build an explanatory model by working out what inputs the neuron has, what these inputs represent, and what transformations the neuron performs on these inputs.

The third similarity between computational and conventional models is functionalism, that

the same abstractly defined computation can, in principle, be carried out by many different representations and algorithms, and the same algorithm instantiated in many different forms of hardware. However, there is a caveat to this which has important implications for research programs. When we try to write down computational descriptions for complex tasks, such as identifying the structure of a visual scene, we tend to do so rather succinctly and abstractly. The neural substrate, as an evolved rather than a designed system, and facing implementational constraints such as limited connectivity and speed, is likely to be capable of instantiating only approximations to such abstract requirements. Phenomena such as visual illusions can result: cases in which the visual system fails to satisfy an apparently natural abstract description of a visual task. These then force us to enrich our computational descriptions, and also provide insight into the neural substrate. Therefore, the system does not really possess functional equivalence between the planes – the implementational planes implement functions that might be slightly different from the idealized ones described in the computational planes.

From the perspective of analyzing neural systems, computational and conventional modeling should work hand in hand. Consider a single level. Experimentally observable phenomena lie at the implementational plane of the computational model. Conventional modeling provides an explanatory account of these phenomena by reducing them to a lower level, where, in turn, they comprise the implementational plane of the lower level of the computational model. At each level in the computational model, algorithmic and computational planes are associated with the implementational plane. Thus, parallel to the conventional reduction from one level to the level below, there is a computational reduction from the planes at one level to the planes at the level below.

The ultimate goal is to have conventional and computational models for neural function that are mutually consistent, extending from the lowest levels of molecular dynamics to the highest levels of ethology. We would then have a complete, quantitative, multi-level understanding of *how* the brain executes *which* tasks. Of course, such exhaustiveness is far off at the moment. The coverage of conventional and computational models of any sort is very poor, and appropriate reductions and interpretations are few and far between.

In practice, computational models are often used synthetically rather than analytically. That is, networks of neurons, described down to some level of abstraction, are constructed to perform a computational task, and the behavior of the model neurons is compared with that observed in physiological (and other) experiments, justifying the model. In such synthetic treatments, the multiple levels of computational modeling can be made explicit, and the reduction between the levels can be shown to be exact. One popular synthetic technique is to start from an idea about optimal or normatively correct ways to perform a task, and to seek implementations involving biologically reasonable components.

DEGREES OF MODELING DETAIL

To a very coarse approximation, one can separate out three different classes of quantitative models in common use: conductance-based models, integrate-and-fire models, and firing-rate models. The different models are naturally couched at different levels of abstraction and, as described in general terms above, are used to account for data that are similarly collected at different levels of abstraction. Not all the models that are built and used fit neatly into these categories, but they nevertheless give a flavor of the differing degrees of neural and analytical detail that are regularly employed.

Conductance-based Models

Conductance-based models place their emphasis on describing single or just a few neurons with a high degree of detail. They typically approximate the structure of an individual neuron by multiple, interconnected compartments, each of which is treated as being electrically compact. The whole set of compartments is designed to be more or less faithful to the geometry of the neuron, including such facets as branching points of dendrites and the diameters and lengths of different parts. There is an elaborate art to representing cells that have complex geometrical structures in terms of just a few compartments, or even just a single compartment, a reduction that is often necessary to make computations involving the models adequately quick. In standard conductance-based models, each compartment is given an assortment of active channels, such as voltage-sensitive or synaptic channels.

Conductance-based models of single cells are ideal for explaining phenomena to do with spikes and the thresholds for initiating spikes, the precise effects of synaptic input, bursting, spike adaptation, spikes that propagate backwards up the dendritic tree, and the like. One problem with these models is that there is rarely good experimental

data on the actual locations on the dendritic tree or the strengths of the active channels. Such data are essential to making the models faithful to the neural substrate. More generally, conductance-based models involve a large number of parameters, and the values of only a few of these can be determined from experiments. A second problem with these models is that they are so complex that they cannot readily be analyzed, and yet can exhibit a huge range of behaviors depending on the exact values of the parameters.

There are various extensions of this single-cell use of conductance-based models. One is that it is common to model networks of neurons by connecting together simple (single-compartment) conductance-based models through model synapses. This allows simple network properties to be explored; more complicated networks are typically modeled using integrate-and-fire models. A second extension is to model important internal states, such as intracellular calcium levels, using the same compartmental structure. This is particularly important for things like calcium-sensitive potassium channels, which can lead to phenomena such as spike-rate adaptation. Although compartmental models capture the electrical geometry of single cells, they rarely capture the three-dimensional milieu in which the cells live.

Integrate-and-fire Models

Integrate-and-fire models lie at a level of abstraction above conductance-based models. Rather than using active channels to implement action potentials, they make the approximation of using a symbolic model of spike generation coupled with a leaky integrator model of a cell when its voltage is below the threshold for spike initiation. They also radically simplify the geometry of cells, eliminating the compartmentalization and including, at best, a stereotyped time course for synaptic input and for other time-dependent factors such as those allowing spike-rate adaptation.

Integrate-and-fire models (and the related spike-response model) are good for simulating large, recurrently connected, networks of neurons. Many mathematical issues about networks, such as the synchronization and desynchronization of spiking across the whole population, and the effects of different sorts and sources of noise, have been explored through using them. Furthermore, evidence suggests that precise time differences between presynaptic and postsynaptic activity control such things as synaptic plasticity. The integrate-and-fire model is the simplest form that still outputs spikes, and so can be used to address these issues. However, integrate-and-fire models pose substantial analytical difficulties themselves, and sometimes end up being an unhappy medium between more realistic, but analytically intractable, compartmental models, and highly abstract, but tractable, firing- rate models.

Firing-rate Models

The most abstract level of characterization of neurons abandons spiking altogether, and instead treats the output of cells as being continuous-valued, time-varying firing rates. This can be derived as an abstract approximation to integrate-and-fire neurons, under some assumptions about the time constants of processes inside cells. Networks of firing-rate models can be constructed, in which the influence of one cell on another is given by the product of the presynaptic cell's firing rate and the synaptic strength for the connection.

The main advantages of the firing-rate models are their empirical and analytical tractability. Firing-rate models usually involve a mild nonlinearity, turning an internal continuous variable like somatic voltage or current into a firing rate (which must be positive). Therefore, networks of neurons described using firing-rate models can be treated as coupled, nonlinear differential equations that can be shown to exhibit dynamic behaviors such as attraction to one of a set of fixed points, oscillations or chaos. In contrast to conductance-based models, these often evolve to relatively simple fixed-point or limit-cycle attractors. The regularities implied by attractor and oscillatory dynamic behaviors make them ideal as substrates on which to hang analyses of network computation.

Although it is possible to study the effects of synaptic plasticity in the context of conductance-based or integrate-and-fire models, by far the bulk of the work on computational analyses has been performed using firing-rate models. Here, with the exception of studies on recurrent attractor networks, a majority of the work has focused on non-recurrent, feed-forward network models, which are analytically much simpler to handle. These models take information represented in one way at one level of a processing hierarchy by the firing rates of a population of neurons, and transform and manipulate it to represent it in a different way by the firing rates of a population of neurons at a higher level of the hierarchy. Rules for plasticity have been seductive for computational modeling, since they offer an obvious way for large

networks of fairly simple processing units to come to perform computationally sophisticated tasks, apparently without requiring sophisticated programming.

Although the boundaries between them are somewhat blurred, there are three main classes of learning model. Unsupervised learning models act in a self-organizing manner, extracting statistical structure from input data. They are often used to capture activity-dependent adaptive processes that are assumed to be operational during development. Reinforcement learning models use evaluative information (rewards and punishments) in temporally complex and controllable environments (such as mazes) and specify how to predict future returns and choose actions in order to maximize these returns. Supervised learning models are rather special in that adaptation is based on information about both the inputs to the network and the desired outputs.

Supervised learning is extensively used outside the context of neural modeling. However, in two incarnations, it is important for neural modeling too. One case is when the output of one network is used to train another network. This requires an intricate dance by which neurons in the trained network must have two sets of input, one of which controls synaptic plasticity in the other. It has been suggested that this might take place under the control of neuromodulators. The other case for supervised learning is when the key question is whether a particular design of network of neurons is capable of executing a particular computational task or exhibiting some particular behavior, or whether the activity of some neurons in a network is consistent with their playing a role in the solution of a task. In this case, one can attempt to train the network (for instance by minimizing the discrepancy between the target and the actual outputs), using procedures that need have no relation to the rules governing neural adaptation.

CONCLUSION

Partnering conventional, multi-level, reductive models of experimental observations on neural mechanisms are models offering computational interpretations, couched at exactly the same multiple levels. These models indicate how the neural mechanisms implement computations, in the sense of representing information and performing algorithmic manipulations which are appropriate for solving a computationally well-specified task. The computational and conventional models should ideally mesh completely at all the levels. Few existing conventional and computational models actually achieve this degree of mutual coherence. Most current modeling is either conventional, at the compartmental and integrate-and-fire level, or computational, using sophisticated models of synaptic adaptation in the face of extremely simplified models of individual neurons, but rarely both conventional and computational.

There are suggestions that modeling should really proceed top-down, from the definition and computational decomposition of abstract tasks to the reductive neural implementation. However, such a strict policy is not productive as a strategy for analyzing neural systems, because it means throwing away constraints from the experimental data, and because it relies on adequate, multi-level accounts of the underlying computational tasks, which we currently lack. Instead, both conventional and computational modeling at multiple levels should progress together.

CONTENTS

Long-term potentiation and depression are enduring changes in synaptic efficacy following brief high-frequency or low-frequency electrical stimulation of nerve fibers. Both are considered to be candidate mechanisms of learning and memory.

INTRODUCTION

It is widely believed that memories are stored in the brain as modifications of the synaptic strength between neurons. As new events are experienced, the synaptic connections between neurons increase and decrease in order to encode the memory within the specific network of neurons that are active during the event. When memories are recalled, it is believed that the same patterns of synaptic connections are reactivated in order to recreate the image or event being remembered. The leading experimental models used to study the cellular mechanisms underlying learning and memory include an activity-dependent increase in synaptic strength, known as long-term potentiation (LTP), and an activity-dependent decrease in synaptic strength, called long-term depression (LTD). Most studies continue to examine these two forms of plasticity in the hippocampus, a region of the brain critical for learning and memory processes. In addition, these forms of plasticity have been found in other structures of the brain such as neocortex, cerebellum, and peripheral nervous system. (*See* **Long-term Potentiation, Discovery of**)

The Hippocampus

The hippocampus derives its name from the Latin word for 'seahorse', because of its characteristic shape like the letter C (Figure 1). The hippocampus is composed of an evolutionarily older cortex that contains only three layers of cells, unlike the newer cortex (neocortex), which contains seven layers of cells. The hippocampus consists of the hippocampus proper (fields CA3, CA2, and CA1) and the dentate gyrus. The interconnections of neurons within the hippocampus make up what is known as the 'trisynaptic circuit'. Information enters the hippocampus through axons of the perforant path, which synapse onto dentate granule cells. The axons of dentate granule cells form a bundle of

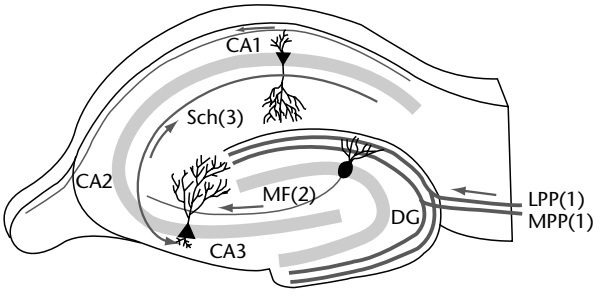

Figure 1. The trisynaptic circuit in a transverse section through the hippocampus of the rat. Shaded areas show the principal cell layers: granule cells of the dentate gyrus and the pyramidal cells of areas CA3, CA2, and CA1. There are three major excitatory pathways: 1, the perforant pathway (lateral/medial) from the entorhinal cortex to the dentate gyrus granule cells; 2, the mossy-fiber pathway that extends from the granule cells to the CA3 pyramidal cells; 3, the Schaffer collaterals which project from the CA3 pyramidal cells to the CA1 pyramidal cells. The arrows show the direction of information flow. DG, dentate gyrus; MF, mossy fibers; LPP, lateral perforant path; MPP, medial perforant path; Sch, Schaffer collaterals. Adapted from Bliss and Collingridge (1993).

fibers (the mossy fibers), and these synapse onto CA3 pyramidal cells. The CA3 pyramidal cells then send their axons to the pyramidal cells in CA1 via the Schaffer collateral pathway. Several forms of LTP and LTD have been identified in each of these pathways, some of which are discussed below.

LTP and LTD as Information Storage Devices

One of the major questions in neuroscience is whether LTP and LTD act as information storage devices. To answer this question, we must first explain how LTP works.

To date, most studies have focused on the properties of LTP in the Schaffer collaterals to CA1 (Figure 2). Electrodes can be placed within the cell body or dendritic layer of CA1 in order to record the basal synaptic activity of pyramidal neurons evoked by single electrical stimulations. After a stimulation, the axons of the CA3 neurons will release neurotransmitters (glutamate) into the synapse between the CA3 axon (presynaptic element) and the dendrites of the CA1 cells (postsynaptic element), causing the CA1 cell to respond by producing an excitatory postsynaptic potential (EPSP). By measuring the slope of the EPSP or the amplitude of the response, one can determine how the synaptic connections between these neurons change following electrical stimulation. Applying high-frequency stimulation (100 Hz) to the axons of the Schaffer collaterals causes a large, long-lasting increase in the slope and amplitude of the EPSP recorded in the CA1 neurons; this long-lasting increase in EPSP response is referred to as LTP. Alternatively, low-frequency stimulation (1–5 Hz) causes a long-lasting decrease in the EPSP response known as LTD (Figure 3).

How might this form of plasticity be used to store information? It is believed that information can be stored within the synaptic connections between neurons. If a group of neurons are activated following high-frequency stimulation causing the postsynaptic cells to persistently respond with greater intensity, then a 'memory' for that event has been stored at these synapses, allowing an enhanced response to the same synaptic input. Similarly, LTD could be induced in the surrounding fibers to reduce the synaptic activity, thereby increasing the signal-to-noise ratio, or LTD could be induced in the same fibers to return formerly potentiated responses back to baseline to perhaps erase a memory. Together, these two forms of plasticity provide an attractive model to explain how memories are stored in the brain.

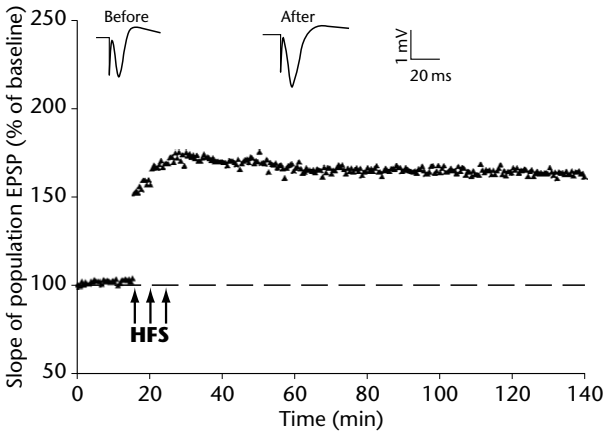

Figure 2. Long-term potentiation (LTP) in the Schaffer collateral CA1 pathway of rat hippocampus *in vivo*. The slope of a population excitatory postsynaptic potential (EPSP), i.e. the initial slope of the larger and slower deflection (see the traces in the insets), is plotted versus time. The population EPSPs are evoked by single shocks in presynaptic Schaffer collaterals (axons) and recorded extracellularly in the postsynaptic CA1 dendritic area at 15 s intervals. Delivery of three trains of high-frequency stimulation (HFS, 1 s of 100 Hz) separated by 5 min induces LTP lasting for hours. Traces in the insets (before/after tetani) show the change of population EPSP (i.e. the postsynaptic response).

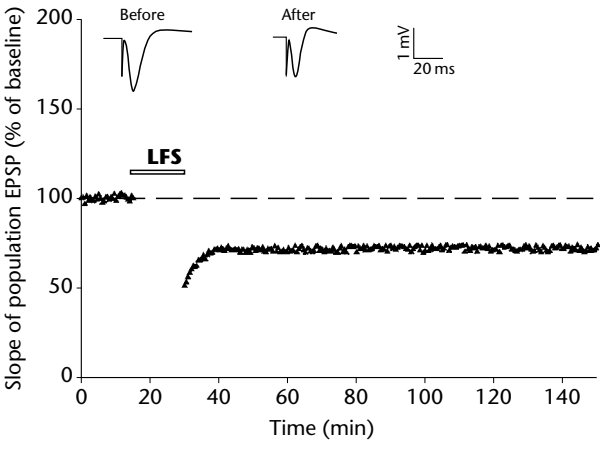

Figure 3. Homosynaptic long-term depression (LTD) in the Schaffer–CA1 pathway in rat hippocampal slices. The extracellular population excitatory postsynaptic potential (EPSP) recorded in CA1 dendrites is plotted against time. The LTD is induced by low-frequency stimulation (LFS, 900 pulses at 1 Hz). Traces in the insets (before/after tetani) show the change of population EPSP. Adapted from Lee *et al*. (2000) *Nature* **405**: 955–959.

DISCOVERY OF LTP

Although it is generally agreed that LTP was discovered by Bliss and Lomo in 1973, the story dates back to the 1950s, when the precisely organized afferent systems in hippocampal and associated structures were revealed by scientists in Oxford and Oslo. At that time, just a few groups of neurophysiologists, such as Per Andersen in Oslo, John Green and Ross Adey in Los Angeles, and Eric Kandel and Alden Spencer in Karl Frank's laboratory at the National Institutes of Health, were interested in taking advantage of this unique hippocampal arrangement to study central synaptic transmission and epileptic phenomena.

In the early 1960s, Kandel and Andersen intracellularly recorded the synaptic transmission to the pyramidal cells in the hippocampus. At that time, these researchers generally knew that repetitive electrical stimulation with moderate strength and duration could increase signals of neural cell discharges, and this proved useful in their experiments. When the signals were fading, they could be easily recovered by turning the stimulus rate to a higher frequency for a few seconds. When Terje Lomo joined Andersen's laboratory, this phenomenon of frequency potentiation elicited his interest. In 1966, he reported his pioneering observations that repetitive stimulation (6–50 Hz) of the perforant path fibers induced a large potentiated response. This response was seen as an increase in the amplitude and a decrease in the latency of the population spike (population action potentials, i.e. synchronous firing of action potentials by a group of neural cells) lasting for hours, depending upon the stimulation frequency.

Later, Timothy Bliss joined Lomo in Oslo, and started to systematically examine this phenomenon of frequency potentiation in the hippocampus. Before long, their collaborative effort led to the well-known paper published in the *Journal of Physiology* in 1973. This was the first time that long-term potentiation was quantitatively described. In anesthetized rabbits, Bliss and Lomo measured the amplitude of the population EPSP (i.e. summation of postsynaptic potentials) and the amplitude and latency of the population action potential extracellularly, following stimulation of the perforant path fibers to the dentate area with single shocks. In general, the levels of the population EPSP and action potential remained stable over time; but when a short train of shocks was applied at a high frequency (e.g. 15 Hz for 15 s) to the synapses, both measurements rose sharply and remained elevated for hours afterwards. In a subsequent paper, Bliss and Gardner-Medwin repeated these experiments on unanesthetized rabbits, and the effect of potentiation lasted for months. However, in most of the original publications, the term 'long-lasting potentiation' was used until the term 'long-term potentiation' was introduced by Douglas and Goddard in 1975. Since then, the acronym LTP has been generally adopted because it is easier to pronounce than alternatives such as LLP (long-lasting potentiation), LTE (long-term enhancement) or LTSE (long-term synaptic enhancement). In 1977, the first intracellular measurements of LTP in transverse hippocampal slices were made by Andersen and co-workers. They observed both an enhanced EPSP and an increased probability of firing action potential, verifying Bliss and Lomo's original findings through extracellular measurements.

Not unexpectedly, LTP has attracted great attention because it has been and still may be the best candidate mechanism for the information storage in the brain. Much of the subsequent work on LTP has focused on exploring its properties, the conditions required for its induction, mechanisms of its induction and maintenance, and its correlations with learning and memory. In addition to the high-frequency electrical stimulation used by Bliss and Lomo, many other stimulus patterns have been found to efficiently induce LTP. These include theta burst stimulation (TBS) – several short, high-frequency (e.g. 100 Hz) bursts of a few pulses delivered at an interburst interval of 200 ms, which mimics the endogenous hippocampal theta rhythm in rats, and primed-burst stimulation – a single priming stimulus followed 200 ms later by a burst of four shocks at 100 Hz. Subsequently, different forms of LTP have been observed in a variety of brain structures and species as described below.

LONG-TERM POTENTIATION

Properties of LTP: The Hebbian Synapse

Since its discovery, LTP has attracted the attention of numerous scientists because it has properties that are highly suggestive of an information storage device. In addition to its long-lasting nature (several hours in an anesthetized animal, and days or even weeks in an awake, freely moving animal), LTP has three distinguishing properties: cooperativity, associativity, and input specificity. Cooperativity occurs following stimulation of a sufficient number of afferent fibers to collectively surpass a

stimulus threshold necessary to induce LTP. Subthreshold stimulation or stimulation of too few fibers will not, on its own, induce LTP. One of the more intriguing properties of LTP, known as associativity, led some researchers to suggest that it is a memory mechanism. For instance, if a weak (subthreshold) stimulation in one afferent is simultaneously paired with a strong (suprathreshold) stimulation in a separate afferent to the same cell population, then the weakly stimulated afferent also exhibits LTP. This may be relevant to associative or relational features of learning and memory, because associative induction implies the capacity to relate two arbitrary patterns of pre- and postsynaptic neural excitation. Finally, LTP is input-specific, because only the tetanized afferents show potentiation, whereas other inputs to the same neurons that are not active at the time of the tetanus do not exhibit LTP. A synapse-specific mechanism might endow greater storage capacity than would changes in cell excitability.

As a physiological model, LTP more closely resembles the plastic synapse that Hebb postulated for associative learning than anything else presently available. In his now-classic 1949 book, *The Organization of Behavior*, Donald Hebb proposed:

> When an axon of cell A is near enough to excite cell B and repeatedly or persistently takes part in firing it, some growth process of metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased.

In other words, the process of learning involves intense or repeated activity at particular synapses, which become stronger as a result of the activity of the pre- and postsynaptic cells. This associative strengthening of synapses that are active during the learning process in turn forms the 'memory' of what has been learned. The synapses that are modified in this manner are referred to as 'Hebbian synapses'. Hebb's postulate is very close to the definition of LTP.

The Hebbian concept that memory depends on the modification of neuronal synapses, or synaptic plasticity, has led scientists interested in the cellular basis of memory to focus their research on elucidating the processes of LTP and the molecular mechanisms underlying these processes.

Mechanisms of LTP

Two major forms of LTP have been identified in the hippocampus and a variety of other tissues (see below). One form requires the activation of *N*-methyl-D-aspartate (NMDA) receptors, known as NMDA receptor-dependent LTP, while the other, NMDA receptor-independent LTP, does not require activation of such receptors. (*See* **Neurotransmitters**)

NMDA receptor-dependent LTP

In most regions of the hippocampus, the induction properties of LTP can largely be attributed to a specialized receptor called the NMDA receptor. These receptors are a unique subtype of voltage-dependent glutamate receptors. For the induction of LTP, the NMDA receptor must be activated by the neurotransmitter glutamate and simultaneously there must be sufficient depolarization of the postsynaptic membrane to relieve a magnesium ion block in the NMDA receptor-associated ion channel. Release of this Mg^{2+} block subsequently allows the entry of calcium ions into the postsynaptic terminal. The calcium ion influx activates any number of Ca^{2+}-sensitive second-messenger cascades, including various protein kinases and phospholipases. Because optimal activation of NMDA receptor channels requires both presynaptic transmitter release and postsynaptic depolarization, the NMDA receptors act as Hebbian coincidence detectors. Thus, activated NMDA receptors at synapses that are close to active sites of depolarization may be depolarized sufficiently to relieve the magnesium ion block and initiate the cascade of events that leads to LTP induction. This cascade may occur even though the activity of that particular synapse alone was not sufficient to induce LTP. Thus, NMDA receptors can account for the association of two separate afferent projections to the same cell, one strongly and the other weakly active, and for the cooperative requirement that a threshold number of fibers be active.

The maintenance of NMDA receptor-dependent LTP is less well understood. It is generally agreed that LTP has distinct temporal phases. The short-term early phase of LTP lasting about 1 h requires only covalent modification of preexisting proteins, such as protein kinase activation and protein phosphorylation. Long-term potentiation can be further maintained and converted to the more stabilized form, late-phase LTP, when accompanied by new protein synthesis from existing messenger ribonucleic acid (mRNA) molecules and gene expression. There are at least three possible explanations for the cascades of events that lead to the expression and maintenance of NMDA receptor-dependent LTP: an increase of presynaptic glutamate release; an increase in the number of postsynaptic glutamate receptors; and morphological changes that favor efficacy of synaptic transmission.

NMDA receptor-independent LTP

In 1986, Harris and Cotman discovered that unlike LTP in CA1, the induction of mossy-fiber LTP was not dependent on the activation of NMDA receptors, and could be reliably induced even in the presence of NMDA receptor antagonists, suggesting that this pathway uses different mechanisms for the induction and expression of LTP. This form of LTP is also be found in the lateral perforant path to the dentate gyrus and CA3 (see Figure 1).

In accordance with the finding that LTP in the mossy-fiber and lateral perforant pathways does not require the activation of NMDA receptors, immunohistochemical studies demonstrate that the synaptic terminals of these pathways contain sparse numbers of NMDA receptors and large numbers of opioid receptors. In an attempt to identify the mechanisms for mossy-fiber LTP induction, it was found that the mossy-fiber and lateral perforant pathways contain and release opioid peptides. Studies have shown that the induction of mossy-fiber LTP is blocked by the opioid receptor antagonist naloxone. At least two mechanisms of opioid receptor-dependent LTP induction exist in the hippocampus. Induction in the mossy fiber to CA3 and lateral perforant to CA3 pathways depends on the activation of μ, but not δ, opioid receptors, whereas induction in the lateral perforant to dentate pathway depends on both μ and δ opioid receptors.

The cellular and molecular mechanisms required for the induction and expression of mossy-fiber LTP and the site of induction, either presynaptically or postsynaptically, remain a heavily debated issue. There is evidence to suggest that mossy-fiber LTP induction is dependent on brief high-frequency stimulation (with a minimum of 30 pulses at 100 Hz) sufficient to (a) depolarize the postsynaptic cell and activate voltage-gated Ca^{2+} channels, and (b) release opioid peptides and activate μ opioid receptors. This leads to an increase in intracellular Ca^{2+} levels in addition to the activation of group I metabotropic glutamate receptors, which results in the release of calcium ions from internal stores. This, in turn, acts through a signal transduction pathway mediated by cyclic adenosine monophosphate (cAMP) to activate protein kinase A and induce new protein synthesis. The requirement for cAMP-mediated signal transduction has also been found to be involved in the presynaptic mechanisms associated with mossy-fiber LTP induction and expression. Additionally, endogenously released opioids may induce mossy-fiber and lateral perforant path LTP indirectly by reducing inhibition, or disinhibiting the synapses, allowing LTP to occur. Taken together, these data suggest that activation of μ opioid receptors plays an important part in the induction of mossy-fiber and lateral perforant path LTP in area CA3.

Like the NMDA receptor-dependent LTP, the induction of mossy-fiber LTP in hippocampal slices (*in vitro*) also has a protein-independent early phase and a protein-dependent late phase. However, Barea-Rodríguez and co-workers have provided evidence suggesting that protein synthesis is necessary for mossy-fiber LTP induction in anesthetized rats (*in vivo*). This may be due to the significant differences in time course between these two forms of LTP: in contrast to its rapid onset *in vitro*, mossy-fiber LTP *in vivo* has a very slow onset and takes about 1 h to reach its maximum augmentation.

LTP at Various Brain Sites

Most of our knowledge about the properties and potential mechanisms of LTP comes from studies in the rodent and rabbit hippocampal formation. This is due not only to the discovery of LTP in the hippocampus, but also to the distribution of LTP which, in various forms, is evident at the three principal synaptic connections in hippocampus (see Figure 1): in the dentate gyrus granule cells by stimulation of the perforant pathway as originally described by Bliss and Lomo, in the CA3 pyramidal cells by stimulation of the mossy fibers, and in the CA1 pyramidal cells by stimulation of the Schaffer collateral branches of the CA3 neurons.

Long-term potentiation has also been well examined in the intrinsic connections of the neocortex such as the somatosensory, visual, and motor neocortex, which function as a structure for long-term storage. Associative Hebbian LTP can be reliably induced in the superficial layers of the neocortex, using high-frequency stimulation at the middle layers of cortex in anesthetized animals or in slice preparations. It is input-specific and dependent on activation of postsynaptic NMDA receptors. In contrast, for the induction of neocortical LTP in adult, freely moving rats, the stimulation trains must be spaced and repeated over a period of days. Tetanic stimulation of the white matter, in sharp contrast, consistently failed to elicit LTP in the superficial layer of cortex unless a γ-aminobutyric acid (GABA) type A receptor antagonist was applied, or the white matter and the middle layer simultaneously received tetanic stimulation.

It is well known that the entorhinal cortex sends much of its output both to the hippocampus and back to the neocortex. Although the entorhinal

cortex receives inputs from various cortical sites, its major inputs are the projections from the perirhinal cortex and the parahippocampal cortex, which receive their inputs from sensory and association cortices. Long-term potentiation is found in all pathways between the hippocampus and neocortex, but the induction and the decay are slower in the neocortex than in the hippocampus and associated structures, which may reflect some aspects of LTP in memory processing.

With few exceptions, such as the lateral olfactory tract, LTP can be produced throughout the limbic system (amygdala, entorhinal cortex, dentate gyrus, subiculum, septum, and hippocampus), although the LTP is relatively larger in the hippocampal pathways. Because of its good correlation with emotional learning and memory, LTP in the amygdala is also extensively studied as a laboratory model. The first examination of LTP in the amygdala was performed in awake rats by stimulation in the piriform cortex. More recently, LTP has been reported in both thalamoamygdala and hippocampoamygdala projections *in vivo*. There are two forms of LTP in the amygdala: the NMDA receptor-dependent LTP in the basolateral nucleus, and a form of LTP dependent on α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors in the interneurons.

In addition to the brain structures described above, LTP can also be induced in the deep nuclei of cerebellum by stimulation of the inferior peduncle fibers, the ventral horn of spinal cord by stimulation of the dorsal horn–intermediate nucleus region, and the superior cervical ganglion by stimulation of the preganglionic nerves. Furthermore, LTP is not only limited to the mammalian brain, such as rabbits, rats, monkeys, and humans, but has been described in other vertebrates as well, including goldfish, bullfrogs, birds, and lizards. It has also been found in some invertebrates, suggesting that phenomena fitting the general description of LTP occur ubiquitously throughout the nervous system.

LONG-TERM DEPRESSION

Long-term depression is characterized by a depression of evoked synaptic responses. It was first described in the hippocampus and was induced by persistent low-frequency stimulation (typically 1–5 Hz for 5–15 min). Studies have now shown that 900 pulses of 1 Hz stimulation can reliably induce LTD in the Schaffer collaterals to CA1 (Figure 3). This form of LTD is induced only in the specific fibers that receive stimulation, and hence is termed 'homosynaptic' LTD. This process is interesting because it suggests that it could serve as a mechanism for forgetting, following studies demonstrating that LTD induced in previously potentiated synapses would return synaptic responses back to baseline levels. It could also serve to enhance recent representations by depressing synapses that are less active, and therefore sharpen sparsely encoded memories. The finding that LTD requires postsynaptic factors, including NMDA receptor activation, suggests a more direct role for LTD in information storage.

Long-term depression is also found in the cerebellum. Evidence indicates that the cerebellum is important in eyeblink classical conditioning. Indeed, the memory trace of this form of learning is localized in the cerebellum. Although LTP may be induced in the cerebellum, the predominant form of plasticity observed in this structure is LTD. Studies have indicated that LTD may be a neural substrate for the conditioned eyeblink response in the cerebellum. One research group found that mice lacking one type of glutaminergic receptors did not exhibit LTD and were impaired in learning a conditioned eyeblink response.

Mechanisms of LTD

Studies investigating the mechanisms of LTD induction in the hippocampus focus on homosynaptic LTD in the CA1 region. Interestingly, the mechanisms of LTD induction are similar to those underlying homosynaptic LTP in that both postsynaptic calcium ion influx and NMDA receptor activation are necessary. Although both calcium ions and NMDA receptors are necessary for LTD induction in CA1, it seems that the intracellular Ca^{2+} concentration determines whether LTP or LTD is induced. According to some studies, a small influx of calcium ions, which produces a low intracellular Ca^{2+} concentration, may activate selective protein phosphatases (calcineurin) whose actions lead to the induction of LTD. Selective inhibitors of protein phosphatases block the induction of LTD in CA1. Thus, LTD induction, at least in CA1, may require the activation of protein phosphatases.

Researchers suggest that LTD occurs when conditions approach, but do not meet, the requirements for LTP induction. This may serve as a mechanism of contrast enhancement, and ensure that a minimum number of synapses contribute to a given representation.

CONCLUSION

Although their relationship with learning and memory remains controversial, we believe that LTP and LTD are the best candidates for a cellular process of synaptic change that underlies learning and memory in the vertebrate brain. The absence of proof that LTP and LTD are involved in memory results from the current uncertainties about what a memory is and how we should observe it. Are the different forms of LTP and LTD associated with the different forms of memory known to exist? The fact that there are multiple forms of LTP and LTD, together with the distributed nature of information storage, makes it difficult to identify the processes necessary for memory known to implicate specific cellular processes in behavioral measures of memory. The same may be true for cerebellum-related learning.

Long-term Potentiation, Discovery of

Introductory article

Preston E Garraghty, Indiana University, Bloomington, Indiana, USA

CONTENTS

Long-term potentiation is an increase in the strength of connections between neurons due to changes in the inputs to a neural circuit. It is widely regarded as the best model for studying the ways the brain changes as we learn and remember.

INTRODUCTION

Long-term potentiation (LTP) is a persistent change in the strength of connections between neurons. It has been studied intensively and extensively, as it represents the best current model of how memories might be stored in the brain. More specifically, it serves as a potential means by which associations might be formed and maintained.

The first formal explication of learning through association can be attributed to the seventeenth-century British philosopher, Thomas Hobbes. Hobbes was the first proponent of a philosophy of mind based on the assumption that nothing exists aside from matter and energy, and consequently that all human behavior can be understood materialistically – that is, in terms of physical processes, particularly in the brain. Hobbes' principle of association stated that ideas come to be thought together if their corresponding sensations occurred together initially. These ideas included ones of reward and punishment, and thus, how the anticipated consequences of actions could influence their probabilities. Hobbes' ideas proved to be profoundly influential, helping to stimulate the development of a philosophy of mind that came to be known as British empiricism. According to the British empiricists, the mind of a newborn is a *tabula rasa* (blank slate) on which is written the associations between elementary ideas that arise from sensory experience. These associations permit thought, and the construction of consciousness.

This notion of learning by association proved to be a powerful idea in the emergence of experimental psychology, but it was not until the serendipitous discovery of classical conditioning by the Russian physiologist, Ivan Pavlov, that an experimental paradigm became available to rigorously evaluate learning by association in a scientific context.

Pavlov demonstrated that after a formerly neutral stimulus (a tone) has been systematically paired with a stimulus (food powder) that naturally elicits a reflexive response (in this case, salivation), the tone comes to 'stand for' the food powder, and elicit a salivation response. In this particular instance, Pavlov termed the food powder the 'unconditional stimulus' (US) and the salivation it elicited the 'unconditional response' (UR), as the former elicited the latter unconditionally. The tone and the salivation response it came to elicit were termed the 'conditional stimulus' (CS) and 'conditional response' (CR) respectively, as the former came to elicit the latter only because of the experimentally imposed conditional relationship between the CS and the US. Pavlov believed that the process of conditioning reflected a strengthening of the connection between a brain region representing the CS and a brain region representing the US. Thus, in his view, as conditioning proceeds, increasing levels of CS-evoked neural excitation spread to the US brain area, and evoke the response. In the language of the British empiricists, the 'idea' of the CS (evoked by its presentation) becomes associated with the 'idea' of the US because the conditioning procedures ensured that the two ideas would be temporally contiguous. Learning by association became an assumption, yet the neural mechanisms were completely unknown.

Memories reflect changes in an organism arising from experience. The minimal requirement for a physiological demonstration of learning is simply to demonstrate that existing synaptic connections can be strengthened as a function of experience.

The first demonstration of learning-related neural plasticity was made quite by chance. In 1935, Durup and Fessard were recording electroencephalographic (EEG) activity in a human subject, as they investigated how a particular EEG rhythm (alpha) ceases when the subject is in an illuminated versus a darkened environment. Thus, they simply switched the lights on and off, and monitored the resulting changes in the recordings. This proceeded for a number of transitions, but on one trial, the switch failed to illuminate the room as expected because the bulb failed. Even though the room remained darkened, the alpha rhythm ceased as if the room had been illuminated. Additional experiments revealed that the sound of the light switch had become a CS because it had been reliably paired with illumination (the US), and thus, came to elicit a CR (alpha reduction). This clearly represented a learning-related change in brain activity, but it reflected changes at literally millions upon million of synapses. Certainly, the acquisition and storage of some bit of information, say the abbreviation of 'long-term potentiation', has affected far fewer of your synapses.

Scientists continued to search for evidence of changes in synaptic strength at individual synapses, and, in 1947, Larrabee and Bronk provided such evidence at a far more 'local' level. They recorded the summed activity of neurons in the stellate ganglion of cats while stimulating preganglionic axons. Any change in the amplitude of the postganglionic response would reflect the effects of the stimulation. They found that a brief period of repetitive (tetanic) stimulation was followed by an increase in the magnitude (potentiation) of the postganglionic response that persisted for about three minutes (post-tetanic potentiation). Clearly, three minutes of strengthened synaptic transmission cannot account for the persistence of memory, but these results clearly demonstrated changes in the strength of connections as a function of experience.

DISCOVERY OF LTP

In 1973, Bliss and Lomo reported that repeated, intense stimulation of projections to and within the hippocampus (the perforant pathway, the mossy fibers or the Schaffer collaterals; Figure 1) resulted in enhanced neuronal responsiveness of postsynaptic hippocampal neurons. This increased synaptic strength persisted for weeks, making this the first demonstration of sustainable changes in synaptic connectivity in the mature brain. Donald Hebb had predicted in his 1949 book, *The Organization of Behavior*, that such sustainable changes in the strength of neural connections must be possible if one is to account for such behavioral phenomena as learning and memory. Many behavioral neuroscientists and computational modelers now refer to changes in synaptic strength (or weight) as being due to 'Hebbian-like' processes.

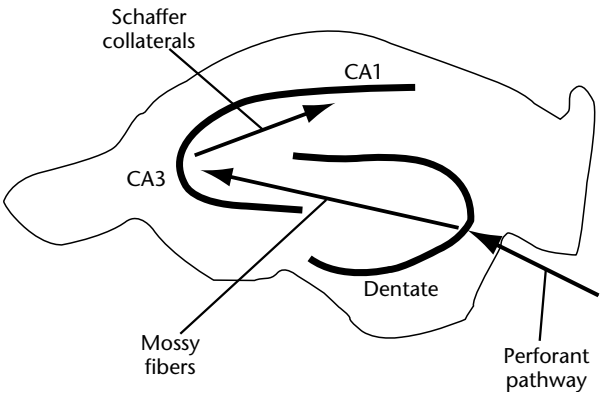

Figure 1. A cross-section through the hippocampal formation. The perforant pathway represents the primary extrinsic input into the hippocampus. Fibers of this pathway synapse with neurons in the dentate. Dentate neurons project as mossy fibers onto neurons in the CA3 region of the hippocampus; CA3 neurons synapse with CA1 neurons via Schaffer collaterals. Tetanic stimulation of any of these fiber tracts can produce long-term potentiation in the target neurons.

Since the classic Bliss and Lomo study, LTP has been observed in many other brain areas, such as the cerebellum and cortex, and has been fairly well accepted as an exemplar of a biological model of learning and memory.

PUTATIVE MECHANISMS OF LTP

It must be noted at this juncture that there are multiple forms of what can be called LTP. Here we will look at a form of hippocampal LTP that is dependent upon a particular subset of glutamatergic receptors (glutamate is the principal excitatory neurotransmitter in the brain), but even in mammalian hippocampus at least one other form of LTP exists, and it is dependent on opioid peptides and not glutamate. (*See* **Neurotransmitters**)

To address issues related to the mechanisms of LTP, at least a rudimentary knowledge of hippocampal anatomy is necessary. Information coming into the hippocampus arrives in the dentate via the perforant pathway. From there, mossy fibers project to area CA3 (CA is derived from *cornu ammonis*, another name for the hippocampus), which in turn projects to area CA1 via Schaffer collateral fibers

(Figure 1). Feedforward inhibitory modulation is present in the dentate and CA1 layer, utilizing the inhibitory neurotransmitter GABA (γ-aminobutyric acid). Importantly, these inhibitory loops are activated only during repeated bursts of activity (i.e. tetanus: a level that is significantly higher than 'normal' synaptic transmission).

The development of LTP requires not only a sufficient level of presynaptic activity, but also temporally correlated activation of postsynaptic neurons. Stimulation of the presynaptic circuits (inputs) can clearly account for the first requisite, and a reduction in postsynaptic inhibition has been proposed to 'prime' the circuit for synaptic potentiation. That is, hippocampal feedforward inhibitory circuits are active only when the stimulation intensity is sufficient to evoke bursting of projection neurons (as opposed to tonic firing levels). Support for the notion that changes in inhibitory influences play a part in the development of LTP has come from studies showing that the application of compounds that reduce inhibition facilitates the induction of LTP, while increasing inhibition attenuates LTP.

Glutamate is the primary neurotransmitter used for propagation of information through the hippocampus. As with all known neurotransmitters, glutamate is a ligand for several classes of postsynaptic receptors, including NMDA and AMPA receptors – so called because exogenous compounds with those acronyms (NMDA, *N*-methyl-D-aspartate; AMPA, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid) bind selectively to those subsets of glutamate receptors. These receptor subtypes differ in two important functional respects. First, unlike the classic excitatory postsynaptic receptor that opens sodium channels when bound with a neurotransmitter molecule, the NMDA receptor gates calcium channels. Second, this gating of calcium ions occurs only when the ligand is present and the postsynaptic membrane is relatively depolarized with respect to its resting potential. Thus, AMPA receptors are ligand-gated while NMDA receptors are ligand- and voltage-gated. Therefore, activation of AMPA receptors simply requires presynaptic activity, whereas activation of NMDA receptors requires presynaptic activity and residual depolarization due to recent excitatory and/or disinhibitory inputs. In sum, AMPA receptors are used for routine cellular communication, whereas the NMDA receptor system appears to be recruited when inputs are out of the ordinary (e.g. tetanic stimulation).

At least one form of LTP is dependent upon the NMDA subset of glutamate receptors for its initiation. That is, application of compounds that block NMDA receptors attenuate the induction of LTP in the CA1 region of the hippocampus, while compounds that activate NMDA receptors accentuate the response. After LTP is induced, however, blockade of NMDA receptors fails to prevent its continued expression. This finding suggests that other mechanisms are responsible for the maintenance of the increased synaptic strength once it has been established, and it has been reported that the number of postsynaptic AMPA receptors was elevated in the hippocampus of rats after LTP had been established. This increase in AMPA receptor number would clearly result in larger depolarizations arising from excitatory synaptic inputs. Thus, for this form of long-term potentiation, NMDA receptors are necessary for its induction while AMPA receptors are necessary for its maintenance.

ATTEMPTS TO RELATE LTP TO LEARNING AND MEMORY

There are a number of reasons why LTP has been so fervently embraced as a model of learning and memory.

1. LTP can be induced by conditioning stimuli within the physiological range; that is, the frequencies of stimulation used are not unlikely to occur in the intact nervous system.
2. Unlike post-tetanic potentiation, LTP can last for weeks.
3. It is most prominent in brain regions that are strongly implicated in learning and memory (for example, the hippocampus and neocortex).
4. It does not occur in the absence of tetanic stimulation, and, presumably, such increased firing rates in the intact system would reflect the processing of inputs having increased relevance to the organism (Figure 2).
5. Associativity can occur whereby a weak input can be strengthened if its stimulation is paired with tetanic stimulation of strong inputs (Figure 2).
6. Long-term potentiation requires the Hebbian property of correlated presynaphic and postsynaptic activity.
7. Pharmacological interventions that block LTP induction have also been shown to impair some forms of learning. For example, NMDA receptor antagonists that block the induction of LTP also interfere with spatial learning in rats. Blocking NMDA receptors impairs the learning of a Pavlovian discriminated eyeblink reversal in rabbits and the acquisition of a tone-signaled avoidance response after appetitive instrumental training in rats.
8. Mutant mice in whom hippocampal LTP is severely attenuated show learning deficits.
9. The blockade of NMDA receptors interrupts neural plasticity in animal models in studies of injury-induced brain plasticity, and it seems reasonable to

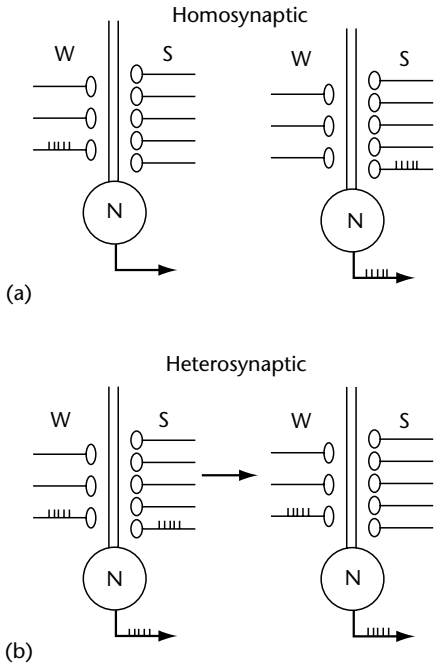

Figure 2. (a) Homosynaptic facilitation reflects the strengthening of a set of connections due to appropriate patterns of stimulation of the presynaptic fibers. On the left, the 'W' reflects either weak stimulation or the stimulation of a set of inputs with weak connections (the series of vertical lines represents stimulation of this pathway). There is no change in the output of the neuron receiving the synapses (N). On the right, the 'S' input represents a strong tetanic stimulation, and the increase in the responsiveness of the postsynaptic neuron is represented by the series of vertical lines on its axon. The association here relates to the increased correlation between pre- and postsynaptic activity. (b) Heterosynaptic facilitation reflects the strengthening of a weak set of inputs because of a correlation with a strong set of inputs. This is reflected on the right where the weak inputs have gained strength because of their correlation with the strong inputs (left).

assume tentatively that altering inputs using nerve injuries is akin to altering inputs with tetanic stimulation or the demands of some learning tasks.

CONCLUSION

The reasons that NMDA-dependent LTP has been suggested as a model of learning and memory are compelling. It must be recognized, however, that they represent a series of inferences. Using the language of jurisprudence, the above-listed set of observations represent circumstantial evidence, not an eyewitness account. Thus, it is prudent to view NMDA-dependent LTP as an interesting model of synaptic plasticity that may represent the neural substrate for some manifestations of learning and memory. It is also important not to lose sight of the fact that several forms of synaptic facilitation have been demonstrated that are not dependent on NMDA glutamatergic receptors. Thus, the brain has at its disposal a number of mechanisms by which synapses can be strengthened; no one of them is likely to emerge as the sole substrate of learning and memory. Finally, the emphasis throughout this brief review has been on how synaptic couplings can be strengthened. It is of crucial importance to recognize that reductions in synaptic efficacy are likely to be as important for learning and memory in particular, and neural flexibility in general, as LTP.

McCulloch–Pitts Neurons

Intermediate article

James A Anderson, Brown University, Providence, Rhode Island, USA

CONTENTS

The 'McCulloch–Pitts neuron' is an abstraction of the computational functions of a biological neuron. This model 'neuron' has two states, on or off, it sums activation from other neurons, and it enters the on-state when the sum of its inputs exceeds a threshold. Networks composed of such abstract "neurons" can compute any finite logical expression.

ASSUMPTIONS

In 1943, Warren S. McCulloch and Walter H. Pitts wrote a paper for the *Bulletin of Mathematical Biophysics* entitled 'A logical calculus of the ideas immanent in nervous activity'. In this article, generally considered to be the first and most influential paper on neural network modeling or computational neuroscience, McCulloch and Pitts boldly proposed a model both of the neuron and of what groups of such neurons could compute.

The paper proposed several assumptions that formally defined what has since been known as the *McCulloch–Pitts neuron*. First, 'the activity of the neuron is an "all-or-none" process' – that is, it is a binary unit that can exist in only two states. These states can be variously interpreted as on or off, zero or one, active or inactive or, most portentously of all, true or false. Secondly, the neuron can be connected to other neurons and to input lines. For a neuron to become active, a certain number of input connections ('synapses') had to be excited within a specific time period. This assumption as usually implemented contained three parts. (1) All synapses have the same strength. The connections, as well as the neurons, are 'all or none'. (2) Time in the network is quantized in units of time based on the integration time needed to sum the active synapses. (3) Each neuron has a threshold – that is, the number of simultaneously active synapses required to put the neuron in the active state.

There are several less important assumptions. First, the only significant time delay in the nervous system is the delay that even then was known to exist at synapses. Secondly, there is no learning – that is, connections and neuron thresholds do not change with use. Thirdly, inhibition is absolute – that is, any active inhibitory synapse forces the neuron into the inactive state. The paper referred to above itself shows that this form of inhibition is not necessary, and that subtractive inhibition gives the same results.

Figure 1 shows a simple McCulloch–Pitts neuron. The original notation used in the 1943 paper is opaque and is now rarely used. The notation used here is that employed by Minsky in his classic book, *Computation: Finite and Infinite Machines* (Minsky, 1967), which discusses the properties and uses of McCulloch–Pitts neurons in considerable detail. The neuron in Figure 1 has two excitatory inputs, a and b, denoted by arrows. It has a threshold of 1. Suppose that during the nth time quantum neither synapse a nor synapse b is active. Therefore there are no active synapses and the neuron threshold of 1 has not been exceeded, so during the $(n+1)$st time quantum this neuron is in the inactive state. Suppose, however, that during the nth quantum input a is active and input b is inactive. The number of active inputs is one, the threshold has been reached, and the neuron becomes active during the next time step. Similarly, if input b is active and input a is inactive, or if both input a and input b are active, the unit will become active.

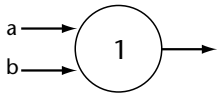

Figure 1. A single McCulloch–Pitts neuron with threshold 1 and two inputs, 'a' and 'b'. This neuron realizes the logic function 'Inclusive OR' because, in words, the unit becomes active when 'input a is active' OR 'input b is active' OR 'both inputs a and b are active'. Arrowheads correspond to excitatory (positive) connections.

There are four possible activity states of the two inputs, a and b, each of which leads to the unit becoming active or inactive during the next time quantum. If these states are enumerated, it can be seen that the unit is realizing the truth-table of the logic function '*Inclusive or*'. In other words, this neuron becomes active if input a is active *or* input b is active *or* both input a and input b are active.

Suppose that we interpret activity or inactivity of the unit as corresponding to particular patterns of truth (activity) or falsity (inactivity) at the neuron's inputs. Then we see that, singly or in groups, McCulloch–Pitts neurons can be considered to be computing logic functions based on the truth-values of the inputs together with the neuron's threshold. The first line of the abstract in the 1943 paper states this precisely: 'Because of the "all-or-none" character of nervous activity, neural events and the relations between them can be treated by means of propositional logic' (McCulloch, 1965, p. 19).

IMPLICATIONS

This paper does a great deal more than merely suggest a biological abstraction that can be used to compute logic functions. The main finding of the paper is reported in the next sentence: 'It is found that the behavior of every net can be described in these terms … and that for any logical expression satisfying certain conditions one can find a net behaving in the fashion it describes' (McCulloch, 1965, p. 19). This result is of breathtaking generality and power, as it means that *any finite logical expression can be realized by a properly constructed network of McCulloch–Pitts neurons*. With a memory added to the system, a network can become a fully general computing device – that is, a Turing machine.

The implication of the paper is that we now know exactly what the brain is doing – it is computing logic functions. As the paper puts it, 'in psychology, introspective, behavioristic or physiological, the fundamental relations are those of two-valued logic' (McCulloch, 1965, p. 38). The strong suggestion which is made in the paper is that psychology and neuroscience have become branches of logic.

GENESIS

Every scientific paper, even one of such great originality and elegance, has roots. It is striking that the paper itself has only three references (Carnap, *The Logical Syntax of Language*; Hilbert and Ackerman, *Foundations of Theoretical Logic*; and Whitehead and Russell, *Principia Mathematica*). Clearly, the sources for the paper were in the fields of logic and philosophy. There were no biological references.

This conclusion is confirmed by Professor Jerry Lettvin in his description of the paper's origin:

> And so early in 1942 Warren invites Walter and me to live with him and his family. Warren and his wife, Rook, were always enormously generous. We settled in, and it was in the evenings then that Walter and Warren got together on 'A Logical Calculus of Ideas Immanent in Nervous Activity.' Walter at that time had read Leibniz, who had shown that any task which can be described completely and unambiguously in a finite number of words can be done by a logical machine. Leibniz had developed the concept of computers almost three centuries back, and had even developed a concept of how to program them.
>
> I didn't realize that at the time. All I knew was that Walter had dredged this idea out of Leibniz, and then he and Warren sat down and asked whether or not you could consider the nervous system [as] such a device. So they hammered out the essay at the end of '42.
>
> (Anderson and Rosenfeld, 1998, p. 3)

LIMITATIONS

Groups of McCulloch–Pitts neurons can build a general-purpose computing device that will have the same limitations and computational power as any digital computer. In fact, one can regard any current digital computer as being built from a limited subclass of McCulloch–Pitts neurons. However, this does not mean that the neurons as described in the paper do everything equally efficiently. Technically, McCulloch–Pitts neurons realize what is sometimes called 'threshold logic', a logic family at one time commercially available in very large-scale integration (VLSI). Certain types of computations can be performed more easily with threshold logic than with more standard logic. Figure 2 shows one example, namely a 'majority' neuron that becomes active if any three or more of its inputs are active. Such a function requires a

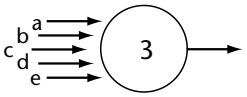

Figure 2. A McCulloch–Pitts neuron can easily compute some logic functions that can require more complex networks of standard logic functions. This unit with threshold 3 and five inputs computes the function 'majority', that is, it becomes active when any three, four, or five of its inputs become active.

combination of several simpler logic functions to realize with traditional semiconductor logic families. However, the slight advantages that threshold logic shows for functions such as 'majority' are lost when computing other simple logic functions (e.g. exclusive OR). A threshold logic unit by itself is basically monotonic in the way in which it responds to excitatory inputs. Once the threshold has been exceeded, the neuron stays on as more and more inputs are excited. However, Exclusive OR and related logic functions such as parity are non-monotonic – that is, increased input excitation can make the unit become inactive.

Figure 3 shows what is required to build a network of McCulloch–Pitts neurons that computes Exclusive OR. The open circle represents an inhibitory synapse. Clearly, this logic function is nowhere near as simple to compute for McCulloch–Pitts neurons as Inclusive OR. (Many simple neural networks also have considerable difficulty in computing highly non-monotonic functions such as Exclusive OR, and for similar reasons, a computational limitation was pointed out in the late 1960s for simple neural networks by Minsky and Papert (1969) in their book, *Perceptrons*.)

More fundamental problems arose with McCulloch–Pitts neurons when the latter were considered for their proposed role as models of the brain. These abstract neurons were simply an inadequate model of the biological neuron. Real neurons frequently seem to act more like analog computers, often using a continuous value as an output parameter (e.g. frequency of action potentials).

McCulloch was very aware of the results that were being obtained from neuroscience. In 1947, he and Pitts wrote another paper, 'How we know universals' (Pitts and McCulloch, 1947), which took a much more modern and also much less general approach to nervous system computation in the cortex and superior colliculus. The models that these researchers proposed used distributed representations and were specialized to perform highly specific computations. In their model for the colliculus, a structure which controls eye movements in primates, they suggested that the eyes were directed to the center of brightness of the visual image – a distributed computation using continuous values, and one which is very similar in spirit to modern models of the colliculus. The great logical generality of the 1943 paper was replaced by a more realistic and specialized approach to neural computation that made extensive use of continuous mathematics.

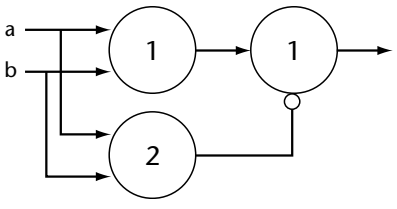

Figure 3. Some elementary logic functions are more difficult to compute with McCulloch–Pitts neurons than others. Although 'Inclusive OR' is easy (see Figure 1), 'Exclusive OR' is more difficult and requires a small network to compute. In words, the output unit in this network becomes active when 'input a is active' OR 'input b is active' but NOT 'both inputs a and b are active'. The circle corresponds to an inhibitory (negative) connection.

There are a number of areas where the human nervous system presents a dual computational aspect. Higher-level cognition, especially language, presents considerable evidence for rule-based operations on discrete symbols, as seen for example in syntax. These are clearly the types of operations for which McCulloch–Pitts neurons seem to be well suited. Yet ample evidence also indicates that there are powerful 'analog' aspects to many nervous system operations, even at the highest levels of cognition.

McCulloch was aware of this problem. He and Pitts had put the discrete, logic-based operations at the lowest level of nervous system hardware – at the neuron level. However, in an essay from 1951 entitled 'Why the mind is in the head', McCulloch suggested that the picture was more complex:

> The nervous system is par excellence a logical machine. Sense organs and effectors are analogical. For example, the eye and ear report the continuous variable of intensity by discrete impulses, the logarithm of whose frequency approximates the intensity. But this process is carried to extremes in our appreciation of the world in pairs of opposites. As Alcmaeon, the first of the experimental neurophysiologists, so well observed, 'the majority of things human are two – white–black, sweet–bitter, good–bad, great–small.' (McCulloch, 1965, p. 73)

McCulloch suggests here that there is an important continuous-to-discrete transition taking place in mental computation. The McCulloch–Pitts neuron and its resulting networks locate the transition at the level of the single neuron. However, it is possible that they had it the wrong way round. Low-level neural processing may be largely continuous, and the discreteness that is so valuable in cognition may arise at the higher levels through other mechanisms. One modern model for such a transition would be discrete attractor states arising from an underlying continuous nonlinear dynamic system.

INFLUENCE

The 1943 paper by McCulloch and Pitts was influential in a large number of places, some of them unexpected. In the realm of mathematics itself this paper is often given credit for founding the important field known as finite state automata theory.

However, its influence went even further. The paper was published at the height of the Second World War. At that time there were a number of projects in progress to build practical computing machines for various military purposes. The teams involved became aware of the McCulloch–Pitts paper very early on. As Norbert Wiener comments:

> In the summer of 1943, I met Dr J. Lettvin … who was … a close friend of Mr Pitts and made me acquainted with his work. He induced Mr Pitts to come out to Boston. … From that time it became clear to us that the ultra-rapid computing machine, depending as it does on consecutive switching devices, must represent an almost ideal model of the problems arising in the nervous system … the construction of computing machines had proved to be … essential for the war effort … and was progressing at several centers. … There was a continual going and coming of those interested. … Everywhere we met with a sympathetic hearing, and the vocabulary of the engineers soon became contaminated with the terms of the neurophysiologist and the psychologist. (Wiener, 1948, pp. 21–23)

One of those influenced was John von Neumann, who sketched what has become known as the 'von Neumann computer architecture' in a famous 1945 technical report. In the report he made the following comment:

> In existing digital computing devices, various mechanical or electrical devices have been used as elements. … It is worth mentioning that the neurons of the higher animals are definitely elements in the above sense. … Following W. PITTS and W. S. MACCULLOCH [sic] … we ignore the more complicated aspects of neuron functioning. … It is easily seen that these simplified neuron functions can be imitated by telegraph relays or by vacuum tubes. (von Neumann, 1945, republished 1982, pp. 388–389)

The proposed similarity between the computer and the architecture of the brain was taken very seriously by computer scientists at the time. When early computer scientists referred to computers as 'giant brains' they were not just using a metaphor, but were referring to what they thought were two computing systems based on the same principles but using different hardware.

From the early 1940s the McCulloch–Pitts neuron was considered by many non-neuroscientists to be the most appropriate way to approach neural computation, largely because the work of McCulloch and Pitts was so well known. The idea that biological neurons were acting primarily as logic devices was an article of faith for decades. Paul Werbos described a discussion he had with Marvin Minsky in the early 1970s. Werbos reported the gist of Minsky's comments as follows:

> Everyone knows a neuron is a 1–0 spike generator. That is the official model from the biologists. … If you and I come out and say the biologists are wrong, and this thing is not producing 1s and 0s, no one is going to believe us. (Anderson and Rosenfeld, 1998, p. 344)

The McCulloch and Pitts paper suggests first that a paper does not have to be correct in its initial domain of application – in this case brain theory – for it to be immensely valuable in many other places and at many different levels, and secondly, that a tight coupling between brain science and computer science has existed from the earliest beginnings of both fields, and has enriched both.

Memory Consolidation

Introductory article

Morris Moscovitch, University of Toronto and Rotman Research Institute – Baycrest Centre, Toronto, Ontario, Canada

CONTENTS

In memory consolidation, biochemical and psychological processes form new memories and assimilate them into a person's pre-existing body of knowledge.

INTRODUCTION

The term 'consolidation' was introduced in 1900 by G. E. Müller and A. Pilzecker to describe a time-dependent process that was needed to assimilate an experience and store it permanently as a memory that was relatively immune to disruption. Integrating what was known at that time, W. H. Burnham identified two processes that were implicated in consolidation: (1) a physiological or biochemical process required for the formation and storage of a memory trace or engram and (2) a psychological process needed to assimilate the newly acquired memory into an already existing body of knowledge and allow it, in turn, to influence what will be learned subsequently. Elucidating these processes remains at the heart of research on memory and consolidation.

In 1957, the modern era of research into the neural substrates of memory was ushered in by W. B. Scoville and B. Milner's publication on the effects of excision of the anterior and medial temporal lobes bilaterally to control intractable epilepsy in a single patient, H.M. (Figure 1). Although the surgery was effective in controlling the epilepsy of this patient, one of its unanticipated consequences was that H.M. became profoundly amnesic. The memory loss which characterized his amnesia was typical of that observed in other patients with medial temporal lobe damage who were studied subsequently, and indeed in many individuals with organic amnesia of different etiologies which affected midline thalamic nuclei. Although they lacked substantial portions of the medial temporal lobes or critical diencephalic nuclei, these individuals had a normal short-term memory as measured by a number of tests, including digit-span performance, which involves repeating back a series of numbers. Similarly, it was reported that deficits in remote memory were limited to retrieval of events that had occurred within the past few years, suggesting that older memories were stored, and could be retrieved readily, without the medial temporal lobes. These observations were interpreted as showing that the medial temporal lobes and related diencephalic structures were involved neither in processing short-term memories nor in storing remote memories. Instead, their function was to help to consolidate memories and to encode, store and retrieve them until that process was complete. Indeed, the standard model of consolidation was based on these initial observations, and has been modified little since then although, as will be discussed later in this article, there is some evidence to suggest that the standard model needs to be modified.

The Standard Model

According to the standard model, memory consolidation begins when information, which is registered initially in the neocortex, is bound into a memory trace by the medial temporal lobes and related structures in the diencephalon. This initial binding into a memory trace involves short-term processes, the first of which may be completed within seconds and the last of which may be completed within minutes or at most days. This is referred to as *rapid consolidation* or *cohesion*. A process of *prolonged consolidation* is also believed to occur. During this process, the medial temporal lobes and related structures are needed for storage and recovery of the memory trace, but their contribution diminishes as prolonged consolidation proceeds, until the neocortex alone is capable of sustaining the permanent memory trace and mediating its retrieval. Thus according to the standard model the medial temporal lobes and related structures are considered to be temporary memory systems,

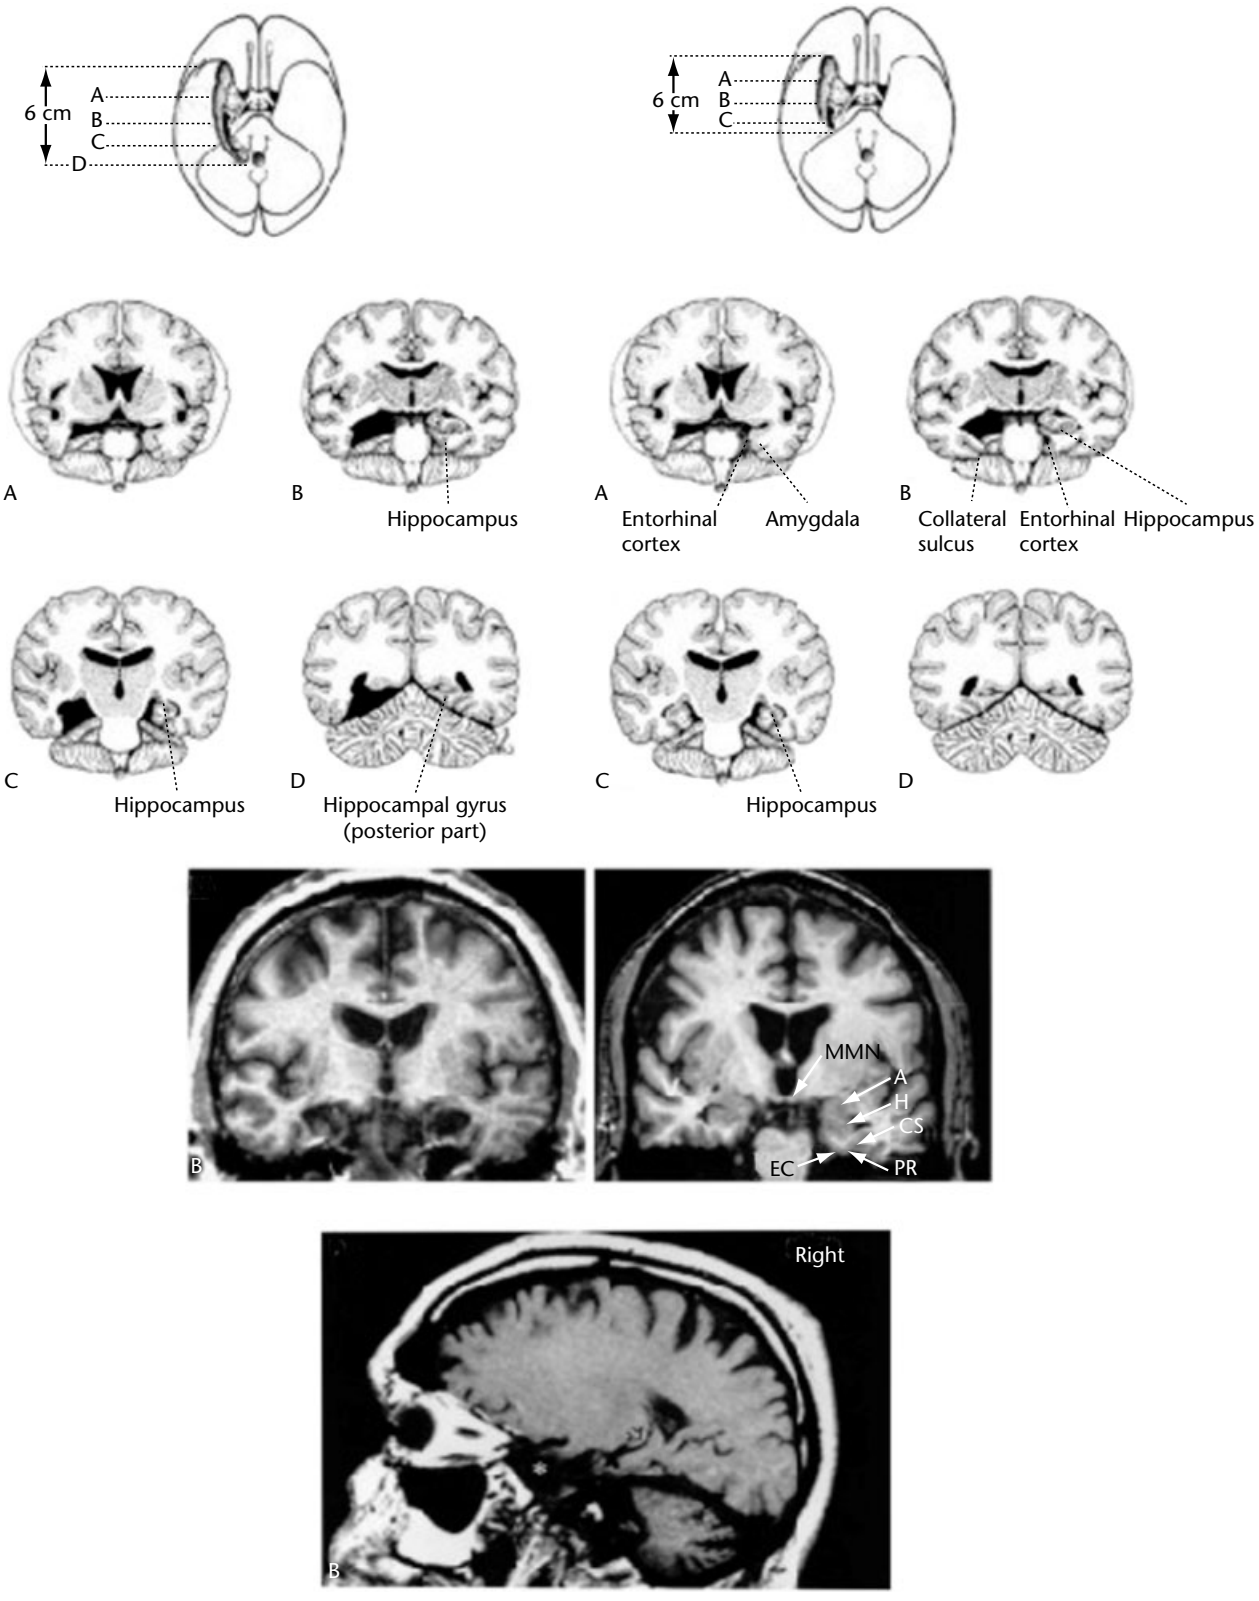

Figure 1. A recreation of H.M.'s lesion from the surgeon's report (Scoville and Milner, 1957) and a recent MRI scan of the lesion (Corkin *et al*., 1996).

which are needed to store and retrieve memories until prolonged consolidation is complete. The time it takes for consolidation to be completed is determined by the temporal extent of retrograde amnesia following lesions of the medial temporal lobes and diencephalon, other insults (concussions, closed head injuries or electrical currents), or the administration of pharmacological agents which permanently disrupt memory.

Rapid Consolidation

The existence of rapid consolidation is not in dispute. Indeed, much has been learned about its cellular and neurochemical (molecular) basis which seems to be similar not only across species but also across different memory systems in the same species. Stimulus presentation initiates a cascade of neurochemical events at the synaptic membrane and within the cell which increase the synaptic strength or efficiency with which neurons that form the memory trace can communicate with (activate) one another. The first of these processes involves local, transient molecular modifications that lead to an increase in neurotransmitter release at the affected synapse, and which may mediate short-term or intermediate memory. If the stimulus is intense enough and/or repeated, additional processes are activated. These involve genetic transcription and protein formation, which lead to long-lasting cellular changes, including the creation of new synapses, that support the formation and maintenance of long-term memory. These processes may last from hours to days. Although we are well on our way to understanding the basic cellular and molecular mechanisms of memory, we are far from understanding memory at a systems level which includes the psychological processes that Burnham emphasized. It is this problem that is inextricably tied to the debate with regard to prolonged consolidation.

Prolonged Consolidation and Memory Systems

By the 1960s, the outlines of the central debate concerning the validity of the standard model were already clearly crystallized in research with amnesic patients, reflecting the assumption that it was damage to the medial temporal lobes and diencephalon that was primarily responsible for the amnesia. The debate continues to center on three questions. (1) What types of memory are implicated? (2) Which neuroanatomical structures in the medial temporal lobes and diencephalon are involved? (3) What is the extent and duration of retrograde amnesia and, by implication, of consolidation, and how is it affected by lesion location and memory type?

TYPES OF MEMORY

Explicit and Implicit Memory

One of the most important recent discoveries of memory researchers is that memory is not unitary but consists of various types, each influenced by different variables, governed by different principles, possibly concerned with different materials, and each mediated by different neural structures and mechanisms that form distinguishable and dissociable systems. Two broad classes of memory were identified, namely *explicit memory*, which refers to conscious recollection of experiences and facts (also called declarative memory), and *implicit memory*, which is memory without awareness. The latter is revealed by the effects that prior experience has on behavior without the individual consciously retrieving the memory or even being aware of having it (non-declarative memory). One example of implicit memory is perceiving a picture of a face or a word more quickly after it has already been seen, although the person may deny that the face or word was familiar (perceptual priming). Other examples include learning a repeated, complex motor sequence, even though the individual may be unaware of the sequence or that it was repeated (procedural memory), or learning to form conditioned responses, although the individual may be unaware of the stimuli controlling the response (conditioning). What is important is that many if not all types of implicit memory can be acquired, retained and retrieved normally even by individuals who are profoundly amnesic as a result of medial temporal or diencephalic damage. It is believed that implicit memory is mediated by the neural structures involved in acquiring information (e.g. the posterior neocortex for perceptual priming) and in executing action, (e.g. the basal ganglia for motor learning). We know little about prolonged consolidation effects in implicit memory, or even whether it occurs. Our discussion of prolonged consolidation will therefore be restricted to explicit memory.

Explicit memory: episodic versus semantic

Explicit memory is itself divisible into two types, namely episodic and semantic memory. Episodic memory is memory for particular, autobiographical episodes that have a distinct spatio-temporal

context, and it involves a detailed re-experiencing of the initial event – what E. Tulving called 'mental time travel'. Semantic memory, on the other hand, is memory for knowledge that lacks a spatio-temporal context, such as knowledge of vocabulary and facts about the world (e.g. history, geography, people) and knowledge about ourselves (e.g. where we were born, where we lived, who our friends were, what schools we attended, what jobs we held). Some authors have called the latter type of memory *personal semantics*, to distinguish it from memory for autobiographical episodes. Episodic memory is assessed by descriptions of autobiographical episodes from different periods in an individual's life, vocabulary (by recognition and definition of words that came into use at different times) and knowledge of people (by recognition of faces and names in the news from different time periods).

Although different types of tests are used to assess episodic and semantic memory, they are considered to be similar with regard to consolidation by proponents of the standard model. According to supporters of the latter, damage to the medial temporal lobes and diencephalon leads to a graded, temporally limited retrograde amnesia for both types of memory. Memories acquired most recently are most severely affected, with more remote memories being retained normally, having been fully consolidated before the insult.

The standard model of consolidation had been challenged by Warrington and her colleagues, who showed that retrograde amnesia can be severe and of long duration following medial temporal lesions. This led them to favor the view that amnesia results from a deficit in retrieval rather than in consolidation. On the basis of the evidence that they collected, M. Kinsbourne and F. Wood argued that amnesia is a deficit only of episodic (autobiographical) memory, and does not distinguish between recent and remote memory. Although few authors endorsed their ideas at the time, L. Nadel and M. Moscovitch have noted a number of problems with the standard model with regard to both the types of memory that are affected and the duration and extent of retrograde amnesia. The latter varies with memory type, decreasing in severity and extent from the autobiographical to the semantic. Retrograde amnesia for details of autobiographical events after large medial temporal (or diencephalic) lesions can extend for decades, or even a lifetime – far longer than would be biologically plausible for even prolonged consolidation to be completed. However, retrograde amnesia for public events and personalities is less extensive and is often temporally graded. This is even more true of semantic memory that pertains to vocabulary, to facts about the world and to personal semantics.

The distinction between temporally extensive and temporally limited retrograde amnesia also applies to spatial memory. Schematic cognitive maps of old neighborhoods that are adequate for navigation are retained, but they lack topographical details and local environmental features, such as the appearance and location of particular homes, that would allow the person to have detailed cognitive maps of their locale.

NEUROANATOMY OF MEMORY

It has also been noted that lesion size and location play a role in determining the nature, severity and extent of retrograde amnesia. The initial studies on retrograde amnesia implicated the medial temporal lobes and diencephalon. These areas themselves consist of a number of separate but related structures (Figures 2 and 3). Initially, the focus of attention shifted quickly from the medial temporal lobes to the hippocampal formation, and then to the hippocampus itself. More recently, however, investigators have begun to appreciate the importance of the other structures, and the different functions each serves, as well as their relationship to each other and to corresponding regions in the diencephalon. Although the precise function of each of the areas is still being debated, a consensus is emerging. It has been proposed that there are two integrated medial–temporal–diencephalic memory systems. One system, consisting of the hippocampus and its connections to the mamillary bodies and anterior thalamic nuclei, mediates recollection

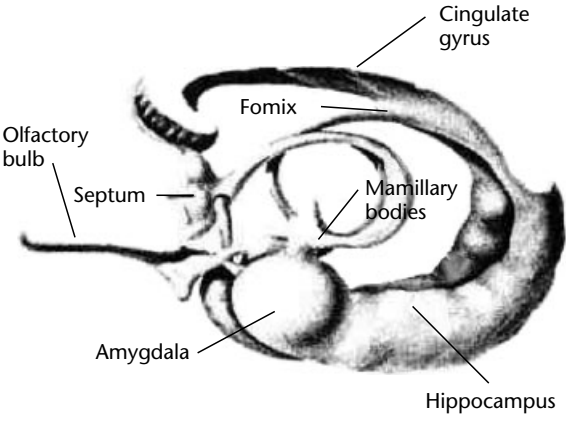

Figure 2. The limbic system and memory circuit (Kolb and Whishaw, 1996).

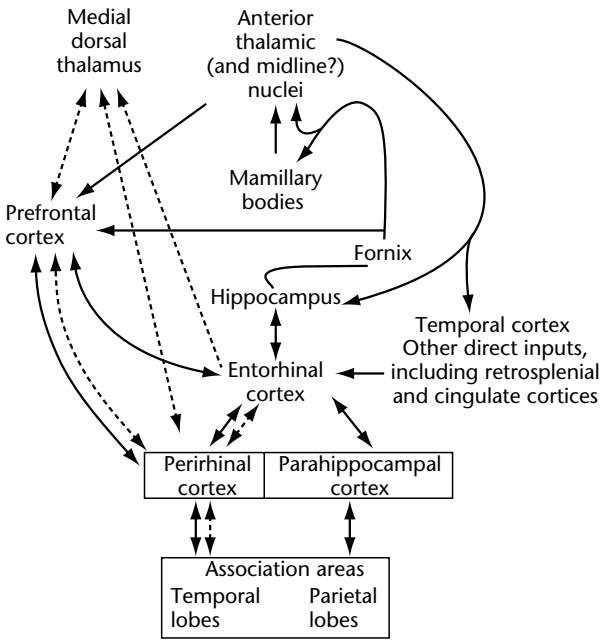

Figure 3. The hippocampal–diencephalic systems (modified from Aggleton and Brown, 1999).

which relies on relational information, including the temporal–spatial context of the memory. Damage to this system causes deficits in spatial memory and in memory for complex relational information that typifies memory for autobiographical episodes. The other system, which consists of the perirhinal cortex and its connections to the dorsomedial nucleus of the thalamus, is necessary for item recognition based on familiarity judgments without a spatial–temporal context. Damage to this system will impair recognition of even single items. The function of the parahippocampal cortex is less well understood, although it seems to be necessary for forming memories of places or for associating objects with particular locations.

Defenders of the standard theory argue that the temporally limited memory applies only to the hippocampus, and that permanent memories are consolidated in the adjacent regions. Such an argument would represent a significant departure of the standard theory from its origins in response to evidence brought against it. Until recently, standard theory assumed the locus of consolidated memory to be in lateral and posterior neocortex, not in the parahippocampus or other structures in the medial temporal lobes adjacent to the hippocampus. Those structures were regarded as part of the extended hippocampal system or complex in the medial temporal lobes, whose function was to help to consolidate memories, not to be involved permanently in storing and retrieving them. Indeed, as we learn more about the separate functions of these regions, it may be reasonable to consider the possibility that each of them is involved in retention and retrieval of those aspects of information which they specifically process. Moreover, more recent studies have shown that damage which is confined largely or exclusively to the hippocampus can often lead to extended retrograde memory loss for autobiographical events, the severity of this loss being dependent on the extent of hippocampal damage (Figure 4).

Damage to extrahippocampal structures in the medial temporal lobes can lead to loss of remote memories for facts, events and people, the latter being particularly associated with damage to the anterior temporal pole. Loss of semantic memory, including vocabulary and personal semantics, is associated with damage to posterior neocortical structures, particularly the lateral aspects of the temporal lobe. Such loss is evident in many patients with dementia and neocortical degeneration, but is most revealing in individuals with semantic dementia whose medial temporal lobes are relatively spared. They show a reverse temporal gradient, with recent memories being preserved and remote memories being impaired. Although the reverse gradient has been observed in some patients for both episodic and semantic memory, in other patients it has been noted only for semantic memory, with episodic, autobiographical memories being spared, presumably because they are dependent on the medial temporal lobes. It has yet to be determined what accounts for the individual differences in the patterns of preservation and loss among semantic dementia patients.

Multiple-Trace Theory: An Alternative to the Standard Model

Based on the functional and neuroanatomical evidence that they reviewed, Nadel and Moscovitch concluded, contrary to the traditional consolidation model, that the function of the medial temporal system is not temporally limited, but that it is needed to represent even old memories in rich detail (be it autobiographical or spatial) for as long as the memory exists. Neocortical structures, on the other hand, are sufficient to form domain specific and semantic representations based on regularities extracted from repeated experiences with words, objects, people, and environments. This applies even to autobiographical episodes that one recollects repeatedly, creating a gist of each episode which lacks the details that make re-experiencing it

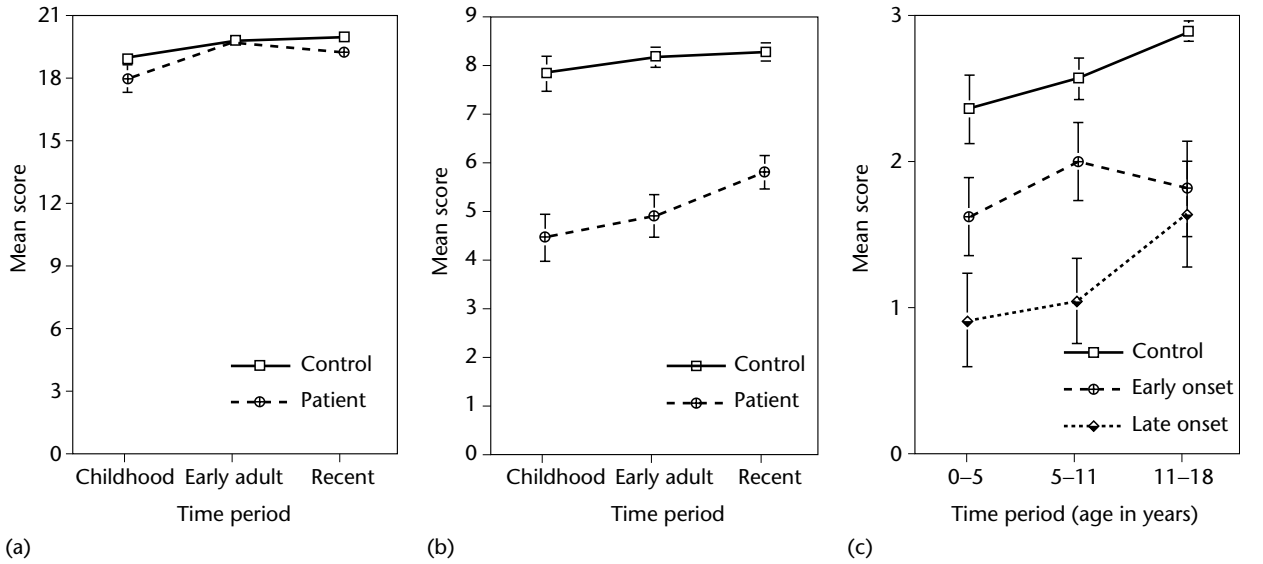

Figure 4. Mean scores on the Autobiographical Memory Inventory (AMI) for control ($n = 22$) and patient ($n = 25$) groups. Vertical lines depict standard errors of the means. (a) Personal semantic component. The maximum score is 21 per time period. (b) Autobiographical episodic component. The maximum score is 9 per time period. (c) Mean scores on episodic components of AMI for control ($n = 22$), late seizure onset ($n = 11$) and early seizure onset ($n = 8$). Late seizure onset describes patients who reported first seizures after the age of 18 years, and early seizure onset describes patients who reported first seizures before the age of 5 years. The maximum score is 3 per time period.

possible. The medial temporal lobe system may have a role in the initial formation of these neocortical representations, but once they have been formed they can exist on their own.

Recent evidence from studies of children whose hippocampus was damaged at birth or shortly thereafter supports this view. F. Vargha-Khadem and colleagues found that these children acquired sufficient general knowledge (semantic memories) to complete high school even though their memory for autobiographical episodes was impaired, although L. R. Squire and S. M. Zola have presented some counterarguments.

Corroborating evidence is also provided by neuroimaging studies of recent and remote autobiographical and semantic memory. These studies found that the hippocampus is activated equally during retrieval of recent and remote autobiographical memories, but not during retrieval of memories for public events or personal semantics (Figure 5). However, remote memory for famous faces shows the expected temporal gradient, particularly in the entorhinal cortex, with recent memories being much more strongly activated than remote ones.

To account for this evidence, Nadel and Moscovitch proposed a *multiple-trace theory (MTT)*. The hippocampal complex (and possibly diencephalon) rapidly and obligatorily encodes all information that is attended (consciously apprehended), and binds the neocortical (and other) neurons which represent that experience into a memory trace. This information is sparsely encoded in a distributed network of hippocampal complex neurons which act as a pointer, or index, to the neurons that represent the attended information. Thus a memory trace of an episode consists of a bound ensemble of neocortical and hippocampal/medial temporal lobe (and possibly diencephalic) neurons which represent a memory of the consciously experienced event. Formation and consolidation of these traces, or cohesion, is relatively rapid, lasting for a period of the order of seconds or at most days.

In this model there is no prolonged consolidation process that slowly strengthens the neocortical component of the memory trace so that, with time, it becomes independent of the hippocampal complex. Instead, each time an old memory is retrieved, a new hippocampally mediated trace is created so that old memories are represented by more or stronger traces than are new ones, and are therefore less susceptible to disruption due to brain damage than are more recent ones. Because the memory trace for autobiographical episodes is distributed in the hippocampal complex, the extent and severity of retrograde amnesia and perhaps the slope of the gradient are related to the amount and

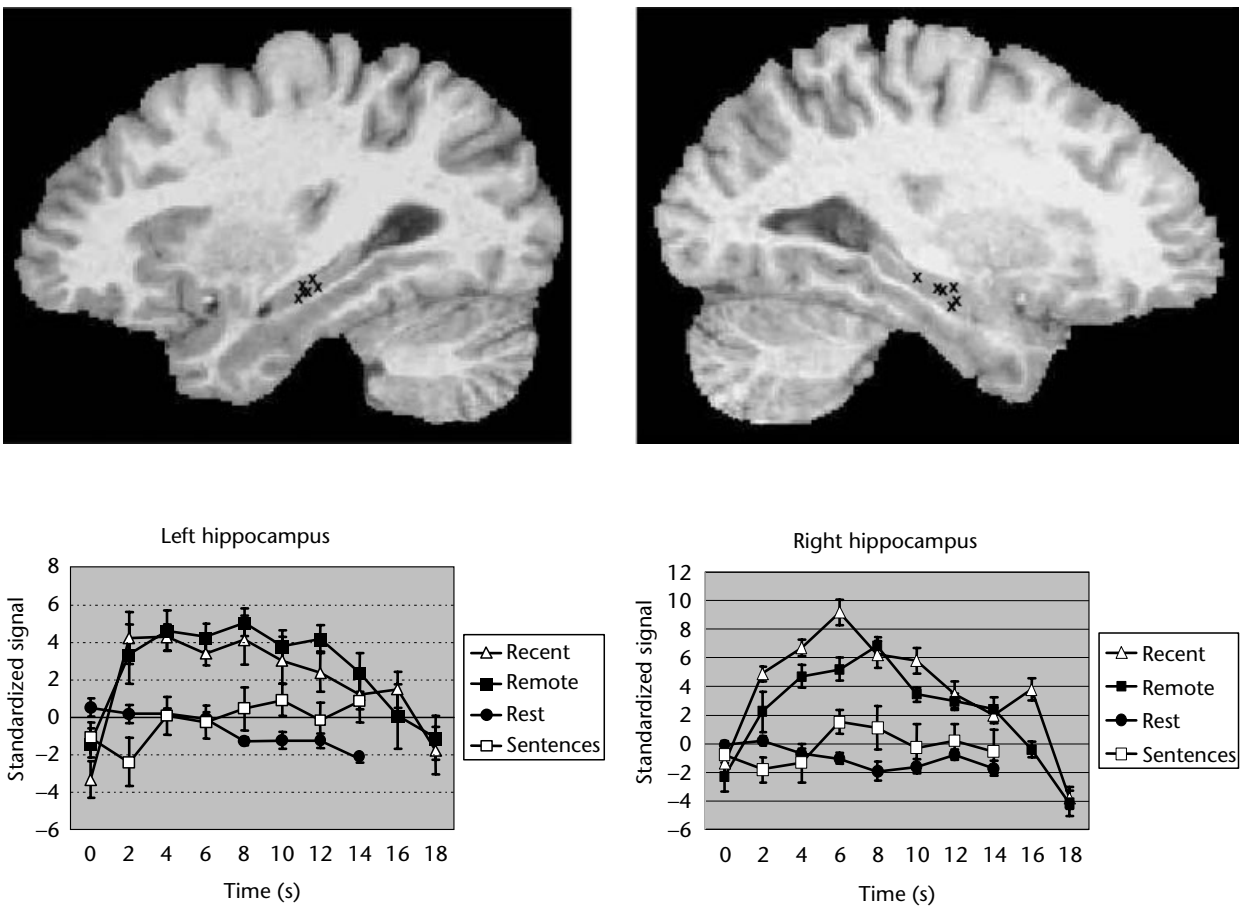

Figure 5. Hemodynamic response of the hippocampus during recall of recent and remote memories, and two baseline conditions (rest and sentence completion) (Ryan *et al*., 2001).

location of damage to the extended hippocampal complex.

Whereas each autobiographical memory trace is unique, the creation of multiple, related traces facilitates the extraction of the neocortically mediated information which is common to all of them, and which is shared with other episodes. This information is then integrated with pre-existing knowledge to form semantic memories that can exist independently of the hippocampal complex. Thus facts about the world, people and events that are acquired in the context of a specific episode are separated from it and ultimately stored independently of it. This process of increased semanticization may give the impression of prolonged consolidation (see below).

Prolonged consolidation for semantic memory: two alternatives

Remote memories for the gist of events, and for personal and public semantics, are not similarly dependent on the continuing function of the hippocampal complex. Instead, the hippocampal complex is needed only temporarily, until the memory is represented permanently in neocortical structures that are specialized for processing the information and capable of being modified while doing so. Semantic memory therefore behaves in a manner consistent with both the standard model and the MTT. However, the two models' explanations of the effects differ. According to the standard model, the memory that is held temporarily in the medial temporal lobes is identical to the memory that is stored permanently in the neocortex. Indeed, many believe that prolonged consolidation effects a transfer of the same memory from one location to another by strengthening neocortical connections. On the other hand, the MTT assumes that the temporary medial temporal memory is fundamentally different to the permanent neocortical one. The former retains its episodic flavor, such that the semantic content is tied to the spatio-temporal (autobiographical) context in which it was acquired. However, the latter is

stripped of its episodic context and retains only the semantic core. By this view, prolonged consolidation refers to the establishment of a semantic trace that can survive on its own, but it does not involve the loss of the episodic trace, nor is it identical to it.

Indeed, according to the MTT, the two types of memories can coexist, so that an individual can have both an episodic and a semantic representation of the same event, object or fact, and they can lose one type of representation without losing the other. The evidence from individuals with semantic dementia supports this interpretation. Having lost the neocortical, semantic representation, they rely on medial temporal representations to identify objects, people, places and facts. Thus they will recognize an object that has autobiographical significance for them (e.g. their own vase or kettle) but not the same type of object which is not their own (e.g. another person's vase or kettle). Conversely, amnesic people with medial temporal damage will recognize objects and individuals regardless of their autobiographical significance, but will be unable to evoke an autobiographical event related to them. However, it should be noted that the detailed episodic trace may also fade in normal people, as most memories do unless they are rehearsed, leaving only the general, semantic memory behind.

Animal Models of Consolidation and Retrograde Memory Loss

A brief examination of the animal literature is instructive because in animal research greater control can be exercised over lesion size and location and over pharmacological and other interventions, many of which cannot be attempted in humans.

For the most part, developments in the animal literature parallel those in human research. Despite the widely held view that retrograde amnesia is relatively brief and temporally graded, even in animals, not all of the evidence is consistent with this pattern. For example, a temporally graded, time-limited memory loss has been observed for a socially acquired food preference, for object discrimination learning and for contextual fear conditioning. On the other hand, extensive retrograde memory loss with a flat gradient has been observed for tests of allocentric, spatial memory, whether measured in a water maze or in a radial arm maze. Such evidence has forced investigators to reconsider the state of premorbid memories following medial temporal and in particular hippocampal damage. As in humans, the extent and severity of retrograde memory loss depend on the type of task and on lesion location. To account for these discrepancies, Rosenbaum and colleagues distinguished between context-dependent and context-free memories, which in humans correspond to episodic and semantic memories, respectively. Only memories that are dependent on relational context, such as spatial ones, show extensive retrograde loss following hippocampal lesions. However, context-free memories, such as memory for objects, may show only a temporally limited, graded memory loss after hippocampal lesions, but an extensive loss with a flat gradient following lesions to extrahippocampal structures, such as the perirhinal cortex. Extrapolating from these results, one can predict that severe and extensive retrograde memory loss in animals, as in humans, would require damage to the entire medial temporal lobe.

Studies on reconsolidation testify to the continued participation of different regions of the medial temporal lobe in memory long after the memory has been learned and presumably consolidated in the neocortex or other brain structures. The point of departure for these studies is the finding that electroconvulsive shock (ECS), lesions and protein-synthesis inhibitors are effective amnestic agents only if administered shortly after learning occurs. Delaying their administration beyond a critical period renders them ineffective, presumably because consolidation is already complete. However, if the memory is re-instated by having the animal perform the learned task long afterwards (even days or weeks later), when consolidation is certainly complete, then the amnestic agent again becomes effective. In other words, the effectiveness of the amnestic agent depends on when it is administered relative to the time when the memory was most recently activated, not relative to the time when it was acquired initially. With regard to consolidation, these studies indicate that memories are vulnerable when they are reinstated, and that they require a rapid reconsolidation process in order to remain permanent. The fact that damage to the hippocampus, or inhibition of protein synthesis in the hippocampus or amygdala, can lead to amnesia of well-learned memories, suggests that these structures – contrary to the standard model – continue to be involved in representing remote memories long after consolidation is presumably complete. These findings, and the idea that each time a memory is reinstated it is again re-encoded (rapid consolidation or cohesion), are consistent with the predictions of the MTT.

CONCLUSION AND FUTURE DIRECTIONS

We are beginning to understand consolidation at the cellular level, particularly those processes that mediate rapid consolidation. Undoubtedly advances will be made in discovering more about the molecular mechanisms that are implicated, and in developing drugs and gene therapies that can be used to treat memory disorders and even improve normal memory.

However, there is still much to be learned about consolidation at the systems level. Are different types of memories consolidated in different structures? Is the time course of consolidation similar for all of them? Are they each susceptible to different amnestic agents? What are the interactions between various structures and memory systems in consolidating information? These questions are particularly relevant when considering prolonged consolidation. As was noted above, recent evidence has challenged the standard model of consolidation, and there is even some dispute as to whether prolonged consolidation exists, at least for some types of memory. The alternative model, namely the MTT, seems to be more consistent with evidence that there are different memory systems, each of which is governed by different principles and mediated by different structures, and has different consolidation processes. It is hoped that future research will help to elucidate the exact nature of these memory systems, the role of various structures in memory representation and consolidation, and the nature of the interaction between the hippocampus and the neocortex, and between these and other brain structures.

Memory, Neural Basis of: Cellular and Molecular Mechanisms

Introductory article

Mark R Rosenzweig, University of California, Berkeley, California, USA

CONTENTS

Through the ages, there has been much speculation about how memory works. The current consensus is that memories are stored in circuits of neurons by plastic neurochemical and neuroanatomical changes at junctions between neurons (synapses), but it remains to be determined which of these changes are necessary and sufficient for memory formation.

INTRODUCTION

Recorded speculations about mechanisms of memory go back over two thousand years, but only in the last fifty years has substantial empirical progress been made in solving this mystery. In Greek mythology, memory was the province of the goddess Mnemosyne. She was the mother of the nine Muses, goddesses who presided over learning and the arts and sciences. This relationship demonstrated the necessity of memory for creativity. We invoke the name of Mnemosyne whenever we call methods to aid memory 'mnemonics' or 'mnemonic devices'.

Speculations about the bodily mechanisms of memory have been related to the technology of each period of history. Thus, classical Greek and Latin authors used as their models or metaphors of memory processes the then-current technology of wax slates and of signet rings impressing wax seals. Socrates assumed that there is a block of wax in our souls, the gift of Mnemosyne. He suggested that the wax varied in quality in different individuals, with finer wax allowing sharper, more detailed impressions. More recent models of memory mechanisms have ranged from telephone exchanges, to computers, to storage of genetic information.

In the Renaissance, when water was used to activate mechanical devices, nerves were thought to be tubes that conducted a fine fluid called 'animal (or animate) spirits'. By the mid-nineteenth century, nerve cells were visualized with the aid of microscopes and dyes, and in the latter part of the century, psychologists had begun to speculate that training could cause the proliferation of contacts between neurons. Such speculations appeared even before the formal announcement of the 'neuron doctrine' – that is, that neurons are separate cells that can affect other neurons but do not interpenetrate them. Some likened the nervous system to a telegraph system, but after telephones entered into commercial use in the 1880s, others likened the nervous system to a telephone system where connections can be made or broken. Synaptic junctions between neurons were named only near the end of the nineteenth century. Not until the middle of the twentieth century was it accepted that transmission at most synaptic junctions is accomplished by neurochemical processes, and then began attempts to understand synaptic plasticity in terms of neurochemistry. Success of this research was soon followed by findings of plastic neurophysiological and neuroanatomical changes at synapses.

CELLULAR MECHANISMS

Hypotheses about neural bases of memory became more specific and detailed as knowledge about the nervous system increased. To understand some of these hypotheses, it will be helpful to review some essential information presented in Figure 1. A typical neuron contains a cell body, or soma, that subserves maintenance of the cell and integration of signals. There are also many dendrites, which are involved in receiving signals, and an axon along which signals are transmitted. A neuron receives multiple inputs at its soma and dendrites, and sends its output through its axon to multiple target sites. The axon terminals form connections with dendrites or cell bodies of recipient neurons through specialized structures called synapses.

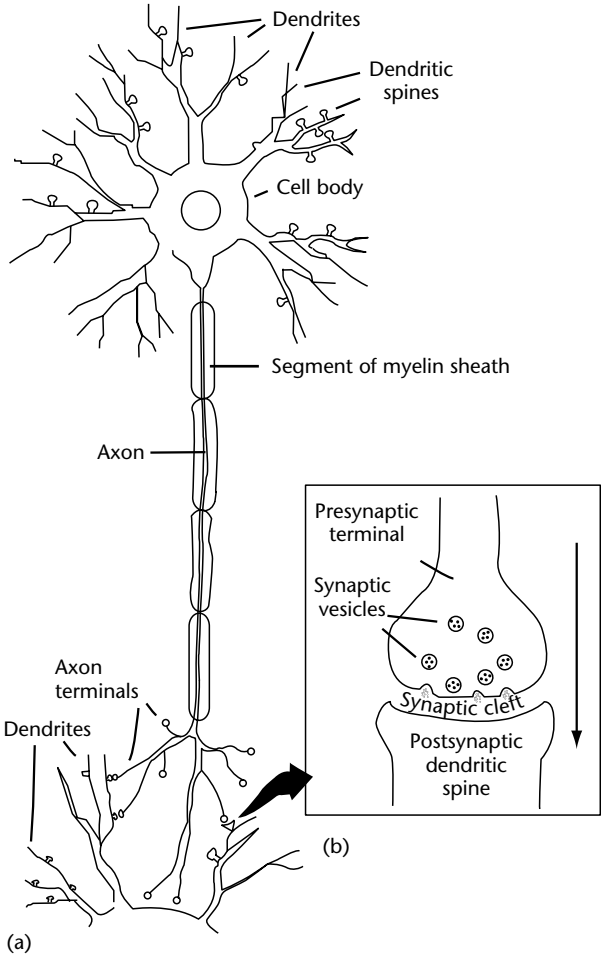

Figure 1. (a) A typical neuron, consisting of a cell body, dendrites involved in the reception of information, and an axon along which signals are transmitted. (b) A synaptic junction. When a neural impulse arrives at an axon terminal, it may lead synaptic vesicles to discharge transmitter molecules which move across the synaptic cleft to receptor sites on the postsynaptic neuron. Adapted from Rosenzweig *et al*. (1999).

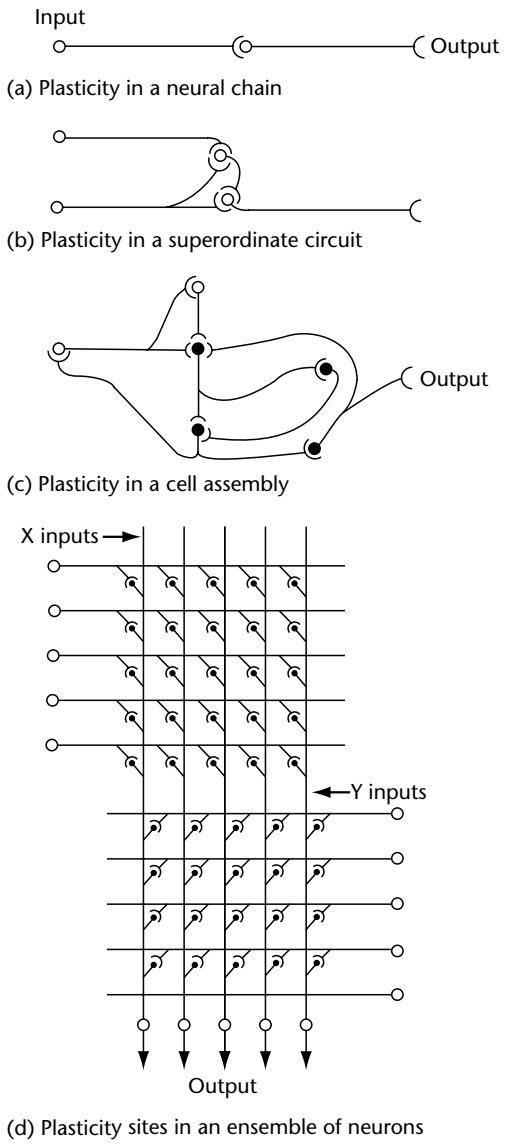

Figure 2. Some basic neural circuits; solid circles indicate sites of plasticity. (a) A neural chain with a plastic synapse. (b) Plasticity in a higher-order segment of a circuit. (c) A cell assembly with several plastic sites. (d) Many or all the synapses may be plastic in a parallel distributed circuit of neurons. Changes at plastic sites could underlie memory storage. Adapted from Rosenzweig *et al*. (1996).

The small gap (about 20 nm) between presynaptic terminals and postsynaptic sites requires signal transmission to be mediated by chemicals called neurotransmitters. There are many different chemicals that serve this purpose at different neurons, and some neurons employ more than a single kind of transmitter. Direct electrical transmission across specialized types of synapses also occurs at some sites in the nervous system.

Changes that underlie learning occur in circuits of neurons, and several kinds of circuits have been studied. Some basic circuits and sites of plasticity are illustrated in Figure 2, with plasticity in (a) a neural chain, (b) a superordinate circuit, (c) a cell assembly, and (d) an ensemble of neurons. Usually, for simplicity, plasticity is studied at a single synapse or at parallel synapses, but it should be recognized that most behavior is governed by elaborate circuits, and changes with learning may occur at several places within the circuit.

Before taking up theories of memory mechanisms, let us consider briefly some different types of memory.

TYPES OF MEMORY

Memories can be classified in a variety of ways, and studied in a variety of animals. A basic classification contrasts nonassociative with associative learning and memories. In nonassociative learning the presentation of a particular stimulus alters the strength or probability of a response. Thus, in habituation, the repeated presentation of a (usually weak) stimulus decreases the strength of the response to it. In contrast, in the kind of nonassociative learning called sensitization, presentation of a strong or painful stimulus makes the organism more responsive to most stimuli. In the sea slug *Aplysia californica*, habituation is found early in development, whereas greater maturity is required before sensitization appears. (*See* **Learning, Psychology of**; **Animal Learning**)

In associative memories an association is formed between two stimuli or between a stimulus and a response. Associative memories are frequently subdivided into declarative and nondeclarative memories. A declarative memory is one that the learner can state or describe, whereas a nondeclarative memory is shown by performance rather than by conscious recollection. One type of declarative memory is called episodic; this refers to a person's ability to recall the events of the person's own life. A different type of declarative memory is called semantic; this refers to general knowledge about facts, people, and events. Nondeclarative memories are sometime called procedural because they are responsible for motor actions such as walking, riding a bicycle or serving a tennis ball. Other kinds of nondeclarative memory include perceptual representation systems and conditioned responses. Studies involving brain lesions and/or brain imaging indicate that learning of these different classes tends to involve different brain regions. Even kinds of learning and memory that seem quite similar may involve different brain structures.

Consider, for example, two kinds of eyelid conditioning that occur when a tone (the conditioned stimulus, CS) precedes a puff of air to the eye (the unconditioned stimulus, US). After repeated pairing of the two stimuli, the CS comes to evoke the eyeblink. If the CS continues until the US begins (in what is called delay conditioning), the circuit responsible for conditioning includes structures in the cerebellum. But if the CS ceases shortly before the US starts (in trace conditioning), then the hippocampus is required.

Another classification is in terms of the duration of the memory. Investigators distinguish between short-term memory (STM), intermediate-term memory (ITM), and long-term memory (LTM). Often new information, unless it is rehearsed, fades away in less than a minute; this is called STM. Other information (such as 'Where did I park my car this morning?') may disappear in a few hours; this is called ITM. Other memories last for days or even a lifetime; this is LTM. Some investigators have found evidence that memories of these three different durations have different underlying neurochemical mechanisms. The fact that a single brief learning trial may, in some cases, be recalled minutes or hours later is often explained by the hypothesis that, for a limited time, changes in synaptic strengths or weights alter how information may flow in neural circuits. The fact that a single trial may, in some cases, lead to LTM suggests that labile STM can be transformed to ITM and then to LTM, and much research supports this hypothesis. On the other hand, some studies indicate that STM, ITM, and LTM may all be initiated at the time of learning and that they develop independently of each other, rather than sequentially.

CURRENT THEORIES OF MEMORY

It is generally accepted that the plasticity that mediates memory occurs at synaptic junctions; this could occur in several different ways, including the following.

1. After training, each nerve impulse in the relevant neural circuit causes increased release of transmitter molecules, thus increasing the size of the postsynaptic potential (PSP).
2. An increase in the number of postsynaptic receptor molecules causes a larger response to the same amount of transmitter release.
3. An increase in receptor affinity for the neurotransmitter or an increase in the mean time the receptor channel remains open when activated also causes a larger response.
4. An interneuron modulates the polarization of the axon terminal and causes release of more transmitter molecules per nerve impulse.
5. A neural circuit used more often increases the number of synaptic contacts.
6. A more frequently used neural pathway can take over synaptic sites formerly occupied by a less active competitor. (*See* **Encoding and Retrieval, Neural Basis of**; **Synaptic Plasticity, Mechanisms of**)

In the 1950s, critics noted that experimental evidence had not been obtained for any proposed neurochemical or neuroanatomical mechanisms of memory. Then, beginning in 1960, a series of papers by an interdisciplinary group at the University of California at Berkeley (Edward L. Bennett, Marian C. Diamond, David Krech, and Mark R. Rosenzweig)

showed that formal training or exposure to an enriched environment caused neurochemical and neuroanatomical changes in the cerebral cortex of laboratory rats. These findings also encouraged other researchers to investigate neural mechanisms of memory. Now evidence has been found for each of the changes listed above, varying with brain region and with kinds of learning; the different mechanisms need not be mutually exclusive. Research is now being done to find which of these changes is (or are) necessary and sufficient for learning and memory storage to occur.

As mentioned above, evidence has been found that STM, ITM, and LTM have different underlying neurochemical mechanisms. In fact, they require different stages of a neurochemical cascade. The cascade can be initiated when sensory stimulation activates sensory receptor organs, which stimulate afferent neurons by using various synaptic transmitter agents such as acetylcholine (ACh) or glutamate. Agents that inhibit ACh activity can prevent STM, and so can inhibitors of glutamate receptors, including both the *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors. Alteration of ion channels in neural membranes can also inhibit STM formation. Preventing formation of STM also prevents formation of ITM and LTM. If STM is formed, inhibition of some further stages in the cascade can inhibit formation of ITM or LTM. Agents that inhibit calcium–calmodulin protein kinases (CaM kinases) prevent formation of ITM and consequently of LTM. Agents that do not inhibit CaM kinases but inhibit protein kinase A or protein kinase C do not inhibit formation of ITM but prevent formation of LTM. Agents that inhibit protein synthesis, such as anisomycin, also prevent formation of LTM, while permitting formation of STM and ITM. Research with the fruit fly *Drosophila melanogaster* shows that alteration of different genes disrupts separately the formation of STM, ITM, or LTM. (*See* **Memory, Long-term**)

DISCUSSION OF ISSUES AND EVIDENCE

Many investigators have proposed what they considered to be universal cellular/molecular mechanisms for memory, in spite of the fact that they had studied only a single kind of learning in a single species. It is true that some similar mechanisms have been found by investigators studying animals as diverse as the fruit fly *Drosophila*, the sea slug *Aplysia californica*, and mammals. Nevertheless, some investigators, such as Seymour Kety, have cautioned that the proposed unity of memory processes may be an oversimplification. Kety noted that so profound and powerful an adaptation as learning and memory is not apt to rest on a single set of mechanisms but rather is likely to employ every opportunity provided by evolution. There were forms of memory before organisms developed nervous systems, and after that remarkable leap forward, it is likely that every new neural complexity, every new neurotransmitter or hormone, was incorporated into processes of learning and memory. So we must be prepared to trace out the cellular and molecular mechanisms for a variety of kinds of memory in a variety of species, noting both the similarities and the differences as they appear. (*See* **Learning in Simple Organisms**)

In the 1980s and 1990s there were disputes among those who held that synaptic plasticity occurred solely or mainly presynaptically in the axon terminals and those who held it occurred solely or mainly on the postsynaptic side of the junction. Gradually evidence accumulated for important changes on both sides of the synaptic junctions as a consequence of training, and some investigators spoke of a trans-synaptic dialogue. Evidence has also shown that, at least at some synapses, a retroactive messenger from the postsynaptic to the presynaptic junction plays an important part in establishing memory. Here again, the picture has grown more complex. Much of this research has involved the phenomenon of long-term potentiation (LTP), which is a candidate mechanism for synaptic changes in memory formation. Although some kinds of LTP show parallels with some kinds of memory formation, it has not yet been established that any of the kinds of LTP is the mechanism for any of the kinds of memory formation.

The discussion above has been limited, for simplicity, to increases in activity and excitatory processes at synaptic junctions, but memory may equally well involve decreases in activity and inhibitory processes.

CONCLUSION

The establishment of memory appears to employ a cascade of neurochemical events operating on both sides of the synaptic junction. In some cases this is complemented by structural changes in axon terminals, dendritic spines, and location of receptor molecules. It remains to be determined which of these changes may be necessary and sufficient for memory formation.

Mirror Neurons

Intermediate article

Giacomo Rizzolatti, University of Parma, Parma, Italy
Vittorio Gallese, University of Parma, Parma, Italy

CONTENTS

Mirror neurons are a class of neurons, discovered in monkey premotor cortex, that become active both when the monkey makes an action and when it observes another individual making a similar action. Similar systems are found in humans.

INTRODUCTION

A fundamental problem in cognition is how we understand actions made by other individuals. How do we know that a person sitting in front of us is eating an apple? A possibility is that the visual occipital and temporal areas provide a pictorial description of the observed scene. On the basis of it, we infer that the person is eating an apple. Another possibility is that we do not infer cognitively 'person eating apple', but understand the observed action by matching its pictorial description on an internal motor representation. Although the two alternatives are not mutually exclusive, recent neurophysiological data render the second hypothesis highly plausible.

The strongest evidence in favor of a direct observation/execution matching comes from the discovery in the monkey of a class of neurons that become active both when the monkey makes an action and when it observes another individual making a similar action. These cells are called 'mirror neurons' (Gallese *et al*., 1996; Rizzolatti *et al*., 1996). Such observation/execution matching systems exist also in humans, and preliminary evidence suggests that they too are involved in imitation.

BASIC PROPERTIES

Motor Activity

Mirror neurons are located in frontal area 5 (F5) of the premotor cortex (Figure 1). Like other neurons of this area, mirror neurons discharge in association with actions of the hand and/or mouth.

Using the effective action as the classification criterion, mirror neurons can be subdivided into various classes, such as 'grasping', 'holding', and 'tearing'. Grasping neurons are the most common; many of these are selective for a particular type of prehension, such as precision grip, finger prehension, or whole-hand prehension. Some mirror neurons discharge during the whole action they code; others are active during a phase of the action such as the opening or closure of the fingers.

Mirror neurons (and F5 neurons more generally) form a 'vocabulary' of potential motor actions. The 'words' composing this vocabulary are constituted by populations of neurons. Some of them indicate the general category of an action (hold, grasp, tear, manipulate). Others specify how the action should be made (e.g., precision grip). Finally, others are concerned with the action's temporal segmentation (Rizzolatti *et al*., 1988).

Visual Properties

Mirror neurons become active when the monkey sees an interaction between an agent and an object. Object presentation alone, even of an interesting object such as food, is ineffective. Similarly ineffective are emotional stimuli such as the sight of faces or threatening actions. The agents most effective in driving mirror neurons are natural effectors (hands, mouth). Actions made using tools typically do not activate these neurons (Figure 2). Similarly, mimicking an action is usually ineffective.

The observed hand actions effective in triggering the neurons are the same as those that excite the neurons when actively executed. More than half of mirror neurons are active during the observation of one action only (e.g., grasping). The remainder responded to two (e.g., grasping and holding) or, rarely, to three actions.

There is a large amount of generalization as far as the precise physical aspects of the effective

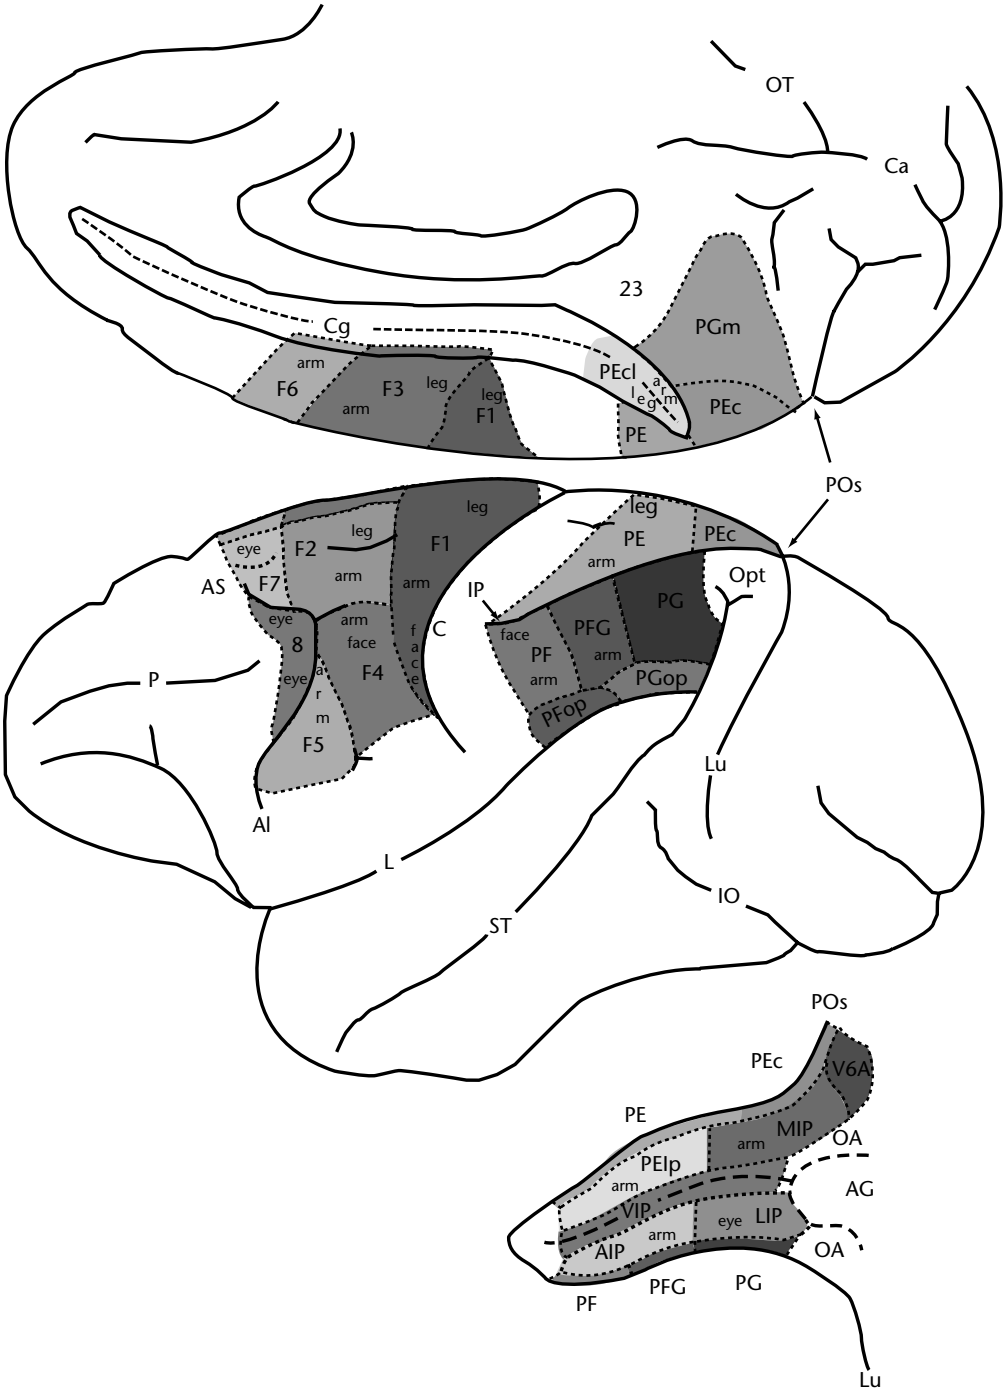

Figure 1. Mesial and lateral views of the macaque brain showing the cytoarchitectonic parcellation of the agranular frontal cortex and of the posterior parietal cortex. The areas located within the intraparietal sulcus (IP) are shown in an unfolded view of the sulcus in the lowest part of the figure. On the basis of the available data, the different body-parts representations are indicated. In the prefrontal cortex the frontal eye field FEF is also defined according to physiological criteria. AG, annectant gyrus; C, central sulcus; Ca, calcarine fissure; Cg, cingulate gyrus; IO, inferior occipital sulcus; IP, intraparietal sulcus; L, lateral fissure; Lu, lunate sulcus; OT, occipitotemporal sulcus; P, principal sulcus; POs, parietooccipital sulcus; ST, superior temporal sulcus; AI, inferior arcuate sulcus; AIP, anterior intraparietal area; AS, superior arcuate sulcus; LIP, lateral intraparietal area; MIP, medial intraparietal area; Opt, occipitoparieto-temporal area; VIP, ventral intraparietal areas.

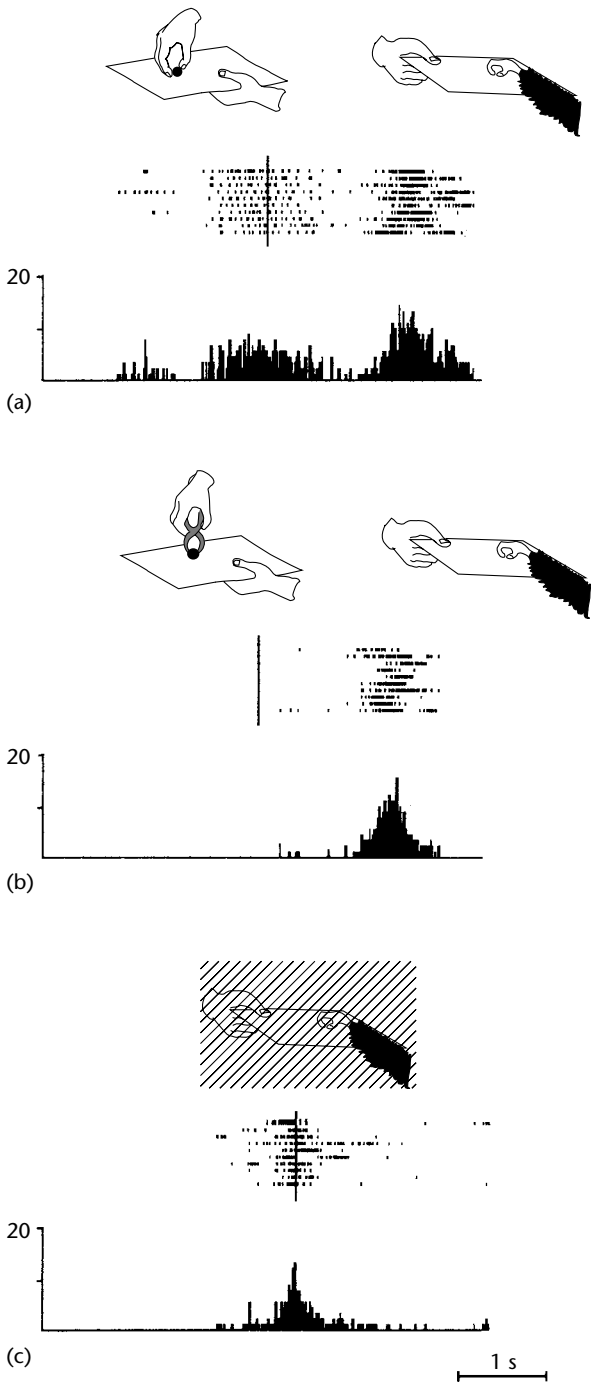

Figure 2. Visual and motor responses of a mirror neuron. Testing conditions are schematically represented above the rasters. Response histograms represent the sum of ten consecutive trials (raster display). (a) a tray with a piece of food is presented to the monkey, the experimenter grasps the food, puts the food again on the tray and then moves the tray toward the monkey who grasps the food. The phases when the food is presented and when it is moved toward the monkey are characterized by the absence of neuronal discharge. In contrast, a strong activation is present during grasping movements of both the experimenter and the monkey. (b) The same procedure is followed, except that the experimenter grasps the food with pliers. (c) The monkey grasps the food with no visual feedback. Rasters and histograms are aligned (vertical line) with the moment at which the food is touched either with the experimenter's hand (a) or with the pliers (b), and when the monkey touches the food with its hand (c). Ordinates, spikes/bin; abscissae, time; bin width, 20 ms (modified from Rizzolatti *et al*., 1996).

agent are concerned. For many neurons the precise hand orientation is not crucial for their activation. Similarly, the distance at which the action is executed does not influence the response in most cases.

Almost all mirror neurons show congruence between the observed and executed action. This congruence can be extremely strict; that is, the effective motor action (for example, precision grip) coincides with the action that, when seen, triggers the neurons (precision grip). Sometimes the congruence is broader: in these cases the motor requirements (for example, precision grip) are usually stricter than the visual ones (any type of hand grasping).

As far as the object that is the target of the observed action is concerned, its meaning does not influence the neuronal discharge. The responses to meaningful objects such as food are the same as those to any three-dimensional solid. The size of the object is relevant in about one-third of the neurons. The selectivity is related to the real size of the object, and not to its size on the retina.

ANATOMICAL ASPECTS

Figure 1 shows a cytoarchitectonic map of the macaque monkey cortex. Mirror neurons are mostly located in the F5 convexity. Visually responsive neurons are present also in the part of F5 hidden in the arcuate sulcus. These 'canonical' neurons, unlike mirror neurons, do not require an agent/object interaction, but respond to the presentation of 3D objects (Rizzolatti *et al*., 1998).

The convexity of F5 is strongly connected with area PF. Many PF neurons respond to the sight of biological actions, and some of them discharge also in association with motor actions, showing properties similar to those of F5 mirror neurons.

An important input to PF comes from the region of the superior temporal sulcus (STS). The studies of Perrett *et al*. (1989) showed that in the anterior part of STS there are a variety of neurons responsive to biological actions. Some of them encode body postures, others code specific body movements, and others discharge during goal-directed

actions. The spectrum of body parts and body movements that are coded in the temporal lobe is wide and, at variance with F5, includes arbitrary postures and movements. Although the issue was not specifically addressed, it does not appear that STS neurons discharge during active movements of the monkey (see Carey *et al*., 1997).

There is thus a rich description of biological actions in STS. Such descriptions, via PF (where some mirror neurons are present), are sent to premotor cortex where they are matched with the motor representation of the same actions. This matching is the origin of the F5 mirror neurons.

FUNCTIONAL ROLE

Although it is likely that the human matching systems use sets of neurons similar to mirror neurons, their functional properties may not necessarily be identical to those of F5 mirror neurons. Two explanations for the activity of F5 mirror neurons come immediately to mind. The first is that their firing depends on abortive movements passed unnoticed to the experimenter; the second is that their activity is preparatory to an impending movement. Controlled experiments have ruled out both these hypotheses. Mirror neurons discharge in response to the appropriate stimulus both when the monkey is still and when it performs movements that have no relation to the observed action. Furthermore, mirror neurons do not fire when an object is moved toward the monkey and made more available for action on it – the opposite of what would be predicted by the motor preparation hypothesis. Discarding these possibilities, the most likely interpretation of mirror neurons is that their activity generates an internal representation of the observed action. This interpretation fits the general notion that motor representations are elicited in motor cortex, in a potential form, by a variety of stimuli. These representations become actions only if specific contingencies render their transformation into action useful.

Potential actions are frequently generated by the sight of an object. In the case of mirror neurons they are generated by the sight of an action. The problem now is to elucidate the functional role of a motor representation generated by the sight of an action. The most likely possibility is that this representation is used for making sense of the observed action. The assumption here (difficult to deny) is that when making (or preparing) an action, the individual predicts ('knows') its consequences. Mirror neurons extend this knowledge to actions performed by others. When a person observes an action performed by another individual, mirror neurons that represent that action become active. The action is hence recognized because it corresponds to that generated during action programming. Might this mechanism lead to confusion between self-generated actions and actions made by others? Hardly so. Signals preceding action initiation as well as proprioceptive signals following movement onset can easily discriminate (at least in normal subjects) self-generated action from action made by others.

Another possibility is imitation. Monkeys, however, do not imitate – or at least do not imitate manual gestures made by another individual. Thus, although endowed with a mechanism that generates internal copies of actions made by others, they are unable to use them for replicating those actions. The intentional use of internal copies of actions appears to have developed only later in evolution.

OBSERVATION/EXECUTION MATCHING SYSTEMS IN HUMANS

Seeing another person making movements activates motor areas in our brain. This phenomenon has been demonstrated in humans by electrophysiological studies (e.g., Hari *et al*., 1998) as well as by transcranial magnetic stimulation. This latter technique showed that the increase of motor evoked potentials during the observation of hand movements is highly specific. It involves those muscles of the observer that the actor is using. Motor evoked potentials increase also during the observation of intransitive (nongoal-directed), meaningless movements (Fadiga *et al*., 1995).

The localization of areas active during action observation was made using brain imaging techniques. Initial studies showed that during the observation of different types of grips performed on a variety of objects there is an activation of the left STS region, the inferior parietal lobule, and Broca's area. This circuit corresponds to that of mirror neurons in the monkey (see Grafton *et al*., 1996).

In a more recent study using functional magnetic resonance imaging, participants were shown actions made with mouth, hand and foot, some of which were object-directed while others were mimed, no object being present. Both object-related and nonobject-related actions determined a somatotopically organized activation of premotor cortex. During mouth actions there was a bilateral activation of the ventral premotor cortex plus an activation of Broca's area. During hand actions a more dorsal part of ventral area 6 plus Broca's area

were recruited. Finally, the observation of foot actions elicited an activation of dorsal area 6 (Binkofski *et al*., 2001). In addition, a difference in activation was found between observations of object-related and nonobject-related actions. When an object is the target of an action the parietal lobe is strongly activated. Parietal activations are also somatotopically organized and depend on the effector used.

These results indicate that when individuals observe an action, a replica of that action is automatically generated in their cortex, recruiting the same circuits that are active when the observed action is internally generated by the observer. The presence of a strong parietal activation in the case of object-related actions is probably due to the fact that the observer makes a 'pragmatic' analysis of the objects similar to that necessary in order to act on the object.

While in the experiments described above the only instruction to participants was to carefully observe the action, in subsequent experiments participants were instructed to observe the actions in order to imitate them either after or during scanning. The most important finding was the observation (in addition to premotor activation) of an activation of the right superior parietal lobe (Grèzes *et al*., 1998; Iacoboni *et al*., 1999), probably due to the need to make an internal description of the precise movements made by the actor, not just to understand what the actor is doing. This requires activation of the right superior parietal lobe, where there is a proprioceptive description of movements.

Studies in humans cannot specify the precise mechanisms that match observed and executed actions. They showed, however, that in humans a mechanism similar to that of the monkey is present during action observation. In addition, in humans observation of intransitive meaningless movements activates the motor areas. Finally, and most importantly, direct matching is used in humans not only for action understanding, but also for imitation. It appears, therefore, that other cognitive functions have developed out of an evolutionarily older mechanism.

Modularity in Neural Systems and Localization of Function

Introductory article

Carlo Umiltà, University of Padua, Padua, Italy

CONTENTS

Modularity assigns particular cognitive functions to particular structures (modules) in the brain. These functional units are viewed as operating relatively independently from one another. This view contrasts with the hypothesis that such functions correspond to the highly interactive operations of many brain components.

INTRODUCTION

The dispute between 'modularists' (or 'localizationists') and their 'distributionist' opponents goes back to the dawn of neuroscience. Modularists assign particular cognitive functions to separate 'organs' or 'modules' in the brain, while distributionists see such functions as corresponding to the interactive operations of many brain components. Modularists see the brain's functional units as operating relatively independently from one another; distributionists regard the brain's components as highly interactive.

In the Middle Ages, mental faculties were thought to be localized in the brain's ventricles. The faculties of the mind, derived from the theories of Aristotle, were distributed among the ventricles, as described by Galen. One ventricle was thought to receive input from all the sense organs and to be the site of the *sensus communis*, or common sense, which integrated across modalities. Fantasy and imagination were located there too. The second ventricle was considered to be the site of cognitive processes: reasoning, judgment and thought. The third ventricle was considered to be the site of memory. These ideas remained prevalent until the sixteenth century, when Vesalius attacked the ventricular doctrine of brain functions. In the eighteenth century, von Haller maintained that all parts of the brain were functionally equivalent.

The localization of different psychological functions in different regions of the brain (of the cerebral cortex, to be more precise) began with Gall, in the early nineteenth century. The central ideas of his phrenological system were that the brain is a machine for producing cognition and emotion, and that it is composed of a set of organs with different functions. Gall and his collaborator Spurzheim postulated nearly forty affective and intellectual faculties and assumed that these were localized in specific organs of the cerebral cortex. Gall argued that 'the brain is composed of as many individual and independent organs as there are forces of the soul.'

The most influential critique of Gall came from Flourens in the mid-nineteenth century. Flourens reported that lesions of the cerebral cortex had devastating effects on mental functions. However, the site of the lesion was irrelevant, demonstrating that all cortical areas contributed equally to these functions. In Flourens' view, 'there are not … different seats for different faculties, nor for different sensations'.

Despite their temporary eclipse under the influence of Flourens' experiments, Gall's notions of punctuate localization stimulated the search for relations between the site of the brain injury and specific psychological deficits in patients as well as in experimental animals. The second half of the nineteenth century thus saw an intense search for the localization of sensory centers in the brain. Gall's general ideas were considered to be confirmed by Broca's demonstration of an association between damage to the left frontal lobe and aphasia, and, later, by Fritsch and Hitzig's experiments on the stimulation of the motor cortex. In 1861 Broca presented the case of a patient with severe difficulties in language production (aphasia) and showed that his brain had a lesion in the left frontal lobe. This case corroborated the idea that the human mind could be subdivided into specific functions and that these specific functions were mediated by discrete brain structures. It should be kept in mind, though, that the notion of brain

equipotentiality (or holism) survived, through Charcot and Freud, until Lashley in the 1950s.

THE CONCEPT OF MODULARITY

In the 1970s the concept of modularity became central to cognitive science. Marr thought that this concept was so important as to be elevated 'to a principle, the principle of modular design', according to which 'any large computation should be split up into a collection of small, nearly independent specialized sub-processes'. There is certainly abundant evidence for modularity in the sense of specialized functions. In particular, it is a well-established fact that different brain areas are dedicated to representing information from specific sensory and motor channels. Undoubtedly, the visual system has a modular organization, in which representations of color, shape, motion and location are separable physiologically, anatomically and psychologically at very early stages of information processing. However, one must distinguish between two different meanings of the term 'module'. This word is often used in a general sense to denote any mechanism with a specialized function; in this sense, it actually means 'component or component process that performs a specific computation'. Posner and Shallice among others endorsed this weaker and nonspecific version of modularity, according to which components of the functional architecture, that is 'isolable subsystems', can be distinguished in terms of their specialized functions. For example, according to the modular model of McCloskey, basic number processing consists of three functionally distinct systems specialized for number comprehension, calculation and production. In turn, the calculation system includes memory subsystems for basic numerical facts, rules and procedures. (*See* **Binding Problem**; **Acalculia**; **What and Where/How Systems**)

There is a stronger, more specific, and perhaps more interesting meaning for the term 'module'. It was Fodor who first explicitly discussed what should be meant by 'cognitive module'. In his view, a cognitive module accepts representations as input, transforms them through a set of specialized computations, and transmits the transformed representations onward. Thus, the output of one module is the input to the next module down the line. According to Fodor, cognitive modules are distinguished from other computational mechanisms by strict criteria. Modules are domain-specific, innately specified, informationally encapsulated, hard-wired, autonomous and not assembled. They process information automatically (i.e. their operations are mandatory) and produce a shallow output. They are associated with a fixed neural architecture, when lesioned they manifest a specific breakdown pattern, and, during development they manifest a specific pace and sequencing.

According to Moscovitch and Umiltà, the most important criteria of modularity are domain specificity, informational encapsulation (or cognitive impenetrability) and shallow output. Domain specificity indicates that each module processes information from only a restricted domain, that is, it only responds to stimuli of a particular class (e.g. human faces). Informational encapsulation indicates that the computations that take place within a module are not affected by computations that take place within other modules or in higher-order central systems. Thus, modules are cognitively impenetrable and deliver only a shallow output to other modules and to central systems. An output from a module is considered to be shallow when it is not semantically interpreted. The interpretation of the output is the responsibility of central systems that relate it to general knowledge (i.e. to semantic memory).

Different modules do not interact with one another, except when one has completed its processing, at which point it makes the end product available to other components downstream. That is, a module carries out its computations without being affected by other information available in other modules or in central systems. These characteristics of modules ensure that the computations they perform are not distorted by beliefs, motivations and expectancies. Modules, therefore, act as special-purpose devices, especially suited to picking up information from their restricted domains, processing it efficiently and automatically, and delivering precise – but narrow and presemantic – information to other modules or to central systems for semantic interpretation. As Fodor put it, they are 'stupid' but efficient mechanisms that are necessary for 'representing the world veridically, and making it accessible to thought'.

Moscovitch and Umiltà have argued that modules may be decomposed into a set of smaller modules and this decomposition stops when a level is reached at which all the components are primitive processors. In this view, there can be higher-order systems that have an internal modular structure. These assembled modules, made up of more basic components, do not violate the most important criteria of modularity: they perform specialized functions, do not interact with other modules, are not influenced by semantic systems,

and their outputs are not semantically interpreted – i.e. they are domain-specific, informationally encapsulated and deliver shallow outputs.

AN ALTERNATIVE APPROACH

The parallel distributed processing (PDP) framework is the most recent example of the alternative, distributionist view. The distributed, interactive, graded processing in PDP systems contrasts sharply with the encapsulated, staged, all-or-none processing in modular systems.

According to Farah, the three essential features of PDP systems are distributed representations, gradedness and interactivity. In PDP systems representations consist of patterns of activations distributed over a population of processing units. Different inputs can therefore be represented in the same set of units, because the patterns of activations over the units is distinctive. Knowledge (i.e. semantic memory) is distributed too, because knowledge is encoded in the pattern of connection strengths (weights, as opposed to activations) distributed over a population of units. In PDP systems processing is graded rather than all-or-none. Representations can be partially active. Similarly, partial knowledge can be embodied in connection strengths. The units in PDP systems are highly interconnected and thus mutual influence among different components of the system occurs. (*See* **Backpropagation**; **Hebb Synapses: Modeling of Neuronal Selectivity**; **Synapse**)

The PDP approach therefore assumes that human information processing is graded, distributed and interactive. The representation that is being processed is distributed over a number of units of the network, rather than being localized in a few units. The knowledge involved in a process is distributed throughout a number of connectionist weights of the network, rather than being localized in particular components. Processing is graded and continuous rather than being staged and all-or-none, making partial results in one part of the network continually available to other parts. Groups of units representing different types of information are highly interactive, instead of receiving inputs from only a few other components.

RECONCILING THE TWO APPROACHES

It is unnecessary to represent modular models of cognitive processes as being in conflict with connectionist models. Behind this putative dispute there is a conflation of levels of analysis. If modular models and PDP models are viewed as descriptive of the same processes but at different levels of analysis, the dispute dissolves. This becomes clear if one considers Marr's division of levels of analysis. Functions that need to be computed in a complex cognitive process are specified at the computational level. How those functions are to be computed is specified at the algorithmic level. How the algorithms are physically realized is specified at the implementational level. Cognitive processes can be modular at the computational level, whereas at the implementational level they are distributed and interactive. (*See* **Computational Models: Why Build Them?**; **Computer Modeling of Cognition: Levels of Analysis**; **Connectionism**)

A similar way of reconciling the modular and the PDP approaches is to consider both the macrostructure and the microstructure of a cognitive process. Modular models concern the macrostructure: that is, the level of description that identifies the components of the functional architecture. In contrast, PDP models concern the microstructure: that is, the nature of the operations that go on within the architectural components. Thus, in explaining cognitive process, one should first derive the macrostructural model, in which the relevant components of the functional architecture are identified, and then investigate the microstructure of each component's internal operations. Modular models say very little about the underlying computational mechanisms, which instead are addressed in details by PDP models.

CONCLUSION

The modularity hypothesis assumes that the human brain possesses a functional architecture made up of cognitive modules, that is, of a set of relatively independent information-processing computational mechanisms. A module accepts representations as input, transforms them through specialized computations, and transmits the transformed representations onward. Each module carries out its computations without being affected by information available in other modules. Modules interact only when one has completed its computations, at which point it makes the end product available to a relatively small number of other processing systems.

In contrast, the PDP hypothesis assumes that human information processing is graded in nature, highly interactive, and characterized by distributed representation of knowledge. The two hypotheses may be reconciled by proposing that modular

models identify the components of the functional architecture of the brain, whereas PDP models concerns the operations that are performed within each component.

Motion Perception, Neural Basis of

Introductory article

Norberto M Grzywacz, University of Southern California, Los Angeles, California, USA
David K Merwine, University of Southern California, Los Angeles, California, USA

CONTENTS

Animals perceive motion by extracting velocity information from their visual inputs. Differing aspects of the information are computed in a hierarchical series of sequential stages from the retina through the temporal cortex.

INTRODUCTION

For most animals, the ability to perceive motion is vitally important. For example, a predator must have the ability to track moving prey in order to hunt and survive, whereas prey must detect the smallest movement of a potential predator. Another example is that of locating and communicating with a potential mate, which often involves motion detection. Self-navigation is also critically dependent on one's perception of motion relative to surrounding objects. It is therefore not surprising that the ability to perceive motion appears throughout evolution. Animals as simple as the fly contain motion detectors within their visual systems. Most vertebrates are able not only to detect motion, but also to extract its parameters. This article will focus on vertebrate vision. (*See* **Motion Perception, Psychology of**)

According to Newton, in order to know the motion of a point (or particle), one needs to measure three things, namely direction, speed and acceleration. The first computation related to motion direction occurs within the eye, and this information is sent to both cortical and subcortical areas of the brain. Within the visual cortex, motion direction is independently determined again from non-directional inputs, and is subsequently refined through a succession of cortical stages. However, retinal and most cortical neurons are not speed selective. Some individual neurons in higher cortical areas, such as the middle temporal cortical area (MT), appear to be speed selective. However, it is generally believed that speed is determined by the combined responses of several neurons. Biological systems are extremely good at determining the direction of a motion, and are quite good at determining its speed. However, they are poor at determining acceleration, an issue that we shall not explore further here.

One of the most fundamental sources of visual motion is an animal's own movement, namely egomotion. The overall motion of the visual field that results from egomotion is called *optic flow*. For example, if one moves forward in a straight line, the visual flow will spread out from the center-of-heading (Figure 1a), a type of optic flow that is termed *expansion*. In contrast, self-movement backwards results in *contraction* of the optic flow. Sideways movements yield *translation* (Figure 1b), and tilting the head sideways yields *rotation* (Figure 1c). Figures 1a and c illustrate how despite being globally coherent, local-motion directions can be very different and even opposite. Such visual inputs are termed *complex motions*. Many neurons at the higher stages of the motion-processing pathway selectively respond to these types of complex motions.

Motion perception is computed hierarchically – that is, in successive stages within the brain. This article will follow the hierarchy. The computation begins in the retina with a local computation related to the direction of object movement. In the first visual cortical center, namely the primary visual cortex (V1), motion direction is computed again, independently and somewhat differently. From there, a subset of cells sends information to the MT, and from the latter to the middle superior temporal cortex (MST), and so on. The response properties of the neurons along this path are progressively refined. Thus cells in the higher cortical areas respond specifically to complex aspects of

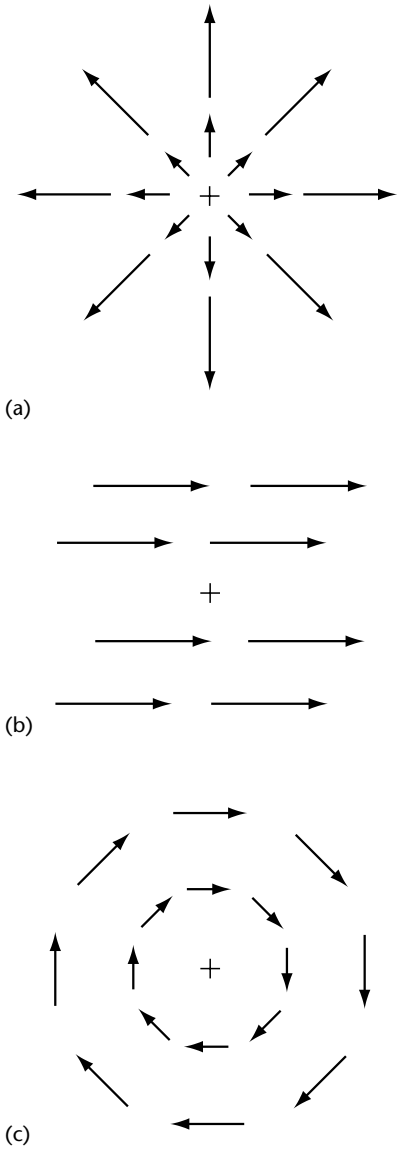

Figure 1. Examples of optic flow. The arrows indicate the direction and speed of motion at each point in space. (a) Expansion. (b) Translation. (c) Rotation.

motion, such as expansion of the optic flow or object rotation in three-dimensional space. (*See* **Modularity in Neural Systems and Localization of Function**)

DIRECTIONAL SELECTIVITY IN THE RETINA

Basic Description

The electrophysiological study of retinal information processing began with H. Keffer Hartline, who later won the Nobel Prize for his research. He discovered that ganglion cells (the retinal output) would alter their firing rates in response to local changes in brightness. The area in which these luminance changes could influence the firing of a cell was termed the receptive field (RF). Horace B. Barlow subsequently made the first reports of motion-selective ganglion cell responses in frog retinas in 1953. He found that there were many cells in the frog retina that would fire continuously so long as a visual object moved within the cell's RF. (Interestingly, when the target neurons of a motion-detecting neuron were electrically stimulated, the frog would snap at the corresponding point in space. The motion-detecting neurons were therefore termed 'bug detectors'. This was one of the first demonstrations of a link between neural activity and behavior.) Later, together with Richard M. Hill and William R. Levick, Barlow recorded the first directionally selective (DS) motion responses in a mammalian retina. (*See* **Single Neuron Recording**; **Receptive Fields**)

Barlow and his colleagues found two types of DS cells in the rabbit retina. The commonest one is the On–Off DS cell. An On–Off DS cell will respond weakly to a small spot that is flashed on or off anywhere within its RF. However, it will fire strongly if a spot (light or dark) is moved through its RF in an appropriate, 'preferred' direction (Figure 2). Motions in the opposite or 'null' direction yield essentially no response, while orthogonal motions yield intermediate responses. The On–Off DS cells are divided according to their preferred directions into up, down, left and right subgroups, each of which independently tiles the retinal surface. The other DS cell type is the on DS cell. These cells will only respond to bright objects, and they prefer larger objects and slower speeds than do the

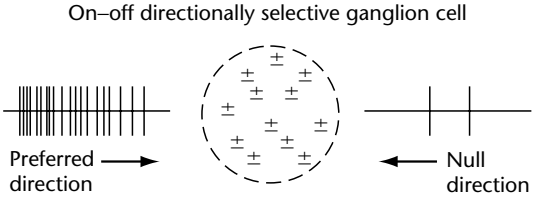

Figure 2. On–Off DS ganglion cell responses. The rabbit retinal on–off DS cell will respond to both the onset and offset of a small spot flashed within its RF (the area enclosed by the broken circle), as indicated by the ± symbol. This cell will respond vigorously to a spot, slit or edge moved in its preferred direction (to the right in this example), but will respond poorly to motions in the opposite or null direction. Upward or downward motions elicit intermediate responses. In this and subsequent figures, the vertical lines denote spikes.

On–Off DS cells. There are three subgroups of on DS cells, whose preferred directions of motion align with the semicircular canals of the vestibular (balance) system.

Species Comparison

The retinas of mammals, birds, reptiles and amphibians have all been shown to contain DS cells (fish are the only major vertebrate class in which DS cells have rarely been reported). However, as with the two rabbit DS cell types described briefly above, there are many differences in DS cell properties between species. Preferences for light versus dark objects, slow versus fast speeds, sensitivity to object shape and level of dendritic ramification all vary according to the species. Even the percentage of DS cells in the retinal population varies widely. Directionally selective cells are reported to represent between 2% (in cats) and 40% (in turtles) of the retinal ganglion cell population. These percentage differences largely reflect the differences in neocortex available to these species for processing visual information. Thus species with little or no neocortex devote many retinal neurons to computing directional selectivity, while those with large neocortices do not. Nevertheless, despite differences in detail, there is a highly conserved plan among vertebrate species with regard to the use of DS cell output. For all species this information is sent to the accessory optic and pretectal brainstem nuclei. These structures participate in the vestibulo-ocular and optokinetic systems which stabilize the eyes during rotatory head movements, or during rapid global image movements on the retina. Thus these systems are crucial for determining whether image motions on the retina are due to eye, head or body movements or reflect the movement of external objects.

Detailed Response Properties of On–Off DS Cells

Many studies have been undertaken to elucidate further the properties of the rabbit retinal On–Off DS cell, the aim being to understand the mechanisms responsible for its behavior. For example, it has long been known that an object does not have to pass through the entire RF of an On–Off DS cell in order to generate a DS response (the opposite applies to simple cortical DS cells). Anatomically, the dendritic trees of the On–Off DS cell contain many 'loops', which are consistently around 40–50 μm in diameter. Therefore it was proposed that these cells contained multiple 40–50 μm subunits, each of which performed the DS computation independently. This proposal was consistent with earlier measurements by Barlow and Levick, who attempted to determine the shortest motions that produce DS responses. However, it was recently demonstrated that these cells can discriminate direction of motion for movements as small as 26″ of visual angle (*c.* 1 μm on the retinal surface!). This result severely limits the possible mechanisms for computing directional selectivity, implying that they act very locally, they probably involve only a few synapses, and they exist essentially everywhere within the cell's dendritic tree (or those of its inputs). At the time of writing, the function of the dendritic loops remains unclear. (*See* **Neurons, Computation in**)

Another interesting feature of these cells' responses is that their directional selectivity is invariant to other aspects of a stimulus. For example, consider speed. It is true that an On–Off DS cell will respond best to motions within a narrow speed range. Nonetheless, this cell will respond significantly better to a preferred-direction motion than to a null-direction motion, regardless of the speed. The same is true for temporal frequency. Responses to moving sine- and square-wave gratings may be better for certain temporal frequencies than for others, but the cell always responds better to a preferred-direction stimulus, regardless of the temporal frequency. Finally, imagine that one presents an On–Off DS cell with two simultaneous, nonparallel, drifting sine- or square-wave gratings (so that their overlap forms a 'plaid', as shown in Figure 3). In this case, the cell will respond best when the 'plaid' motion is in the preferred direction. In other words, retinal DS responses are independent of the orientation of the gratings. (This is similar to pattern cells higher in the cortical motion pathway; see below.) In essence, if the cell can 'see' the motion stimulus, it will respond to it in a directionally selective manner. Thus it seems that this cell sacrifices information regarding the exact location, speed, size and shape of stimuli, so that

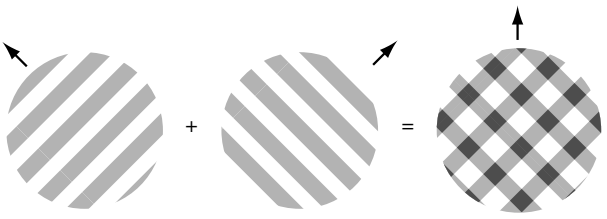

Figure 3. Plaid motion. Two moving gratings are superimposed to form a moving plaid.

it may robustly indicate their motion direction. The 'lost' information is encoded along the cortical motion pathway.

DIRECTIONAL SELECTIVITY IN THE CORTEX

The Motion Hierarchy

Inputs from the retina pass through the thalamus on their way to the primary visual cortex, also known in primates as V1 (Visual Area 1). From V1, visual information is split along two primary pathways. One path extends into the temporal cortex and contributes to the recognition of objects. The other path, which we shall discuss here, is extended into the parietal cortex and is used to analyze visual motion. This pathway is hierarchical – that is, the information is processed in a series of stages. At each stage, the information is progressively refined. Thus cells at the beginning of the hierarchy respond only when presented with an appropriately oriented, moving edge in a well-defined spatial location. In contrast, cells at higher stages in the hierarchy respond to complex motions, regardless of spatial location. However, it should be noted that the computation of motion is not simply sequential. There is crosstalk with other cortical as well as subcortical areas, and there are back-projections to earlier stages along the hierarchy. Recent experiments suggest that these connections may be crucial for attention, visual awareness and image segmentation (the parsing of the image into regions of relatively homogeneous properties). (*See* **Parietal Cortex**)

The parietal-motion pathway begins with signals from directionally selective V1 cells. These cells project to the middle temporal cortex (MT or V5) and to V2, whose neurons also project to the MT. From the MT, the motion pathway proceeds to the middle superior temporal cortex (MST). In turn, MST cells project to the lateral and ventral intraparietal areas (LIP and VIP), as well as to V7a. These latter stages in the pathway also carry information for motor planning and control, which are among the main goals of the motion-processing system.

V1 Cells

The first DS cells along the cortical path appear in the input layers of V1. Nearly all of the so-called 'simple' cells there show some directional selectivity. Indeed, nearly all neurons in V1 are directionally selective to some degree. However, this selectivity is weaker than that in the retina. Moreover, the simple-cell selectivity is dependent on the size, location, spatial frequency and orientation of the visual stimulus. A simple cell contains separate on and off subregions and responds weakly to a spot flashed in these locations. The best response of this cell occurs when an oriented edge passes entirely through the cell's RF in its preferred direction. As with retinal DS cells, the preferred direction of motion cannot be explained by any spatial organization of the cell's dendritic tree. However, it is often possible to predict the preferred direction of motion for a simple cell by examining its response to flashed spots. Thus directional selectivity in these cells has been explained using a simple additive scheme, which we shall discuss in the section on models and mechanisms of directional selectivity below.

The simple cells project to the upper and lower layers of V1 where 'complex' DS cells are found. These cells do not respond to flashed spots, nor do they have separate on and off subregions. Like simple cells, complex cells prefer oriented edges moving in a particular direction. However, it is no longer necessary for an object to pass through the complex cells' entire RF in order to generate a DS response. It is still unclear to what extent (if at all) the directional selectivity of simple cells contributes to that of complex cells.

MT Cells

A subset of DS V1 cells projects to the MT. Cells in the MT have large RFs, often 10 times larger than those of cells in V1. MT cells will respond to an object moving in their preferred direction anywhere within their RF. In addition, J. Anthony Movshon and colleagues found that approximately one-third of the cells in the MT (called pattern cells) could detect the motion of a plaid in a DS manner. That is, suppose that the cells are presented with two overlapping sine waves moving in different directions (Figure 3). In this case, these cells will respond best when the composite motion of the sine waves, not their individual motions, is in the preferred direction. This behavior is illustrated in Figure 4. In contrast, the component MT cells (the other two-thirds) behave similarly to cells earlier in the cortical hierarchy – that is, they respond whenever either of the two gratings is moving in the preferred direction of the cell. Not surprisingly, human subjects see the coherent plaid motion under many stimulus conditions (i.e. subjects often see the motion 'reported' by the pattern cells). However, under some conditions (e.g. when the sine waves have

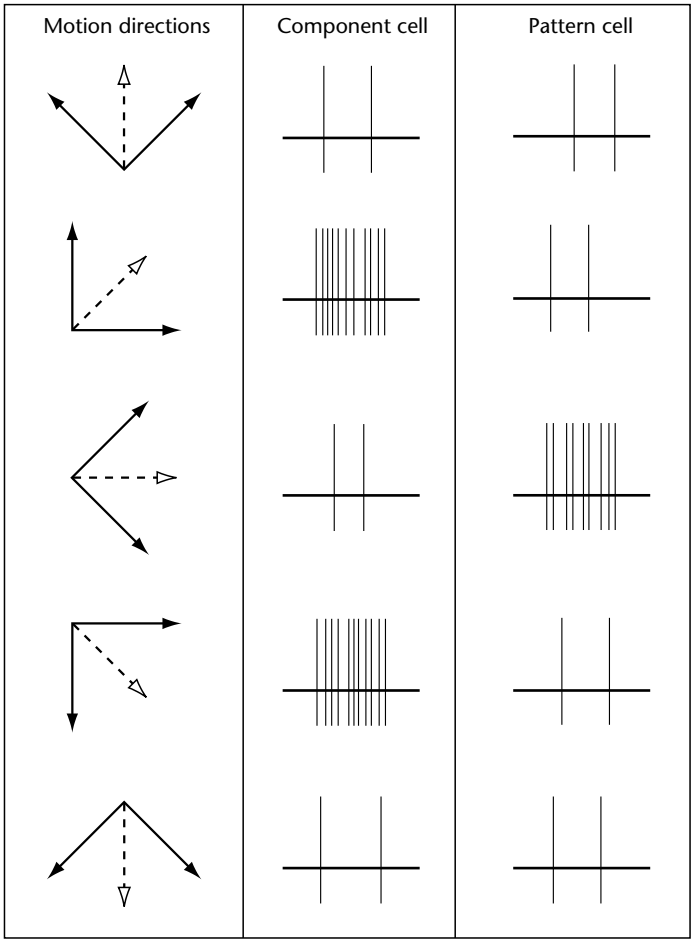

Figure 4. Responses of component and pattern MT cells. The left-hand column shows motion stimuli, while the center and right-hand columns show the responses of component and pattern MT cells, respectively. For the motion stimuli, the solid arrows indicate the motion directions of two identical sine-wave gratings. The broken, open arrows show the motion of the plaid formed by the combination of the gratings (Figure 3). A component cell will respond whenever either grating is moving in the preferred direction (to the right for both cells in this figure), as shown in the second and fourth rows of the second column. This cell does not respond when the plaid motion is in the preferred direction (third row of second column). A pattern cell, on the other hand, will not respond to the individual gratings, but will respond to the plaid motion.

very different contrasts and spatial frequencies), subjects see the sine waves sliding past each other. This percept is termed transparency.

MST Cells

Cells in the MT primarily send their outputs to the middle superior temporal cortex (MST). Here DS information from several cells converges to create neurons with very large RFs. Neurons in the MST are the first motion neurons in which RFs are bilateral – that is, they extend across the visual midline. Some neurons in the dorsal region of the MST have RFs that cover most of the visual field. These cells combine DS inputs in such a way that they are sensitive to complex visual motions, such as contraction, expansion or rotation of the optic flow. A subregion of the MST is also devoted to encoding translational motions. Interestingly, the cells that respond to translational motions are active so long as the stimulus is present. Cells that are attuned to rotational or expansive motions, although they show a strong sustained component to their response, also display a strong transient response to the onset of a complex motion. This signal may prove crucial for navigating through the environment while simultaneously moving one's head and eyes. We shall discuss these responses in more detail in a later section.

Before we leave this section, we would like to mention an area located lateral and anterior to human MT/MST. (This newly discovered area

and the MT/MST complex are both in the superior-temporal sulcus.) This area is interesting because it extends the capabilities of the MST to the detection of biological motions, such as 'point-light walkers'. Point-light walkers are images produced by placing lights on the joints of a moving person. Subjects readily recognize these displays, and can even report the gender of the 'walker'. The newly discovered area is specifically activated by such displays.

Correlation between Cell Responses and Perception

William T. Newsome and colleagues have performed a fascinating series of experiments with MT neurons. The aim was to investigate whether motion perception is genuinely determined by their activity. These scientists trained monkeys to report their perception of the direction of a group of moving dots. Some of these dots were correlated (i.e. moving in the same direction), while others were not. By varying the percentage of correlated dots, Newsome and colleagues discovered that the monkeys' discrimination mirrored directly the activity of the cells in the MT. Furthermore, as the responses varied because of noise, the discrimination also varied in a predictable manner. These researchers further showed that they could control the monkeys' reported perception by injecting small amounts of current into the MT during the experimental trials. Thus they provided strong evidence that the firing rate of these neurons directly encoded the animals' perception.

MODELS AND MECHANISMS OF DIRECTIONAL SELECTIVITY

Models of Directional Selectivity

During their studies of retinal directional selectivity in insects, Werner T. Reichardt, Tomaso Poggio and their colleagues described the theoretical requirements for any model of directional selectivity. The first requirement is a spatial asymmetry. That is, if a neuron responds better to motions coming from the left than to motions coming from the right, then there must be some difference in the neural inputs from the left and right sides of the cell's RF. Essentially, all DS models propose that this asymmetry is temporal. In other words, some difference in time course exists between the left- and right-side inputs. However, this need not be the case. For example, the left-side input could 'gate' the right-side input. In this case, the cell will only fire if the motion comes from the left and opens the gate before the right-side input is activated.

The second requirement for producing directional selectivity is a nonlinear mechanism (i.e. a mechanism that does not simply additively sum its inputs to determine its output). A spatial (plus temporal) asymmetry as described above can generate a directional difference in the response (i.e. differing response waveforms depending on the direction of stimulus motion). However, this alone is not sufficient to produce two different single-number responses for preferred- and null-direction motions. The work by Poggio and Reichardt proves that, without a nonlinear mechanism, the numbers obtained by integrating (summing over time) the waveforms of the responses must be equal for all directions of motion. Some nonlinearity, perhaps as simple as a threshold, must be present. (A threshold nonlinearity operates by only allowing responses when the input exceeds some minimum value.)

Figure 5a illustrates the simplest model proposed for insect retinal directional selectivity, known as the Reichardt model. For clarity, the model uses inputs from only two locations, although more complex versions are possible. (The mechanism is presumably replicated many times within the RF of the DS cell.) The proposed spatial asymmetry in this model is temporal. Inputs from the side first encountered by an object moving in the preferred direction (left in the figure) propagate to the interaction site slowly compared with those from the null side. The proposed nonlinearity for their interaction is multiplication. Therefore if an object moves in the preferred direction at the right speed, the slowness of the left-side path is compensated for by the earlier arrival time of the stimulus. This allows both inputs to arrive at the interaction site at the same time, yielding a positive multiplication. For null-direction motions the inputs will arrive separately, and the result of the multiplication will be zero. Interestingly, many psychophysical models of human motion perception follow variants of this multiplicative Reichardt model. (*See* **Computational Neuroscience: From Biology to Cognition**)

Retinal Mechanisms for Directional Selectivity

As part of their study of rabbit DS cells, Barlow and Levick performed a series of two-slit apparent-motion experiments. These scientists drew attention to the responses to two adjacent slits that were flashed as if an object was moving in the

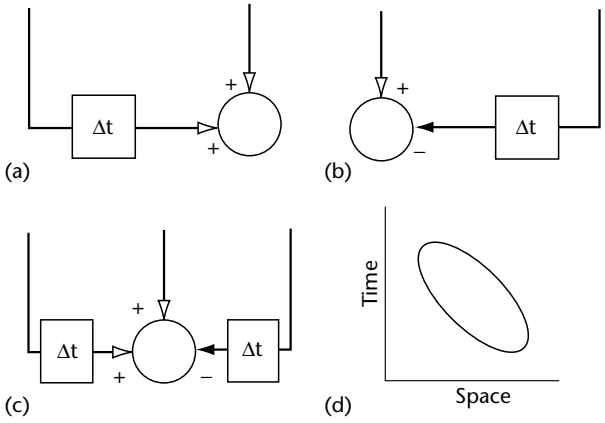

Figure 5. Models of theoretical DS mechanisms. In the retinal models (a, b and c), the lines with arrows represent inputs to nonlinear interaction sites (denoted by circles). Boxed Δt symbols denote slow or delayed input lines. Movement proceeding from the slow line to the fast line can create signals that arrive at the interaction site simultaneously. In this figure, these signals are such that all of the illustrated models prefer rightward motions. (a) In the Reichardt model, the proposed interaction is facilitatory (multiplication). (b) In the Barlow and Levick model, the proposed interaction is inhibitory (now believed to be division-like). (c) In the two asymmetrical pathways model, both facilitation and inhibition operate, allowing for robust DS to a variety of motion stimuli. (d) Spatio-temporal inseparability. The horizontal axis indicates the spatial location of a visual stimulus, while the vertical axis shows the time of peak response. For a cell with spatio-temporally inseparable responses, the tilted oval bounds the response region. Thus there is an orderly progression between space and time, such that only for motion in a particular direction will the responses from several points in space coincide in time.

null direction. The response generated by the DS cell under study was far less than the sum of the responses for each slit flashed alone. Barlow and Levick concluded from this that directional selectivity in these cells was produced by a nonlinear, inhibitory mechanism that 'vetoes' responses to null sequences. As shown in Figure 5b, their proposed spatial asymmetry has two components. The central component is excitatory and propagates quickly. The second, inhibitory component is offset to the null side and propagates slowly. Thus an asymmetry exists in both the sign and the time course of the two spatially separated components. Therefore motions in the preferred direction will yield responses, while null-direction motion responses are vetoed. Studies performed more recently by Franklin R. Amthor and colleagues have shown that these cells cannot perform a perfect veto, and that a better description of the inhibitory interaction is a division-like nonlinearity.

In addition, the response of a DS cell to a preferred-direction apparent motion is greater than the sum of the responses to each slit alone. This is called preferred-direction facilitation. Under some circumstances, preferred-direction facilitation can be as strong as null-direction inhibition. The excitation responsible for facilitation appears to originate from starburst amacrine cells which release the neurotransmitter acetylcholine. It has been shown that there is a spatial asymmetry in the input–output relationship of the dendritic trees of these cells. Their dendrites receive excitatory inputs along their entire length, but they release excitatory neurotransmitter and may receive inhibitory inputs only at their tips. (These neurons do not have axons!) Several lines of evidence indicate that the tip inhibition acts in a division-like manner. Therefore each dendrite contains a spatial asymmetry and a nonlinearity, and can act as an autonomous DS unit. For this reason it has been proposed that DS signals appear presynaptically (before the DS ganglion cell itself), and flow from the dendrites of the starburst amacrine cell to the DS cell. A DS cell could therefore generate its responses by preferentially sampling from starburst-cell dendrites with a common preferred direction.

However, there is accumulating evidence that both pre- and postsynaptic asymmetries may be involved in producing retinal directional selectivity. Complete blockade of starburst-cell outputs with acetylcholine antagonists does not entirely eliminate this selectivity to moving bars. The residual direction selectivity appears to be postsynaptic. In turn, blocking the inhibitory input to a DS cell (with antagonists of the neurotransmitter GABA) does not always eliminate retinal directional selectivity. Moreover, such blockade occasionally even reverses the cell's preferred and null directions. Computer simulations of the starburst dendritic directional selectivity can account for these reversals because of synaptic saturation. Thus asymmetrical postsynaptic inhibition and asymmetrical presynaptic facilitation may act cooperatively (Figure 5c) to produce robust directional selectivity in On–Off DS ganglion cells.

Cortical Mechanisms for Directional Selectivity

There are two classes of models that have been proposed to account for cortical directional selectivity. One class, advanced by George Sperling and colleagues, is based on human psychophysics,

and is similar to the Reichardt model shown in Figure 5a. Another class consists of the motion-energy models advanced by Edward H. Adelson and James R. Bergen. As with all DS models, motion-energy models require a spatial asymmetry. The proposed spatial asymmetry is that successive adjacent locations in the cell's RF will respond with gradually decreasing sluggishness. The cell's RF profile is therefore tilted in space and time, as shown in Figure 5d by the slanted oval. This property is known as space–time inseparability. As can be seen in the figure, for this type of space–time arrangement only one direction of object motion (to the right) can result in the DS cell's inputs all arriving simultaneously. As before, simple linear summation will result in differential response waveforms for preferred- and null-direction motions, and some nonlinearity must exist to convert this directional difference into directional selectivity. The most commonly proposed nonlinearity is squaring, which is described as extracting the motion energy from the directional difference. (*See* **Psychophysics**)

Robert M. Shapley and colleagues obtained physiological evidence for space–time inseparability in both the on and off subregions of the inputs to the simple DS cells found in V1. However, the correlation between the simple cell space–time profile and direction selectivity varies widely in V1. Cells in some layers of V1 show a very high correlation, while those in other layers show a very low correlation, despite equivalent directional tuning. Thus space–time structure alone cannot completely account for simple DS cell responses. In addition, these models of DS simple cells generally overestimate non-preferred responses and sometimes underestimate preferred responses. Moreover, these models do not predict onset transients, which are commonly observed. Therefore both inhibitory and excitatory feedback interactions between cortical cells have been proposed to account for these discrepancies. The exact mechanisms for producing directional selectivity in these cells are still the subject of debate.

Because the complex DS cells of V1 do not respond to flashed spots, they cannot show space–time-oriented RFs. However, it has been demonstrated that the interactions between two sequentially stimulated locations in a complex cell's receptive field are space–time inseparable. This behavior is termed second-order space–time orientation. Dynamic nonlinearities have been proposed to account for the directional selectivity of complex DS cells. These nonlinearities would facilitate or inhibit, respectively, the responses to preferred- or null-direction motions. Similarly, space–time-separable simple cells have also been shown to display some second-order space–time structure. Because there is ample evidence for interactions between complex and simple cells, it is possible that second-order space–time inseparability in simple cells arises from complex-cell inputs.

The directional selectivity in MT neurons is more sophisticated than that in V1, especially in pattern cells (Figure 4). Many models have been advanced to account for the orientation independence of pattern cells. These models often begin by pointing out the aperture problem of V1 cells – that is, the difficulty in determining the true direction of motion through small apertures (e.g. small RFs). This is because they only reveal small, straight portions of contours, and it is impossible to tell the direction of motions parallel to straight edges. Models of pattern cells combine the responses of V1 (or component) cells with many preferred directions to disambiguate the direction of motion of multi-orientation patterns.

SELECTIVITY TO SPEED

The visual system measures not only the directional component of the velocity vector but also its magnitude – the speed. Measuring speed is important for vision. For example, humans appear to use both direction and speed signals to obtain a precision of 1–2° in the estimation of heading direction. Furthermore, Richard Andersen and colleagues have shown that both humans and primates benefit from speed information when estimating the three-dimensional structure of objects from motion cues. Psychophysical findings also indicate that one can segment images based solely on gradients of speed signals. Moreover, smooth pursuit and saccades are made precise because speed signals are used in their computations. Finally, the visual system must somehow use speed signals to achieve effective deblurring. (Motion blurring occurs when one leaves the shutter of a camera open for too long when there is motion in the image.)

However, measuring speed is more difficult than measuring the direction of motion. It is difficult to measure the former because it is the magnitude of the derivative of position over time, and thus requires precise spatio-temporal information. In contrast, to measure direction one only requires two relatively imprecise position measurements. Psychophysically determined measurements of local and instantaneous speed have been found to be very noisy. The relative errors in the measurement of local speed are in the range 30–100%.

Nevertheless, humans can measure speed precisely if they are provided with a relatively long trajectory of motion. Under these conditions, the errors made when discriminating speed can be as low as 5%. This high level of precision seems to be achieved by integrating relatively imprecise local-speed signals over time. The 5% precision of velocity determination occurs in many experimental conditions, including motions of dots, edges, sine-wave gratings (of varying spatial and temporal frequencies), plaids and frequency-modulated stimuli. (In the latter, the local-intensity profile is not moving, but the contrast of local portions of the profile increases transiently, and this perturbation propagates with fixed velocity.)

Perhaps the simplest method of measuring local visual speed is by its derivative definition. This involves finding the positions of an image feature in two discrete instances in time and then computing the ratio between the positional distance and the temporal delay. It is essentially the approach proposed by Shimon Ullman in his minimal mapping theory. He proposed that the main problem facing the visual system when measuring motion is to solve the correspondence problem – that is, to find correspondences between image features at one instant in time and (hopefully) the same features at the next instant in time. Ullman suggested that the features correspond to minimize the total distance traveled. After correspondence has been established, distance, delay and thus the velocity of a feature can then be calculated. Serious challenges to Ullman's emphasis on the correspondence problem, and thus his method for measuring visual speed, have been raised by motion psychophysicists, who pointed out that his theory was not immediately consistent with known neural processes underlying motion perception. Moreover, they argued that the correspondence problem is essentially non-existent when one is dealing with real neural RFs. (*See* **Computational Neuroscience: From Biology to Cognition**)

When one looks directly at neural responses for clues as to how the brain measures speeds, a puzzling finding arises. Neurons have a sharp optimal speed if they are stimulated with moving edges, especially in the MT. However, cells in V1 and 40% of the cells in the MT do not seem to detect speeds. If these cells were speed tuned, then if one were to raise the temporal frequency of the stimulus, the spatial frequencies that yield the optimal responses should increase in proportion (Figure 6a). Rather, these motion sensitive cells are tuned to spatio-temporal frequencies, regardless of speed (Figure 6b). Nevertheless, the work of

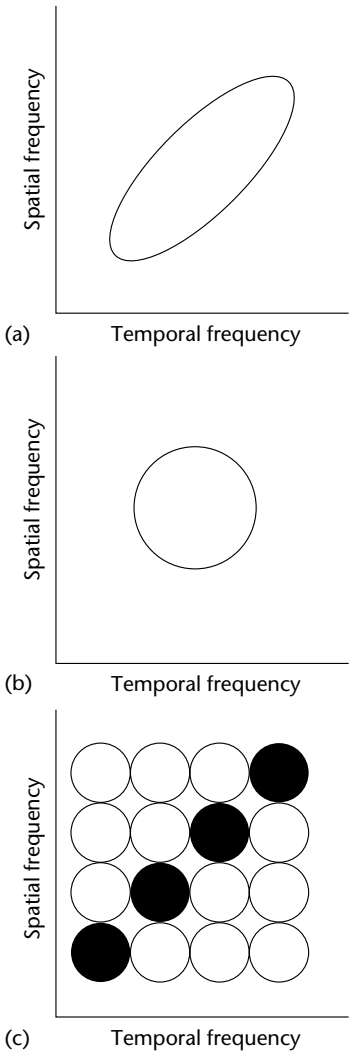

Figure 6. Theories for speed encoding. For (a), (b) and (c), the vertical axis indicates the spatial frequency of a moving sine-wave grating and the horizontal axis indicates the temporal frequency at which the intensity of every point oscillates. (a) Idealized relationship between optimal spatial and temporal frequencies for a cell that can encode speed. For any given speed, as the spatial frequency of the grating increases, the optimal temporal frequency increases in proportion. Therefore speed is indicated by the slant (slope) of the oval response region. (b) Spatio-temporal profile of a non-speed-selective cell on the motion pathway. Most motion-selective cells are band-pass in both the spatial and temporal domains. Non-speed-selective cells do not show the organized relationship (shown in a) that is required for speed selectivity. (c) A population code for speed. Each cell is represented by a circle whose center denotes the optimal spatial and temporal frequencies of the cell. Solid and open circles illustrate responding and non-responding cells during a translation. By looking at a population of cells with band-pass spatio-temporal response properties, a higher-level unit can determine speed regardless of the spatial and temporal frequencies of the stimulus.

John A. Perrone and Alexander Thiele revealed that 60% of MT cells show true speed selectivity. So how do 60% of MT neurons compute speed from inputs that are not speed selective?

A Population Code for Speed

Several investigators have proposed that speed selectivity arises from a population code. In such a code, a speed-selective cell high in the motion-pathway hierarchy could read the speed of the stimulus from the simultaneous firing of many earlier cells. Eero Simoncelli, David Ascher and colleagues obtained psychophysical data that support the concept of a population code. We shall now explain this idea in more detail.

Population-code models for the measurement of local speed begin by looking at the responses of a population of DS neurons with different receptive-field sizes. It is known that V1 neurons with increasingly larger receptive-field sizes are tuned to increasingly lower spatial frequencies when they are stimulated with sinusoidal gratings. Moreover, different neurons tend to be tuned to different temporal frequencies of the gratings. The population-code models for local speed measurement consider a three-dimensional space defined by these tunings. In this space, two axes are the optimal horizontal and vertical spatial frequencies that drive different DS cells, while the third axis represents their optimal temporal frequencies. A point in this space corresponds to a DS cell. This space is of interest when a visual translation of given velocity covers the receptive fields of these cells. The optimal responses tend to fall on a plane in this space. Figure 6c illustrates the projection of this plane on to the plane formed by the temporal-frequency axis and one of the spatial-frequency axes. To measure local speed in population-code models, one must detect the slant of the projecting plane relative to the temporal-frequency axis. Several schemes for detecting this plane have been proposed in the literature. These schemes depend on the exact spatio-temporal properties of the cells, although Ascher and colleagues described how to design good schemes under broad conditions.

Finally, although we first introduced the concept of population codes in the context of determining speed, such codes must occur generally in the brain. Even if a cell is tuned to a particular property, the response of that cell may be modulated by other properties. This would mean that a cell's firing rate was not unique. Consequently, the brain must look at the firing of several cells in order to disambiguate any particular property. In the motion domain, in addition to speed, such a disambiguation also occurs for direction of motion. For example, one can obtain local direction from the tilt of the plane described above relative to the spatial frequency axes. (*See* **Decoding Neural Population Activity**)

SELECTIVITY TO COMPLEX MOTIONS

Interesting Types of Complex Motion and MST

The two preceding sections focused on the measurement of two local variables of motion, namely direction and speed. However, as was shown in Figure 1, the motion of optic flow is in general globally complex. This complexity arises because, for example, as one moves through the environment, neighbor velocity vectors are statistically dependent. A similar dependence occurs when a rigid or quasi-rigid object moves in front of one's eyes. Jan J. Koenderink showed that if one considers small planar patches in the surface of moving, rigid objects, their general motion can be decomposed in terms of translational, radial (expansion and contraction), rotational and shear motions. These types of motion can be modeled with a few parameters describing the dependence of the local velocity vectors. For instance, one can describe a rotation by specifying its center and its angular velocity. In turn, one can specify an expansion by specifying the focus and rate of expansion. Thus if the brain could measure the few parameters of translational, radial, rotational and shear motions, then it could estimate such things as direction of egomotion heading. As was explained earlier, the MST is the first cortical area to be selective for these motions. Neurons in the dorsal portion of this area (MSTd) respond selectively to these motions, either alone or in combination (e.g. spiral motions). Figure 7 illustrates how one sees this selectivity in the electrophysiological recordings. An expansion-selective cell (second column) responds strongly to expansion (a) but not to contraction (b) or rotations (c and d). In contrast, a cell that is selective for clockwise motion (second column) responds strongly to this motion (c) but not to counter-clockwise rotation (d) or radial motions (a and b). These cells also do not respond to translation (not shown in the figure).

Roles of MST Neurons

What are the behavioral functions of the MST cells that are selective for complex global motions? Kenneth J. Britten and Richard J. van Wezel showed that microstimulation of neurons in this

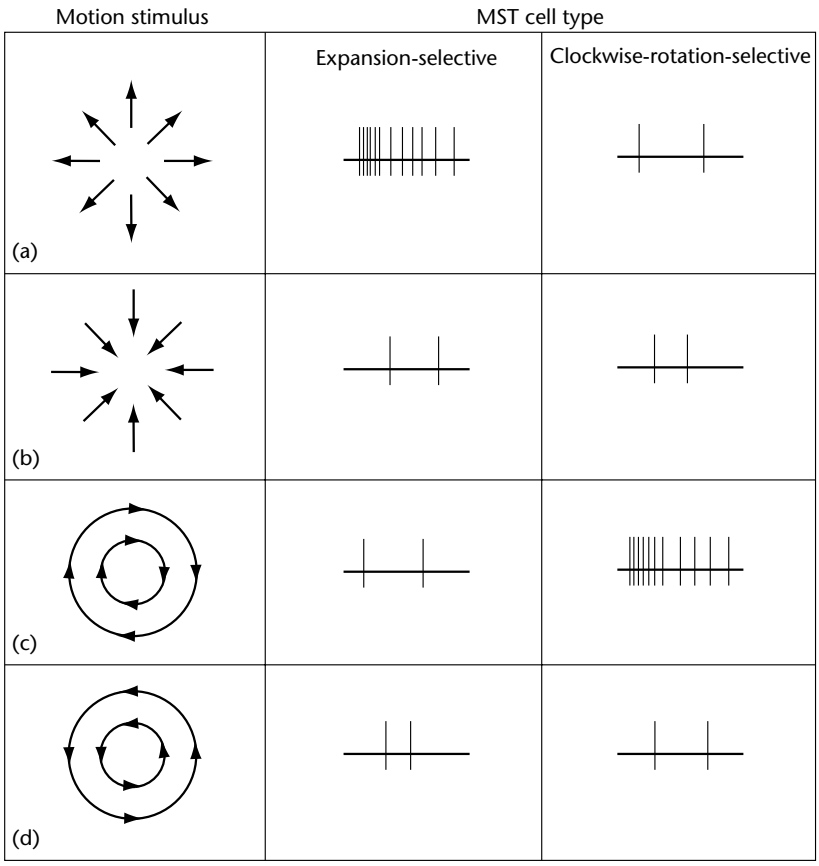

Figure 7. Responses to complex motions by MST cells. The left-hand column shows various complex-motion stimuli, while the center and right-hand columns indicate the responses of expansion-selective and clockwise-rotation-selective cells, respectively. Each cell type responds only to a specific global coherent motion presented within its RF. (a) Expansion. (b) Contraction. (c) Clockwise rotation. (d) Counter-clockwise rotation.

area influences the heading behavior of primates. Related to this, Andersen and colleagues showed that many MSTd neurons shift their focus-of-expansion tuning curves, compensating for retinal motions during eye movements. (This tuning curve is the cellular activity as a function of the focus location of the stimulus.) Because the focus of expansion indicates the direction of heading, this and the results of Britten and Wezel demonstrate the contribution of these neurons to this function. Another of their roles was demonstrated by lesions of the MST, which impaired the animal's ability to execute a smooth-pursuit eye movement when the target moved towards the lesioned hemisphere. (A similar deficit was seen for optokinetic nystagmus movements.) Furthermore, microstimulation within the MST influenced the velocity of smooth-pursuit eye movements. Thus MST neurons must also contribute to the control of eye movements. A final role that we shall mention here is that MST neurons can code the abstract concept of a motion as well as the actual motion of a visual stimulus. In the experiment demonstrating this role, animals saw some stimuli appear and then move in some trials. In other trials, the stimuli appeared, disappeared, and then reappeared at the same final location as the moving stimuli. This simulated a motion that might have occurred behind an occluder. Many MST neurons coded the direction of the occluded motion, which strongly suggested that the MST has a central role in the perception of motion.

Mechanisms of MST Receptive Fields

It is thought that the receptive field properties of MST neurons emerge from the combination of properties of earlier neurons. This is very similar to pattern cells in MT being built out of component cells. For example, one could build a clockwise-rotation-selective cell by using DS cells with leftward, upward, rightward and downward preferred directions. All one has to do is to place these

cells in the bottom, left, top and right visual fields, respectively. However, one problem with this idea is that these cells show position and scale invariance. In other words, although the magnitude of the response may vary with location, the selectivity for a particular pattern of motion remains the same throughout the receptive field, regardless of size. Thus building MSTd RFs is not simple, and may involve dendritic subunits such as those described earlier for the retina. A further complication is that the complex selectivities in MST are also independent of the cues that convey the motion. For instance, effective expansion stimuli could be generated by illusory contours. Consequently, one must explain how any motion that appears perceptually as an expansion will activate an expansion neuron, even if the luminance pattern is not expanding.

It also remains unclear whether MST computations include estimations of all of the parameters of the optic-flow components described by Koenderink. Koenderink himself, and some of his colleagues, performed psychophysical experiments which showed that humans do not metrically discriminate all of the parameters of complex motions. For example, according to these experiments, humans may not discriminate between angular velocities. However, many of the experiments used impoverished visual displays. Experiments that have been conducted more recently with richer displays indicated that humans could measure quantitatively certain complex-motion parameters, including angular velocity.

CONTENTS

The motor areas of the cerebral cortex are those four regions most directly involved in deciding which movements to make and in executing the selected movements – posterior parietal, dorsolateral prefrontal, secondary motor, and primary motor cortex.

INTRODUCTION

In a sense, the entire nervous system functions to animate the body. Based on sensory inputs about external and internal conditions, on stored information about past experience, and on considerations of current and future needs, the nervous system organizes and executes movements intended to optimize the life of the animal. Some of these movements, such as those associated with subtle adjustments of the legs needed to maintain upright posture, are reflexive and are mediated primarily through spinal or brainstem circuits. Others serve more complex purposes, and involve goal-directed voluntary activities such as acquisition of food, creation of shelter, production of tools, and communication through gesture, vocalization, speech, writing, dance, or music. The mammalian cerebral cortex performs much of the complex information processing used in generating these voluntary, goal-directed movements.

With this broad view, the entire cerebral cortex could be considered 'motor'. Here, however, we will focus on four regions most directly involved in deciding which movements to make and in executing the selected movements. Information traditionally is considered to flow from sensory input and perception, to associative decision-making, to execution of motor output. We will therefore consider how the posterior parietal cortex processes visual and somatosensory inputs to guide movements in space; how the dorsolateral prefrontal cortex decides which responses to make; how secondary motor areas participate in selection of movements to perform; and how the primary motor cortex executes movements. During any given movement, neurons in many interconnected regions of the cerebral cortex (and other parts of the brain as well) are active concurrently, and their discharge may share many features.

Figure 1 illustrates where these regions lie in the cortex of a macaque monkey, and how they are interconnected.

ROLES OF THE FOUR MOTOR AREAS

The Posterior Parietal Cortex: Guiding Voluntary Movements in Space

In order to reach out, grasp, and handle an object, two fundamental operations need to be performed. Firstly, the body part that is to interact with the object needs to move into the vicinity of the target object. In primates, this typically is the hand, but could also be the mouth or the foot. Inevitably, this transport function is the responsibility of the appendage (the arm, head, or leg) upon which the interacting body part is fixed. Secondly, the manipulator, such as the hand, needs to be configured appropriately so as to conform to the shape of object to be grasped.

Different types of spatial information are required to perform these operations successfully. For the transport function, information is needed about both the location of the object and the location of the limb. In order to manipulate objects proficiently, additional information is needed about the shape and orientation of the target object. Two major corticocortical inputs converge in the posterior parietal cortex to provide this information: inputs from the dorsal visual stream of the occipital

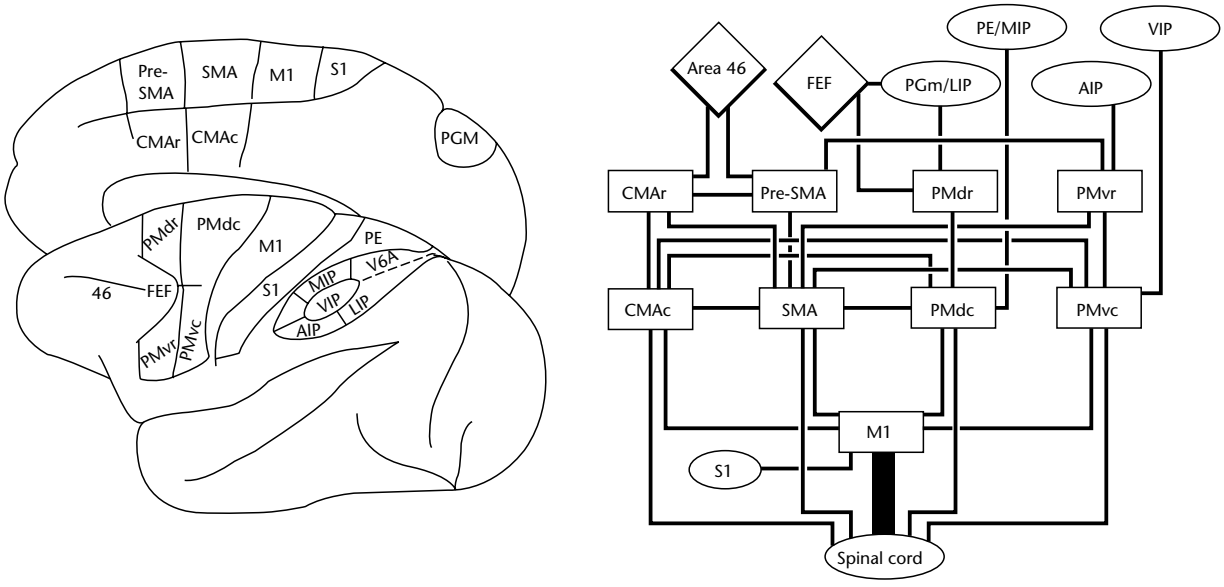

Figure 1. Cortical motor areas of the macaque monkey. (a) Anatomic location. The primary motor cortex (M1) is equivalent to Brodmann's area 4. Brodmann's area 6 on the hemispheric convexity has been subdivided into ventral and dorsal premotor cortex (PMv and PMd, respectively) on the convexity, each with further caudal (c) and rostral (r) subdivisions. Brodmann's area 6 on the medial surface of the hemisphere (shown above), formerly considered the supplementary motor area (SMA), recently has been subdivided into SMA proper and pre-SMA. Additional motor areas have been identified in the cingulate cortex (Brodmann's areas 23 and 24); this cingulate motor area (CMA) again has caudal and rostral subdivision. (b) Major corticocortical and corticospinal connections of cortical motor areas are illustrated in a wiring diagram. Most of the corticocortical interconnections are reciprocal. Thinner lines to the spinal cord indicate that the corticospinal projections from these areas are not as strong as that from M1. Abbreviations: M1, primary motor cortex; S1, primary somatosensory cortex; CMAc, cingulate motor area, caudal; CMAr, cingulate motor area, rostral; PMdc, premotor cortex, dorsal, caudal; PMdr, premotor cortex, dorsal, rostral; PMvc, premotor cortex, ventral, caudal; PMvr, premotor cortex, ventral, rostral; AIP, anterior intraparietal area; MIP, medial intraparietal area; VIP, ventral intraparietal area; LIP, lateral intraparietal area; PE, parietal region E; PGm, parietal region G, subregion m; FEF, frontal eye field; V6A, superior parietal lobe, caudal. Modified from Schieber (1999).

lobe, which processes information on the spatial features of visual objects, and inputs from the somatosensory cortex of the anterior parietal lobe, which processes tactile and proprioceptive information on the position and motion of body parts. (*See* **What and Where/How Systems**; **Parietal Cortex**)

Combining visual and somatosensory information, the posterior parietal cortex plays a major role in guiding movements of the body to interact with external targets. Lesions here impair the ability to guide and orient movements accurately towards visually perceived objects in external space, without impairing the ability to identify and describe an object, or to discriminate it from other objects. In humans, lesions in the posterior parietal cortex may produce the syndrome of apraxia, in which the patient makes inappropriate (though dextrous) movements when handling objects, such as an inability to pour water accurately from one glass into another.

Though much of the posterior parietal cortex is active during any natural movement to reach out and manipulate objects, various regions make different contributions to such movements. These regions have been defined most precisely in macaque monkeys and include area 5 in the superior parietal lobe, area 7 in the inferior parietal lobe, and several regions that lie in the intraparietal sulcus between areas 5 and 7 (Figure 1).

Input to area 5 arises mainly from the primary somatosensory cortex (S1) through which it receives information about the status of joints, muscles, and skin. However, unlike neurons in S1, neurons in area 5 show little response to passive somatosensory stimuli. Instead, neurons in area 5 are active predominately when the monkey reaches toward a desired object in the space immediately surrounding the animal (Mountcastle *et al.*, 1975). Limb movements that are not associated with this type of reaching, such as might occur during aggressive

or aversive behaviors, fail to elicit much activity in these neurons. Moreover, individual neurons in area 5 are broadly tuned to a preferred direction of movement in that they fire most briskly when the arm moves in a particular direction and fire little when the arm moves in the opposite direction.

Interestingly, this directional tuning is unaffected by the application of static loads to the arm which changes the pattern of muscular activity needed to move the arm in a particular direction (Kalaska *et al*., 1990). Therefore, the collective activity of neurons in area 5 seems to provide a robust representation of the trajectory of a limb associated with transporting the hand toward a desired object. Because neurons in area 5 often respond prior to the onset of movement, their activity may not simply reflect the sensory consequence of movements but is probably intimately related to the planning of goal-directed movements. Indeed, area 5 is richly interconnected with the premotor and primary motor areas of the frontal lobe, two regions of the primate brain most directly associated with planning and executing voluntary movements.

While neurons in area 7 are mostly visual in nature, in several respects their behavior resembles that of neurons in area 5. Many area 7 neurons respond when the animal gazes upon or reaches toward an object of interest (Hyvärinen and Poranen, 1974). For example, these neurons become active when a monkey looks at a morsel of food, but will not discharge when the monkey looks at a book, a laboratory instrument, or other object of little interest to a monkey. In addition, the object of interest must be within arm's reach in order to evoke consistent activity in these neurons. Furthermore, activity ceases when the animal becomes satiated if the object is food or a target associated with delivery of food or liquid reward.

Many neurons in area 7 are directionally sensitive and will discharge when looking at or reaching toward an object placed in one location within the peripersonal space but not in other locations. Similarly, some neurons in area 7 are active only during smooth pursuit of an object of interest while it is moved in one direction but not in other directions within the monkey's peripersonal space. Therefore, it seems that one role of area 7 is to encode the spatial attributes of objects in the region immediately surrounding the animal. However, this does not occur in an obligatory fashion; instead, spatial representation by neurons in area 7 is allocated only to the object at any given moment that the animal desires to grasp or touch. Such spatial information is then conveyed to premotor areas in the frontal cortex where it is essential in formulating the motor plan associated with reaching.

The intraparietal sulcus forms the boundary between areas 5 and 7. Several regions within the intraparietal sulcus have been identified and neurons in these regions typically respond to a blend of visuospatial and somatosensory stimuli. Different regions within the intraparietal sulcus, however, seem to make particular contributions to movements of the hand, arm, head, and eyes. For example, the anterior intraparietal (AIP) area lies in the anterior portion of the lateral bank of the intraparietal sulcus and plays a specific part in hand movements (Figure 2).

This area contains neurons that respond differentially depending on the visual shape, size, and orientation of small objects that the monkey might grasp using different hand postures (Taira *et al*., 1990; Murata *et al*., 2000). Some of these neurons respond not only when the monkey sees the object, but also when the monkey grasps the object, even in the dark. When the homologous region in humans is affected by a lesion, the shaping of the hand is abnormal as the patient reaches out to grasp a visually perceived object. The AIP thus makes a crucial contribution to adjusting the posture of the hand to grasp an object based on visual or somatosensory inputs. This area is closely connected to a region in the ventral premotor cortex (see below) that is active during the production and planning of various grasping movements of the hand. Thus, AIP primarily subserves the manipulation component of reaching and grasping, whereas areas 5 and 7 contribute primarily to the spatial representation of the arm and target, respectively, needed to successfully transport the hand to an object of interest.

Visual and somatosensory input associated with arm movement influences the activity of neurons in the caudal aspect of the superior parietal lobe (V6A) and in the medial bank of the intraparietal sulcus (medial intraparietal area, MIP). In V6A, individual neurons respond prior to and during arm reaches or eye movements toward targets located in a particular region of peripersonal space. The response is strongest, however, when both the eyes and arm are allowed to move together toward the target (Battaglia-Mayer *et al*., 2000). This suggests that V6A combines information about target location and about arm position. It thus represents an important node in the parietofrontal network involved in planning and executing goal-directed arm movements.

In area MIP, somatosensory and visual information is combined in a slightly different way.

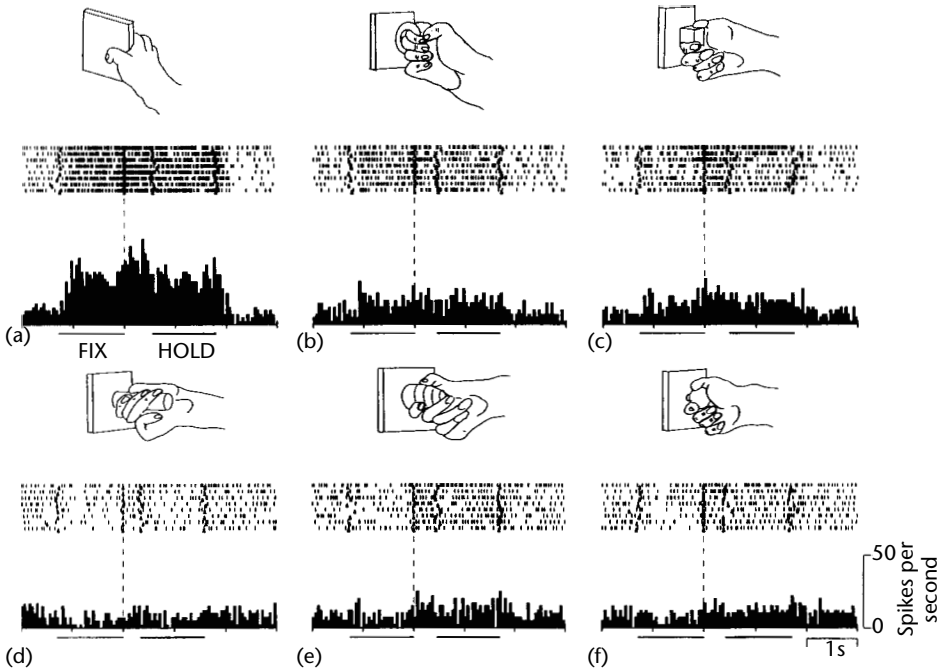

Figure 2. Activity of a neuron in the anterior intraparietal (AIP) area recorded as a monkey grasped six objects of different shape. This neuron became active as the monkey visually fixated a small vertical plate (a, FIX) and continued to discharge as the monkey grasped, pulled and held (a, HOLD) the plate. The same neuron showed less activity if the object was a vertical ring (b) or a small cube (c), and little if any modulation when the object was a cylinder (d), cone (e) or sphere (f). The neuron showed similar, though somewhat lower, discharge if the monkey looked at the plate without reaching out to grasp it, or if the monkey reached out to grasp the plate in the dark (not illustrated). Reproduced from Murata *et al.* (2000).

Neurons in MIP seem to respond to visual targets that are in the vicinity of the arm with activity increasing the closer the target is to the arm. Many of these neurons are bimodal with tactile receptive fields on the arm and visual receptive fields surrounding the arm. Area MIP therefore seems to represent the spatial location of objects with respect to the arm or hand. Intriguingly, if a small rake is used by a monkey in order to obtain food morsels located outside the region that could be normally reached by the arm, the visual receptive field of neurons in MIP expand to encompass the territory that can be reached by the rake (Iriki *et al*., 1996).

The ventral intraparietal (VIP) area, lying in the fundus of the intraparietal sulcus, plays a role in head movements. This area contains neurons that respond to moving visual stimuli directed toward tactile receptive fields of the same neurons located on the head and face. The visual receptive fields remain spatially anchored to the tactile receptive fields on the head even if the eyes move. The VIP area thus is likely to play a role in guiding movements of the head in relation to nearby objects.

Likewise, the lateral intraparietal (LIP) area, lying posterior to AIP in the lateral bank of the intraparietal sulcus, plays a role in eye movements. Neurons of the LIP have retinotopic (visual) receptive fields, though their responses are modulated by proprioceptive information regarding the position of the eyes in the orbit. The responses of LIP neurons are enhanced when the subject must pay attention to a stimulus in its receptive fields, and will continue to discharge after the stimulus disappears if the subject must remember the location. These neurons also discharge just before saccadic eye movements that will shift the line of sight onto a stimulus in the subject's receptive fields. The LIP area, which is interconnected with the superior colliculus and the frontal eye fields, thus seems to participate in selecting visual targets for saccadic eye movements.

The Dorsolateral Prefrontal Cortex: Deciding Which Voluntary Movements to Make

The cortex on the surface convexity of the frontal lobe, anterior to the primary motor and premotor

cortex in the precentral gyrus (see below), can be viewed as one of the most complex association areas of the brain. Along the phylogenetic scale of mammals – from rodents, to carnivores, to primates, to humans – the dorsolateral prefrontal cortex has enlarged more extensively than other cortical regions. Dorsolateral prefrontal lesions in humans impair foresight and long-range planning ability, leading to the general notion that this cortical region serves executive functions that supervise behavior, selecting which behaviors to execute, and which to withhold.

At the neuronal level, some prefrontal neurons have brief responses to particular sensory stimuli, and some discharge as movements are executed, but the striking property of prefrontal neurons is their discharge between an instructional cue and execution of the instructed movement (Funahashi, 2001). This property is brought out experimentally by presenting an instructional cue only briefly, and then requiring a monkey to wait several seconds before finally performing the instructed movement when a separate, nonspecific triggering cue appears (Figure 3).

Many prefrontal neurons will start to discharge shortly after an appropriate instructional cue, and then maintain their discharge after the instructional cue disappears until finally the monkey receives the trigger cue and executes the movement. (Similar activity appears during instructed delays, albeit progressively less frequent, in secondary and primary motor areas.) This activity of prefrontal

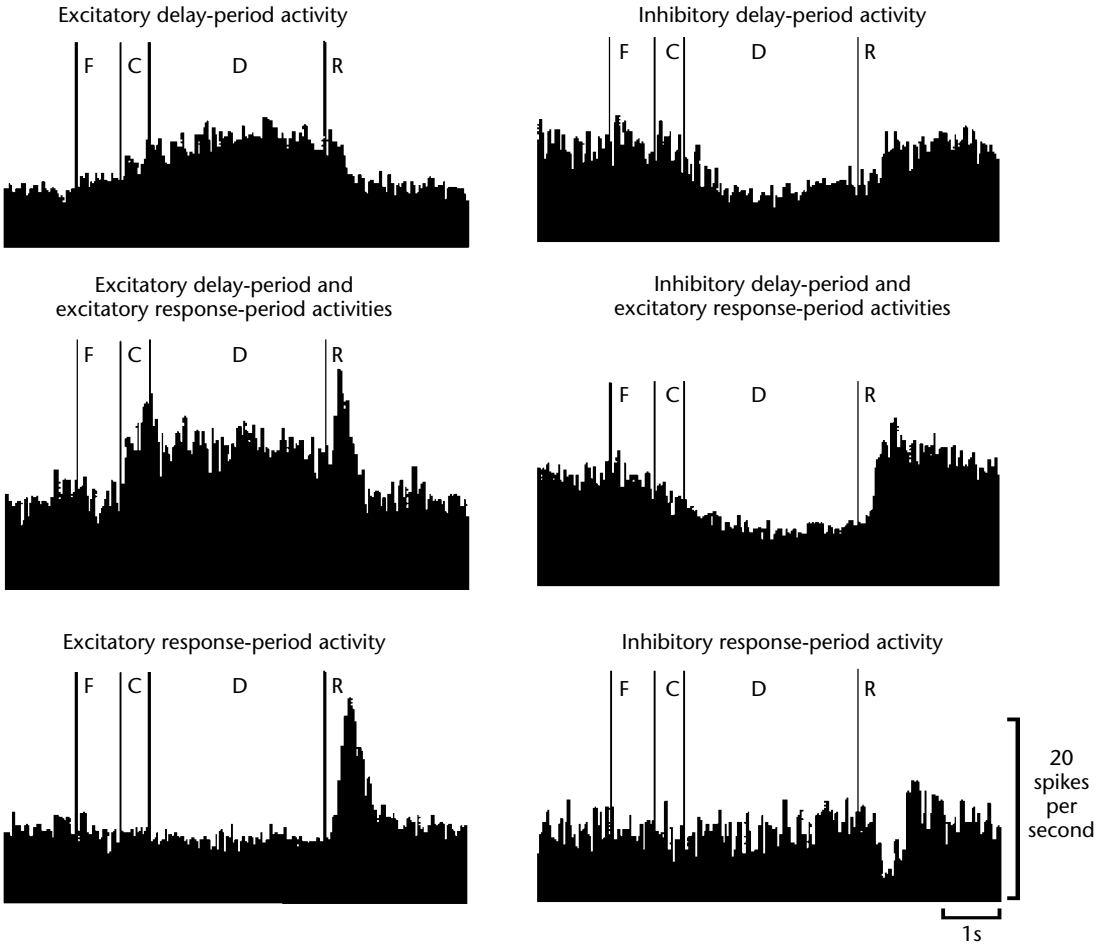

Figure 3. Activity of six different prefrontal neurons during an oculomotor delayed-response task in which the monkey first fixes (F) its eyes on a central target, then receives a transient cue (C) to respond to one of several peripheral targets, and then must wait through a delay (D) period before receiving a second nonspecific triggering instruction, after which the monkey responds (R) by turning its eyes to fix on the cued target. Individual neurons show different combinations of excitatory and inhibitory changes in their discharge immediately after the cue appears, during the delay period, and when the eye movement response is made. Delay-period activity is a prominent feature of neurons in the dorsolateral prefrontal cortex. Reproduced from Funahashi (2001).

neurons during such an instructed delay period appears to serve as a 'working memory', holding information either on which cue was presented, or on which movement to perform, while the monkey waits for the trigger cue. Indeed, when the delay period discharge of such neurons is inappropriate given the instructional cue, the monkey often executes an erroneous movement after the trigger cue. Moreover, lesions of the dorsolateral prefrontal cortex impair the ability to perform delayed-response tasks. Although the subject can make the correct response if the response can be made immediately, if the response must be delayed the subject seems to gradually forget which response was correct.

Different regions of the dorsolateral prefrontal cortex receive different combinations of processed sensory inputs. Inputs from the posterior parietal cortex carrying spatial information are directed chiefly to area 46 around the principal sulcus. Inputs from the inferotemporal cortex of the ventral visual pathway that processes visual information for recognition and discrimination of complex visual stimuli are directed chiefly to areas 45 and 12 inferior to the principal sulcus. Inputs from different regions of auditory cortex also are directed differentially to areas 46, 45, and 12. Consequently some prefrontal neurons discharge during delayed-response tasks when the spatial location of the stimulus must be remembered, while others discharge when nonspatial attributes of the stimulus must be remembered. The discharge of dorsolateral prefrontal neurons also reflects the rule used in selecting the next response; for example, whether the response must be selected based on the spatial location of the instructional stimulus (e.g. is the stimulus on the right or on the left) or the nonspatial attributes of the stimulus (e.g. is the stimulus a picture of a banana or a picture of a whale) (White and Wise, 1999). Dorsolateral prefrontal neurons thus appear to 'keep in mind' various types of information as the subject applies rules to decide what to do next. (*See* **What and Where/How Systems**)

The Wisconsin Card Sorting Test reveals this classic aspect of dorsolateral prefrontal function in humans. Cards with different numbers of colored geometric shapes are presented to the participant, who is asked to sort them into stacks according to a rule that the participant must discern simply from being told whether each card in turn has been sorted correctly or incorrectly. The rule may require sorting according to color, number, or shape. Unbeknownst to the subject, the rule is periodically changed by the experimenter (e.g. from color to shape). Normal participants quickly realize that the rule has been changed and proceed to discern the new rule, but people with dorsolateral prefrontal lesions may fail to look for a new rule even after being told that they have sorted card after card incorrectly. They are unable to adapt flexibly to changing conditions and remain 'stuck in set', following the old rule long after the responses determined by that rule have become inappropriate. Such repeated production of the same voluntary response, initially but no longer appropriate, is termed 'perseveration'. Perseveration may affect behaviors from simple movements to complex acts.

The dorsolateral prefrontal cortex thus appears to have an important role in selecting the next behavioral response based on the combination of recent stimuli and consideration of complex rules and conditions.

The Secondary Motor Areas: Selecting Voluntary Movements

Movements can be evoked by electrical stimulation in only a limited region of the mammalian neocortex, located in the posterior frontal lobe. Corresponding to Brodmann's areas 6 and 4, this region of electrically 'excitable cortex' contains neurons in layer V with corticospinal axons that descend to the ventral horn of the spinal cord. Such corticospinal neurons are most concentrated in area 4. (*See* **Descending Motor Tracts**)

Though once considered altogether as the motor cortex, this region now is considered to contain multiple cortical motor areas distinguished by their interconnections with other cortical areas and with the thalamus, their cytoarchitectonics and neurotransmitter distributions, and their contributions to control of voluntary movement. While multiple cortical motor areas are present in the human premotor cortex, these areas have been distinguished most thoroughly in experimental studies on nonhuman primates.

As shown in Figure 1(a), area 4 is now considered to be the primary motor cortex (M1), whereas area 6 contains multiple secondary motor areas. The premotor cortex on the dorsolateral surface of the hemisphere is subdivided into ventral and dorsal portions, with each of these portions further subdivided into rostral and caudal sections (PMvc, PMvr, PMdc, and PMdr). On the medial aspect of the hemisphere, area 6 contains the supplementary motor area (SMA), and a more rostral pre-SMA. Area 23 in the cingulate sulcus contains rostral and caudal cingulate motor areas (CMAr

and CMAc) as well. As indicated by the interconnection diagram shown in Figure 1(b), the more caudal of these secondary areas have direct, reciprocal interconnections with M1, and have their own corticospinal projections as well. Though varying degrees of activity may be present in many of these areas during any given voluntary movement, the secondary motor areas participate differentially in movement performed in various contexts.

The ventral premotor cortex appears most involved in selecting movements in which the body will be brought into contact with visually perceived objects. Considerable visual and somatosensory input arrives in PMv from the posterior parietal lobe, particularly from areas VIP and AIP in the intraparietal sulcus (see above). Neurons in PMvc have large, often bilaterally symmetric, somatosensory receptive fields on the arms, hands, or face. These neurons also respond to visually perceived objects approaching their somatosensory receptive field. When the body part carrying a neuron's somatosensory receptive field is moved in space, the visually responsive region of space for that neuron moves with the body part. These neurons also discharge more when the monkey reaches for targets in response to visual cues than when the monkey reaches for the same targets based on a remembered sequence (Figure 4).

In PMvr, neurons tend to discharge when the monkey uses its hand in particular ways. One neuron may discharge when the monkey uses a precision pinch to pick up a raisin, while another neuron discharges when the monkey uses a power grip to hold a large bar. Moreover, the same PMvr neuron that discharges when the monkey performs a precision pinch may also discharge when the monkey watches another monkey, or even a human, pick up a raisin with a precision pinch. Consistent with a role for PMv in selecting and guiding movements to interact with visual objects, lesions in the ventral premotor cortex decrease the likelihood that the subject will use the contralateral extremity or move toward targets in contralateral space.

The dorsal premotor cortex appears most involved in selecting movements based on abstract instructions or conditional cues. For example, if a monkey is taught to touch a button on the right when a green light flashes in the midline but a button on the left when a red light flashes in the midline, many PMdc neurons will discharge after the appearance of one light or the other, signaling the impending movement. Indeed, if a neuron seems to discharge in error – for example, if a neuron that normally discharges after a green flash starts to discharge after a red flash – the monkey typically will make the wrong movement.

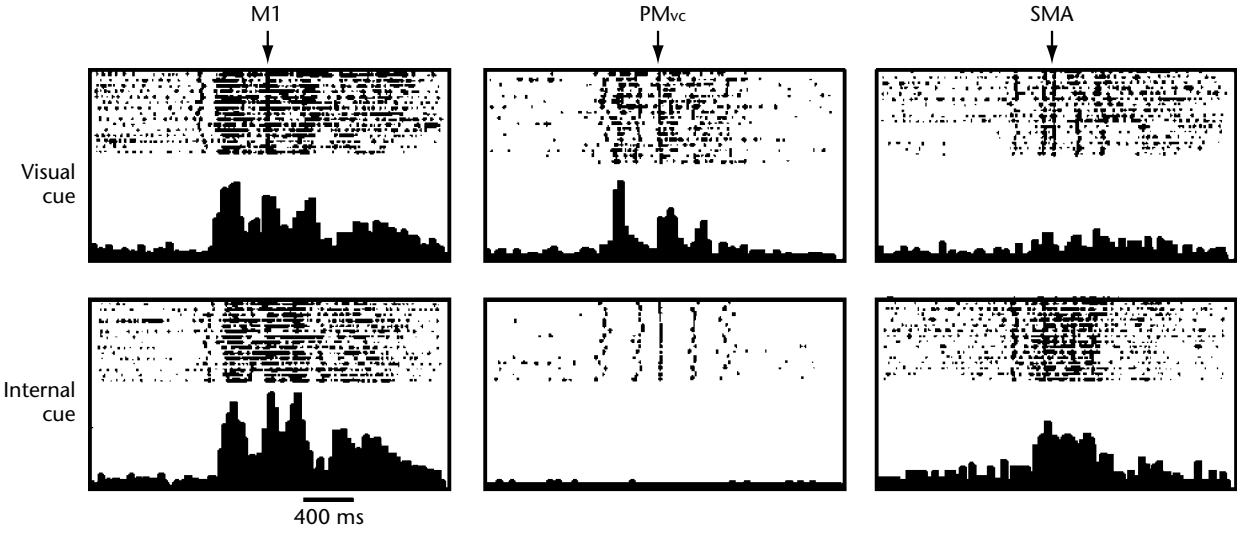

Figure 4. Activity of three neurons – one from M1, one from PMvc, and one from SMA – recorded as a monkey pressed three buttons in a sequence specified at first by lighting the buttons in sequence (visual cues), and then later from memory (internal cues) without the buttons lighting on each trial. Whereas the M1 neuron showed similar activity whether the monkey performed from visual or internal cues, the PMvc neuron was much more active when movements were selected on the basis of visual cues, and conversely the SMA neuron was much more active when movements were selected on the basis of internal cues. Modified from Mushiake *et al.* (1991).

Like neurons in the prefrontal cortex (see above), if the monkey is also taught to wait for many seconds after seeing the red or green light flash, many PMdc neurons will discharge continuously through the delay period after the red (or green) flash until the movement finally is made.

Neurons in the PMdc also participate in learning the arbitrary associations between particular abstract cues and specific movement responses. When the monkey is first presented with a novel cue, a given PMdc neuron may not discharge during the delay period. As the monkey learns by trial and error to make a particular movement in response to the new cue, however, the same PMdc neuron may gradually develop more and more delay-period discharge over several trials. Ultimately, when the monkey has learned to associate the once novel cue with a particular movement response, the PMdc neuron discharges consistently during the delay period.

The discharge properties of PMdr neurons in many ways resemble those of PMdc neurons. The PMdr receives input from the dorsolateral prefrontal cortex, however, and PMdr neurons show more learning and rule-dependent modulation than PMdc neurons. The sector of PMdr closest to the midline participates in selection of eye movements, and is commonly referred to as the supplementary eye field (SEF). Neurons in the SEF discharge when the response to be made is a saccadic eye movement, and they show typical directional selectivity during instructed delay periods. Moreover, as the subject learns to associate a particular instructional cue with a particular saccade direction, individual SEF neurons will develop delay-period discharge selective for that direction. When saccades are made to particular locations on visual objects, SEF neurons discharge selectively for saccades to certain locations on the object, regardless of where the object is in space, indicating an object-centered reference frame.

On the medial aspect of the hemisphere, the SMA and pre-SMA appear most involved in selecting movements based on internally remembered sequences (Figure 4). The SMA neurons are more active when a monkey touches buttons in a remembered sequence than when the monkey touches the same buttons following their illumination (Mushiake *et al.*, 1991). These neurons also may be active preceding a particular movement element of a sequence. The pre-SMA neurons, in contrast, are more likely to be active as the monkey shifts from performing one sequence to performing another.

The Primary Motor Cortex: Executing Voluntary Movements

The primary motor cortex (M1) receives corticocortical inputs from secondary motor areas described above, additional corticocortical input from the primary somatosensory cortex (S1, or areas 3, 1, and 2), area 5, and strong inputs from the basal ganglia and cerebellum arriving via the ventrolateral thalamic nuclei. The primary motor cortex represents the final stage of cortical processing before information controlling movement is delivered via the corticospinal pathway to the spinal interneurons and motoneurons most directly in control of muscle contractions. In addition to the direct corticospinal pathway, two indirect pathways – rubrospinal and reticulospinal – convey M1 output to the spinal cord. The red nucleus (origin of the rubrospinal pathway) and the pontomedullary reticular formation (origin of the reticulospinal pathway) each receive inputs from descending M1 axons.

The primary motor cortex shows an overall organization according to major body parts; i.e. a somatotopic organization. In the M1 of primates, including humans, the face is represented laterally, the lower extremity (or hindlimb and tail) medially, and the upper extremity (or forelimb) in between (Figure 5). Lesions on the lateral convexity of human M1 cause weakness or paralysis of the contralateral face, more medial lesions on the convexity affect the contralateral hand and arm, and lesions on the medial wall of the hemisphere affect the leg and foot. Distal parts of the extremities and acral parts of the face (lips and tongue) are most heavily represented caudally in M1, whereas proximal parts of the extremities and axial movements are most heavily represented rostrally. Those parts of the body that are used for fine manipulative movements (such as lips, tongue, and fingers in primates) are generally represented over more cortical territory than body parts used in gross movements such as ambulation.

At a finer level, however, M1's somatotopic organization is not a one-to-one mapping of body parts, muscles or movements (Schieber, 2001). Within the arm representation, used here as an example because it has been studied most intensively, the cortical territory representing any particular part of the arm overlaps considerably with the territory representing nearby parts. This overlap results from three features of M1's organization. First, M1 neurons whose axons converge on any given spinal motoneuron pool are distributed over

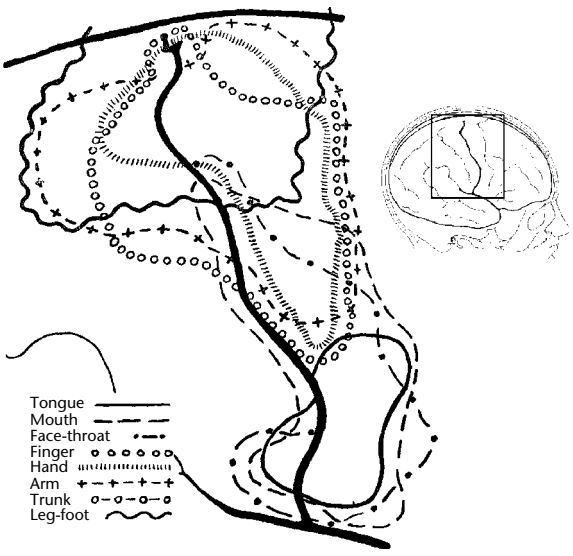

Figure 5. Organization of primary motor cortex. Stimulation of the cortical surface in patients undergoing neurosurgical procedures demonstrated that stimuli delivered laterally along the precentral gyrus evoked movements of the face; more medially stimuli evoked movements of the upper extremity; and most medially, movements of the leg. The region of the brain shown enlarged is indicated by the rectangle drawn on the inset at upper right. Modified from Penfield and Boldrey (1937).

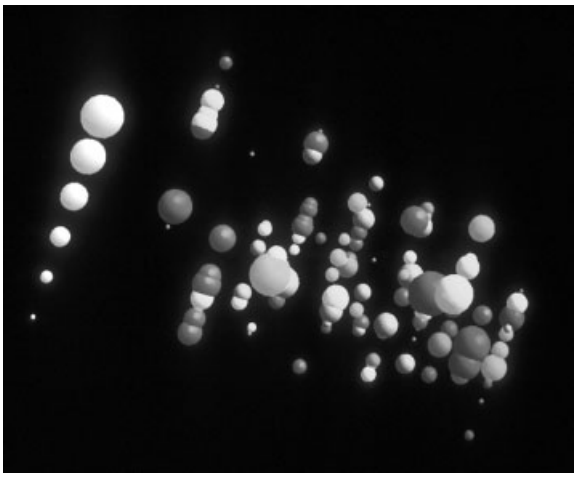

Figure 6. [*Figure is also reproduced in color section.*] Colored spheres each represent a single neuron recorded in the left hemisphere M1 as a monkey performed individuated movements (flexion or extension) of each right-hand digit and of the right wrist. The sphere representing each neuron is centered at the location of the recorded neuron in the anterior bank of the central sulcus, with the hemispheric surface above, white matter below, lateral to the viewer's right and medial to the left. Each sphere is sized according to its greatest change in discharge frequency during any of the movements; the white spheres at left constitute a scale from 0 to 200 spikes per second, with centers 1 mm apart. Each sphere representing a neuron is colored according to the movement for which that neuron's greatest discharge occurred: thumb, red; index finger, orange; middle, yellow; ring, green; little, blue; wrist, violet. Neurons best-related to movements of each digit or the wrist were intermingled throughout the same cortical territory, reflecting the extensive overlap of the representations of movements of different fingers. Modified from Schieber and Hibbard (1993).

a relatively large cortical territory that overlaps extensively with the cortical territory, giving rise to outputs that influence other nearby muscles. Second, single M1 neurons often have axons that diverge to innervate the motoneuron pools of multiple nearby muscles. Third, horizontal axon collaterals interlink neurons through considerable distances within the M1 arm representation. As a consequence of this convergence, divergence and horizontal interconnectivity, neuronal activity is widely distributed in the M1 arm representation even when only a single finger or one more proximal joint is moved (Figure 6) (Schieber and Hibbard, 1993). Such distributed representation provides a substrate for considerable plasticity (Nudo *et al*., 2001). The map of body representation in M1 has been shown to reorganize as normal people acquire different motor skills, as people adapt to peripheral injuries, and as patients recover from central nervous system injuries. (*See* **Reorganization of the Brain**)

The discharge of M1 neurons carries information more closely related to the kinematics and dynamics of incipient movement than the discharge of neurons in other cortical areas. Within the region representing a particular body part, M1 neuron firing rates typically begin to change approximately 50–100 ms before the corresponding movement. The firing rate of individual M1 neurons correlates with the movement direction, force exerted, joint position, and/or velocity of the relevant body part. Most M1 neurons fire at different rates for different values of any given parameter over a considerable range. The actual movement direction, for example, therefore can be specified more precisely by considering the discharge of a population of M1 neurons.

Studies have revealed, however, that M1 also participates with other cortical areas in the sensorimotor transformation from stimulus to movement. In behavioral paradigms that dissociate stimulus direction from movement direction – for example if rightward target movement cues leftward arm movement – the discharge of some M1 neurons is

more closely related to stimulus direction than to movement direction, even as the movement is occurring. Conversely, discharge related to kinematic and dynamic parameters of the movements being executed are found in other cortical areas as well, such as PMdc and parietal area 5.

CONCLUSION

We have considered how different regions of the cerebral cortex participate in various aspects of selection, guidance, and generation of voluntary movements, including deciding which responses to make, selecting which particular movements to perform, guiding these movements in space, and generating the movement *per se*.

As indicated above, many cortical regions are active during any particular movement. Techniques that examine these processes at the neuronal level in real time have revealed, however, that none of the functions described above is performed exclusively by a single region. The time required for transmission of information from one cortical region to the next is short compared with the time the nervous system uses to process input, select action, and execute movement; i.e. reaction time and movement time. Hence during any given response, neurons in many of the cortical regions considered above are active concurrently. When a monkey suddenly sees a morsel of food and reaches out to pick it up, for example, the discharge of dorsolateral prefrontal neurons may participate in the decision to get the food, while almost simultaneously, certain posterior parietal, premotor and primary motor cortex neurons participate in transporting the arm toward the morsel, and other parietal, secondary and primary motor cortex neurons participate in adjusting the configuration of the hand to grasp the morsel. Complex cooperation of multiple motor areas in the cerebral cortex thus underlies the apparently simple act of picking up a raisin.

Multiple Sclerosis

Introductory article

KJ Smith, King's College, London, UK
MK Sharief, King's College, London, UK

CONTENTS

Multiple sclerosis is a neurological disorder characterized by symptoms that either wax and wane or slowly progress, in which immune cells invade the central nervous system and damage nerve fibers, thereby disrupting impulse conduction.

INTRODUCTION

Multiple sclerosis (MS) is the most common disabling neurological disease of young adults, affecting 1 individual per 500–1000 of population in northern Europe, an area with high risk. The cause of the disease is not known, but it is more common in women (the male to female ratio is approximately 2:3), and although MS is neither infectious nor inherited, people can inherit genes that predispose them to acquiring the disease. The nature and pattern of the disease in different patients is highly unpredictable and variable, and there is no known cure. Multiple sclerosis is rare in children, but it is believed to be acquired before puberty, becoming expressed later in life, most often during the third and fourth decades.

PATHOLOGY

The hallmark of MS is the presence of inflammatory demyelinating lesions within the central nervous system (CNS). The distribution of lesions is unpredictable and widespread, and many new lesions (up to a hundred in severe cases) can occur in a year, due to what is believed to be an autoimmune process. An early event in the formation of a new lesion is breakdown of the blood–brain barrier, with the passage into the brain tissue of inflammatory cells, including T cells and macrophages, many of which congregate in a cuff around the blood vessels: local microglial cells become activated. The myelin sheaths of neighboring axons are attacked and removed by macrophages, leaving the axons locally demyelinated, i.e. denuded of their insulating layer of myelin. The fate of the affected oligodendrocytes (the myelin-forming cells of the CNS) is unclear, but many appear to undergo degeneration. Astrocytes (glial cells) become activated, forming a glial (sclerotic) scar. The multiple sclerotic lesions underlie the common name of the disease, also known as disseminated sclerosis. Some lesions, particularly in the earlier stages of the disease, are repaired by remyelination, but remyelinated axons are not protected from future attack, so that demyelinated lesions accumulate over time and are common at autopsy. Apart from demyelination, affected axons can also undergo degeneration, becoming transected within the lesions. Most degenerating axons die during the inflammatory phase of lesion development, but degeneration proceeds at a 'slow burn' once the inflammation has subsided, perhaps owing to the lack of trophic support. Although attention has focused on lesions occurring within the white matter, gray-matter lesions are also common. The extent to which neuronal cell bodies undergo degeneration is unclear, but such degeneration probably occurs, and might be substantial.

ONSET AND COMMON SYMPTOMS

The initial symptoms of MS are often visual (in approximately 50% of patients) typically due to a lesion in the optic nerves, resulting in blurred or double vision, or perhaps partial or complete blindness. Another 40% of MS sufferers present with limb weakness or sensory symptoms (e.g. numbness), and the remaining patients may present with impairments of bladder or bowel function, or

blunting of the intellect. The symptoms can appear quite suddenly, usually upon waking or over a few days. The expression of such symptoms is typically only temporary (e.g. persisting for a few weeks) in relapsing–remitting MS, but it may be more permanent in progressive disease. No specific event – such as viral or bacterial infection, or trauma – can be reliably identified as preceding the onset of the disease. The semirandom distribution of new lesions means that various parts of the brain and spinal cord are affected in different patients, and therefore the range of neurological complaints expressed by patients during the course of their disease is very wide. Most lesions fortunately occur in clinically 'silent' areas of the brain (i.e. they do not cause symptoms), but lesions also occur in more 'eloquent' tracts (such as the optic nerves) where they result in functional deficits appropriate for the pathway affected. Fatigue is common, and can be the most important complaint of patients. Lesions within the cerebellum, or that interrupt the motor and sensory pathways, can cause tremor and interfere with balance and other coordinated movements, making walking difficult (ataxia) and preventing fine hand movements; speech can become slurred. Tingling sensations are common in MS, often appearing intermittently, although they may be persistent. Pain occurs in about 30% of patients at some stage of the disease process. The expression of most symptoms can be surprisingly sensitive to body temperature (warming is deleterious and cooling beneficial), underpinning the earlier 'hot bath' diagnostic test for MS. As the disease advances, spasticity of affected limbs and sexual dysfunction are not uncommon, and there may be incontinence of urine or feces.

COURSE

The course of MS is variable and unpredictable. However, the majority of people with the disease (about 70%) start with an episodic pattern of attacks, constituting a relapsing and remitting course. Clinical relapses (exacerbations) cause seemingly random impairments of neurological functions. The symptoms during these relapses may remit completely, leaving no residual deficit, or partially resulting in variable degrees of permanent impairment. The frequency of clinical relapses varies widely from 0.1 to 10 per year, but in people who are considered to have active MS, the average frequency of relapses is 1.5 per year. In general, relapses in the early stages of MS are followed by complete remission, but in the later stages relapses become less frequent and may be followed by incomplete recovery. The relapsing and remitting course eventually transforms in many patients into a 'secondary progressive' form where clinical fluctuations are replaced by a gradual accumulation of permanent neurological deficit. The remaining patients with relapsing and remitting MS may have only minimal disability even after many years. A minority of MS patients have primary progressive MS where the clinical course is progressive from the onset. In contrast, there is a mild form of MS in which people may have only minor neurological impairments that do not interfere with activities of daily living. This condition, known as benign MS, is seen in approximately 10–15% of cases. The activity of MS, and the distribution of demyelinated plaques, can be monitored by brain magnetic resonance imaging, which is also widely used as a noninvasive diagnostic tool. Although MS is not a fatal disease, the average life expectancy for MS sufferers is 7 years less than normal, or 75–85% of expected survival. The majority of deaths are due to secondary complications such as pneumonia and pulmonary embolism, but the suicide rate in MS is also increased, being more than six times that of the general population.

PATHOPHYSIOLOGY

The symptoms of MS are determined not only by the location of the individual lesions, but also by their pathology: inflammation, demyelination and axonal loss each appear to have major roles. Conduction block is perhaps the most important deficit, contributing to symptoms such as blindness, paralysis and numbness, depending upon the pathway affected. Conduction block arises from demyelination, but it appears that inflammation can also play a part, and inflammatory mediators such as cytokines have been implicated, with attention focusing on nitric oxide in particular. The conduction block and the consequent expression of symptoms may only be temporary, because inflammation can resolve and, even where demyelination persists, conduction can be restored along the demyelinated axons accompanied by changes in the distribution of sodium channels. However, in demyelinated axons, restored conduction is slower than normal (resulting in a diagnostically valuable conduction delay upon electrophysiological examination), and is also less secure, so recovery from symptoms can be incomplete. Demyelinated axons, particularly sensory ones, may not only have conduction restored, but can become spontaneously active, wrongly generating trains of impulses that can be interpreted by the brain as a tingling

sensation referred to the body part normally innervated by the axons. Demyelinated axons can also become sensitive to physical distortion, resulting in movement-induced sensations: for example, people with lesions in the spinal cord in the neck can experience tingling sensations radiating down their body when they bend their neck. Massed, synchronous spontaneous firing of axons by ephaptic (nonsynaptic) transmission might contribute to spasms. Where remyelination occurs, it is accompanied by the restoration of fast, secure conduction, contributing to the restoration of normal vision, walking, and other activities. Axonal degeneration contributes to the permanent loss of function, although the persisting deficit may be ameliorated by compensatory (plastic) changes in the brain.

ETIOLOGY

The cause of MS is unknown. The disease is more common in temperate climates, and people of northern European descent are more likely to develop MS than people from most other ethnic backgrounds. Epidemiological studies have identified two principal etiological factors: a genetically determined susceptibility, and (probably) exposure to environmental agents. Analysis of migration patterns has shown that MS is acquired before an age around puberty, perhaps due to an environmental agent such as climate, diet, sunlight or toxins, although many believe that the agent is likely to be infective, most probably viral. However, direct evidence for a viral cause of MS is still lacking, and if viruses have a role it may be by initiating autoimmunity against CNS antigens. On the other hand, genetic studies have suggested multiple genetic influences on the development of MS. To date, the best-characterized susceptibility-associated gene has been mapped to the human leukocyte antigen (HLA) complex, located on chromosome 6. Different HLA associations have been identified in MS. The HLA-DR2, DR(1*1501), DQ(1*602), DQA102 and DW2 haplotypes are frequently associated with MS. The role of genetic factors has been confirmed by family studies, which have shown that the risk of developing MS increases significantly if other family members are affected. While the risk of developing MS in the general population in the UK is about 1 in 800, first-degree relatives of people with MS have a more than 1 in 100 risk of developing the disease. However, it is important to note that MS is not directly inherited, and that more than 80% of people with the disease do not have affected first-degree relatives.

AUTOIMMUNE DISEASE

Multiple sclerosis is thought to be mediated by autoimmune attacks due to a dysregulated immune system that allows T cells to become activated against brain antigens, enter the CNS and mediate tissue damage through inflammatory demyelination and axonal damage. Abnormalities of the immune system in MS have been detected locally within the brain and cerebrospinal fluid, and also systemically in the peripheral circulation. The exact target of the autoimmune response in MS remains unclear, but may involve components of the myelin layer that surrounds nerve fibers. It is also possible that such antibodies are a consequence of the disease, rather than part of its cause. However, if they are part of its cause one explanation for this autoimmune reactivity against myelin antigens could be molecular mimicry, where a shared molecular structure that exists between a viral protein and a normal human CNS protein might cause an antiviral immune response to mediate CNS damage. Another possibility is that autoimmunity may result from stimulation of T cells by molecules known as superantigens, which interact with a large number of immune cells. Such superantigens, often of viral or bacterial origin, may bind to some T-cell receptors and produce nonspecific stimulation of a large number of T cells. This stimulation may cause expansion of T cells reactive to myelin components, and subsequent demyelination.

ANIMAL MODELS

Multiple sclerosis does not occur in animals, but research has been greatly advanced by the study of animal models that mimic different aspects of the disease. The immunology underlying MS has been studied using experimental autoimmune (allergic) encephalomyelitis (EAE) induced in animals, most commonly rats and mice, by immunization with myelin or myelin components (active EAE), or by administration of T cells activated against myelin components (passive EAE). In either case T cells enter the CNS and attack the myelin sheath, forming scattered lesions that closely resemble those of MS. Affected animals can develop a weak or paralyzed tail and hindlimbs for a few days, but these deficits typically resolve within a week or two. New drugs for the therapy of MS are typically developed and tested using EAE models. Animal models have also been essential for the development of transplantation techniques to introduce cells capable of repairing lesions by remyelination,

and trials of such techniques in humans with MS have now commenced.

TREATMENT

There is no cure for MS, and no treatment completely halts the disease process. However, many of the symptoms can be treated. Antidepressants and antiepileptic drugs may reduce painful sensory symptoms, numbness or fatigue. Fatigue and spasticity may also be relieved by drugs such as 3,4-diaminopyridine, amantadine or methylphenidate for fatigue, and baclofen, tizanidine, diazepam or dantrolene for spasticity. Urinary symptoms may be relieved by drugs that relax the bladder muscles. In addition to symptomatic therapies, the course of MS can be modified by several strategies. Generalized immunosuppression may provide modest reduction of MS activity. Steroids may ameliorate many of the symptoms during clinical relapses by reducing swelling and inflammation, but do not alter the course of the disease. A more specific immunosuppression (or immunomodulation) in MS can be achieved with interferon beta, which reduces relapses by about one-third, probably by reversing some of the T-cell defects, or reducing the ability of T cells to invade the central nervous system. Glatiramer acetate also reduces relapses by about one-third, probably by suppressing immune responses to brain antigens. Experimental therapies now being tested in people with MS include specific targeting of immune cells or inflammatory mediators, stem cell transplantation, and strategies to protect nerve fibers from degeneration.

Navigation and Homing, Neural Basis of

Introductory article

Verner P Bingman, Bowling Green State University, Bowling Green, Ohio, USA

CONTENTS

Navigational ability in animals often relies on memory-based maps of environmental space, typically assisted in birds by external 'compass' clues and in rodents by internal positioning information represented by specialized neurons such as place cells. The hippocampus and related brain structures appear to be integral to the ability to navigate.

INTRODUCTION

During the course of animal evolution, the parallel emergence of the ability to move in space and a structured nervous system to coordinate that movement has contributed to the complexity of brain and behavior observed in modern animals. Virtually all animals who move can do so in a goal-directed manner. Such behavior may be simple and reflexive, for example the positive phototaxis displayed by a hermit crab as it moves toward a light source. Alternatively, such behavior can be complex and learned, for example the map-like spatial memory of a homing pigeon used to navigate home from unfamiliar locations tens of kilometers away.

Broadly defined, navigation is the ability to move to a goal location. This article, however, is specifically concerned with two types of navigation and their neural basis. One is the use of a memorized representation of environmental stimuli, something like a map of the spatial distribution of landmarks, to locate a goal. The other is the use of memories of stimuli generated by the animal's own movement, 'path integration', to locate a goal. Although the following discussion focuses on birds and mammals, memory-based navigational ability is characteristic of all vertebrates and many invertebrate species as well.

HOMING IN BIRDS

The term 'homing' refers to the ability of an animal to return to a familiar location (home) after a journey. Although in birds homing is usually associated with pigeons returning to their loft after being displaced to some distant, unfamiliar location, the term can easily apply to a migratory bird returning to a previous breeding site or overwintering area. In the case of homing pigeons, successful homing is based primarily on three distinct spatial mechanisms that resemble the map and compass of human navigation.

To identify its location relative to home and to return home from distant, unfamiliar locations, homing pigeons use a 'navigational' map. This map is often a memory representation of the distribution of atmospheric odors in the environment, with differences in the distribution of odors serving to uniquely define different locations in space. Similarly, from familiar areas, homing pigeons can additionally navigate using memory of the spatial distribution of previously experienced landmarks, identified not just visually but using other senses as well, that provide a stable spatial reference. This 'landmark' map resembles most what is often referred to in the scientific literature as a 'cognitive' map.

The navigational map and landmark map together enable a pigeon to determine its location in space relative to the home loft. This map information must then be used to compute a compass direction, which the pigeon would rely on to orient itself in a homeward direction. In birds, two sources of compass or directional information are known to be used: the sun, and the earth's magnetic field. These compasses can tell a bird nothing about

where it is, but are crucial in enabling a bird to orient in an appropriate direction – for example north, once the bird has determined it is south of home based on map information. Finally, compass information is probably also used to provide a directional framework for learning about the spatial relationship among atmospheric odors and landmarks that leads to map learning. In other words, pigeons, and probably many other vertebrate species, are thought to exploit the directional reference provided by compasses to learn the memory-based, map-like representations of space necessary for navigation.

DEAD RECKONING, PLACE CELLS, AND HEAD DIRECTION CELLS IN NAVIGATION

Dead Reckoning

Birds are generally diurnal creatures with good eyesight who travel large distances over open countryside, explaining in part why they rely heavily (albeit not exclusively) on the sun and visual landmarks for navigation. Most rodents, in contrast, have poor vision, are nocturnal, and tend to move in natural labyrinths or take paths close to physical boundaries such as walls. It is not surprising, therefore, that although animals such as laboratory rats can certainly use visual landmarks to locate a goal, they also rely heavily on 'dead reckoning' for navigation.

Dead reckoning, or path integration, is a form of navigation in which an animal integrates information about its own motion to locate its present position or return to a starting location. The source of the self-motion information can come from the vestibular system, efference copy from movement commands (information from ongoing motor neuron activity sent to other regions of the nervous system) and other sensory information created by an animal's movement.

Dead reckoning is a reliable source of navigational information over short distances (a few meters), but is generally believed to be prone to the accumulation of errors, and therefore less effective over longer distances. However, this generalization does not preclude the possibility that some animal species have evolved more accurate path integration systems that could support navigation for longer distances. Just like the sun compass of birds, dead reckoning in rodents is thought to serve also as a spatial framework or reference for learning about the spatial relationship among landmarks, which would ultimately lead to the acquisition of a landmark map. Once learned, such a landmark map would provide rodents with a navigational mechanism to locate a goal from distances beyond those for which dead reckoning would be reliable.

Place Cells

The presence of map-like representations of environmental space used by birds and mammals for navigation raises the fundamental question of how these representations are structured in the brain. Although numerous brain regions participate in the representation of space, one structure, the hippocampus, seems to have a particularly important role.

In both birds and mammals, experimental interference with the normal operation of the hippocampus seriously impairs their ability to navigate using map-like representations of space. It should be emphasized that interfering with the hippocampus does not disrupt all spatial ability, but specifically navigation based on map-like representations, and possibly also some spatial behavior mechanisms that support the learning of such map-like representations.

For example, while interference with the hippocampus does not impair sun compass orientation in birds, it has been reported to impair dead reckoning or path integration in rodents. This suggests that in birds the hippocampus may exploit sun compass information for learning a map of local landmarks, but is not essential to the bird's orientation by the sun. In contrast, in rodents the hippocampus exploits the use of path integration information in learning a map of local landmarks, and it may also participate in path integration itself. However, it remains controversial whether the hippocampus is necessary for path integration in rodents.

At the cellular level, how is spatial information in the environment coded in the activity of single neurons? Several different types of neurons in the rodent hippocampus display what are called 'place fields'. Specifically, in a freely moving rat, a typical hippocampal neuron with a place field would display low levels of spontaneous activity (occurrence of action potentials) in much of a familiar local environment. However, that neuron would show a large increase in activity when the rat passes through a particular small part of the local environment – the neuron's place field. Such hippocampal neurons are called 'place cells'. As a rat moves through a familiar environment, the change in activity across a large number (network) of place

cells, varying depending on where the rat is and where it is moving, is believed to keep the rat continually updated on where it is in space. Different place cells would show higher levels of activity in different portions of the environment, and collectively the thousands of place cells in the hippocampus would structure the map-like representations of environmental space used for navigation.

However, although the properties of place cells have been exhaustively studied in rats, it is uncertain whether there are similar hippocampal place cells in birds and even primates. Preliminary research in birds and primates suggests that the activity of some hippocampal neurons changes as a consequence of space, but in ways somewhat different from those found in rats. For example, in primates, and maybe pigeons, it seems that where an animal is looking, rather than its specific location in space, is more important in determining whether a place cell is active or not. The suspected differences in the properties of place cells in primates and birds compared with rats may be related to the highly visual, diurnal lifestyle of the former groups.

Head Direction Cells

In addition to place cells, some brain areas closely related to the hippocampus contain neurons that are preferentially active when a rat is headed or pointed in a particular direction, relative to some directional reference, independent of where it is located in space. Such neurons are referred to as 'head direction cells'. These cells are thought to work together with place cells in structuring the neural representation of space in the hippocampus.

For example, one possibility in rats is that head direction cells provide essential velocity information about an animal's movement in space (dead reckoning) and that this information could then be used to determine the place fields of place cells and the map-like representation of local landmarks that emerges from them.

Head direction cells have yet to be discovered in the hippocampus of birds, but if they were found, it would not be surprising to discover that as directional references they were sensitive to compass information gathered from the sun or earth's magnetic field.

SPATIAL BEHAVIOR IN HUMANS

Although in developed countries much of human navigation is now structured by the grid-like pattern of streets and the routes people take through them, nomadic people who roam freely in open environments navigate by map-like representations seemingly similar to the landmark maps of birds and nonhuman mammals.

Consistent with the idea that humans too learn maps of their environment is the finding that the human hippocampus is an essential brain structure for spatial memory. Individuals who have experienced damage to the hippocampus, perhaps because of stroke or surgical interventions to control epilepsy, are strikingly impaired in navigating in their neighborhoods and remembering where they left objects, much like patients with Alzheimer disease who also experience hippocampal dysfunction. Some of this work further suggests that the hippocampus of the right hemisphere may be more important for spatial memory than the left hippocampus.

The development of powerful brain imaging techniques, such as positron emission tomographic scans and functional magnetic resonance imaging, has revolutionized the ability to investigate regional differences in brain activity that correlate with ongoing cognitive activity in healthy people. With respect to spatial memory tasks, whether people are asked to navigate a virtual maze or taxi drivers are asked to describe a route to an address, the parahippocampal region invariably shows an increased level of activity. Although the hippocampus itself may or may not show higher levels of activity during a spatial memory task, the heightened activation found in the neighboring parahippocampal area, a brain region with strong neural connections to the hippocampus, indicates that a circuit of brain structures that includes the hippocampus participates in memory-based navigation. The imaging work also is consistent with the idea that the right hippocampal area may be more involved in spatial memory than the left.

Human navigation is complex, and it is simplistic to attribute such a complex behavior to a restricted cluster of brain areas like the hippocampus and parahippocampus. The imaging work has identified other brain structures that show heightened activity when people engage in tasks of spatial memory. One interesting brain area is the posterior parietal cortex: this region is important for egocentric orientation, in other words the ability to relate the location of objects in space to one's own body axis. In contrast, the cognitive map-like hippocampus is important for understanding the spatial relationship among environmental stimuli independent of where one is located in space. Imaging data suggest that successful memory-based

navigation requires the integration of the posterior parietal lobe representation of egocentric space (where objects are relative to oneself) with the hippocampal representation of allocentric space (the map of environmental landmarks), which does not change as one moves through space.

COMPUTATIONAL MODELS

The research described above allows attribution of a memory-based, map-like representation of the environment to the hippocampus and related structures. Recordings of the electrical activity of many hippocampal cells have revealed that these cells have place fields, which may represent specific locations in the environment.

However, the map of the environment found in the hippocampus cannot be reduced to a collection of independent single neurons, each responsible for the representation of a restricted portion of space. Rather, at any given time, it is logically assumed that space and navigating through space are represented by the activity in networks of thousands of neurons in the hippocampus and related structures. Unfortunately, investigating the activity in networks of thousands of neurons is beyond the techniques available to neuroscience today, yet ultimately the neural representation of space will have to be understood at this level.

Computational models, most often neural network or connectionist models, are designed to compute a behaviorally interpretable output function based on input variables and system parameters. In the case of understanding how the hippocampus structures memory representations of space, the behaviorally interpretable output could be the place field of a place cell, the input variables could be the network of neurons that modulate the place field of a place cell, and the system parameters could be the connection strengths among the elements in the network.

The properties of neural network and connectionist computational models resemble the properties of networks of neurons in the brain. This includes experience-dependent changes in the strength of connections between elements in a neural network or connectionist model that resemble changes in synaptic strength occurring among neurons in the brain during learning. Consequently, computational models have been successfully exploited to explain how the hippocampus can represent space at the level of networks of neurons.

Computational models are powerful research tools because they can capture the complexity of neural networks in the brain, and make explicit predictions about how the hippocampus and related structures may represent space. In the absence of techniques to measure the simultaneous activity of thousands of neurons, artificial computational models are important in elucidating the complexity of interactions among networks of neurons and their relationship to behavior and cognition.

Neglect

Introductory article

Jon Driver, University College London, London, UK
Patrik Vuilleumier, University College London, London, UK

CONTENTS

Unilateral spatial neglect is the failure to perceive, orient, and act on objects or events towards the side of space opposite a unilateral brain lesion (typically to the right hemisphere). These characteristic deficits are not attributable to primary sensory or motor loss, but involve deficits in higher-level spatial representation and attention.

INTRODUCTION

Unilateral spatial neglect is a common and disabling syndrome following unilateral stroke, especially after infarction of the right middle cerebral artery. The patients typically exhibit a constellation of deficits, but their tendency to ignore information towards the contralesional side of space (i.e. usually the left side) is particularly striking, especially given that this can arise even in patients who have no primary sensory or motor deficit on the affected side. Recent progress in understanding such neglect has come from relating the disorder to the underlying neural systems that are damaged or preserved, and also from relating certain aspects of neglect to 'attentional' phenomena in normal people, who can analogously fail to consciously perceive or respond to stimuli if they do not attend to them.

CLINICAL SIGNS

Although the exact pattern of deficit varies from one patient to another, the following clinical signs may be present in prototypical cases. The patients behave as if half of their spatial world were lost (usually the left side, following right hemisphere damage). They may ignore people or objects on the affected side of space, eat food from only the other side of their plate, shave or make up only one side of their face, dress only one side of their body, miss letters, words or even a whole page on the affected side when reading, and overlook or forget contralesional turns in routes. Notably, many patients with neglect often do not realize that they are missing anything on the affected side (anosognosia). If the brain damage causes paralysis of contralesional limbs, the patients may even remain unaware of this if they also suffer from spatial neglect for that side of space.

In the clinic, neglect is not only observed in daily life, but also demonstrated with a variety of simple paper-and-pencil tests. For example, when patients are required to search for and mark all target shapes on a page (cancelation task), they may mark only a few of those on the ipsilesional side and ignore the presence of the others even when given unlimited time (Figure 1a). When asked to mark the midpoint of a horizontal line (bisection task), some patients may deviate towards its ipsilesional end, as if ignoring or compressing its contralesional extent (Figure 1b). When drawing from memory or copying a picture, they may omit most details from the contralesional side (Figure 1c), even for familiar objects with important unique features on either side that have a prescribed layout (e.g. the numbers on a clock face). Such spatial biases do not arise only in visually guided behavior. Even when blindfolded and exploring objects haptically, the patients may search only for those on the ipsilesional side. When asked to point straight ahead in darkness, or to move a laser-pointer to the subjective straight ahead position, neglect patients may deviate ipsilesionally. When searching for invisible targets in darkness, their eye movement path may show an analogous bias towards the ipsilesional side. Sound localization may also be affected, with inaccurate spatial coding on the contralesional side, and/or mislocations towards the ipsilesional side.

Importantly, such failures to detect, perceive, localize, explore or act towards the affected side

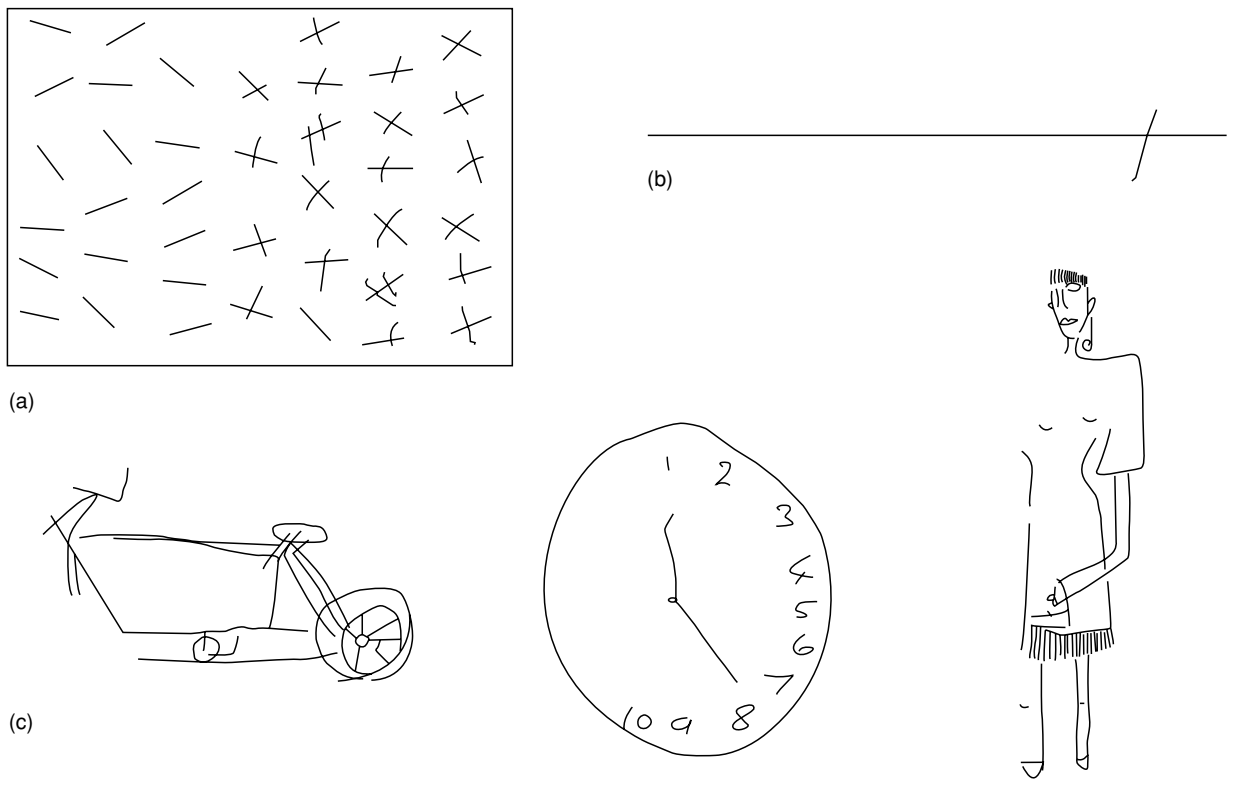

Figure 1. Examples of left-sided neglect after damage to the right hemisphere of the brain, in clinical paper-and-pencil tests. (a) Cancelation; (b) line bisection; (c) drawings of bicycle, clock and woman.

of space in neglect patients are typically not attributable to primary sensory or motor loss. Many patients who do suffer from such primary losses do not exhibit neglect; conversely, other patients can exhibit neglect despite having no paralysis, no visual field cut, and no other primary sensory loss. This is further illustrated by another common component of the syndrome. Perceptual 'extinction' arises in patients who can detect and report a unilateral stimulus presented alone on the affected side of space, but who miss the same stimulus if presented concurrently with another detected stimulus on the ipsilesional side. The ipsilesional stimulus 'extinguishes' awareness of a contralesional stimulus that would otherwise be detected. Such extinction can arise within vision, touch, audition, or even smell. It can also be elicited crossmodally, as when a visual stimulus on the ipsilesional side extinguishes awareness of a touch on the contralesional hand that would otherwise have been felt. It has been suggested that extinction may reflect a pathological bias in attention, which becomes most apparent when multiple concurrent stimuli compete to attract attention. Note that multiple stimulation tends to be the rule rather than the exception in daily life; and that competition between multiple stimuli may also be involved in many other tests for neglect (e.g. cancelation tasks).

Unlike sensory deficits, neglect is often reduced if the patient's attention is directed towards the affected side, even in the presence of competing stimuli. Moreover, neglect is often graded (becoming increasingly severe for increasingly contralesional locations), without the step-function at anatomical midlines that characterizes lower-level sensory disorders (e.g. hemianopia). Finally, unlike sensory disorders, neglect can be influenced by changes in posture. The same retinal stimulation in the contralesional visual field may be detected or neglected, depending on the current direction of the eyes in their orbits, and/or of the head on the trunk. Remarkably, neglect patients may see objects in the left visual field better when just their trunk is twisted leftwards (so that the same retinal stimulation now falls further to the right of their body). Analogously, tactile detection may improve for the contralesional hand if this is placed further towards the ipsilesional side of the body.

In some patients neglect can arise in tasks of mental imagery or of memory, again demonstrating some independence from sensory deficits. The

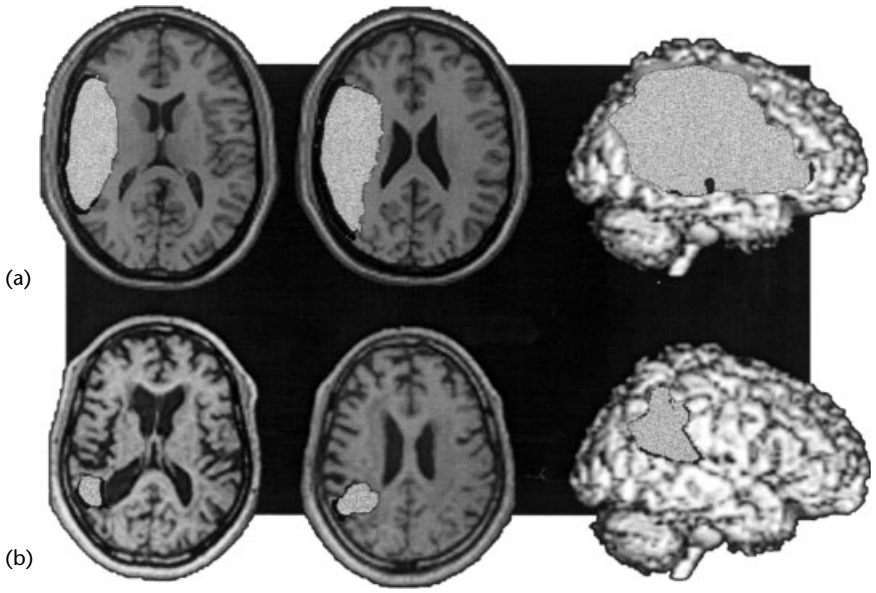

Figure 2. Reconstructions of typical lesions in neglect. (a) Damage after a massive stroke involving middle and anterior cerebral arteries in the right hemisphere, in a patient with enduring left neglect and extinction. Many combined deficits would be expected after such diffuse damage; these different deficits may interact and exacerbate each other to produce the clinically observed syndrome. (b) More focal damage centered on the right inferior parietal lobule, in another patient with enduring left neglect and extinction. Although the lesion is smaller, it will still affect many distinct parietal areas, each with subtly different functions, to produce a combined deficit. Note that underlying white matter may also be damaged, potentially affecting other areas via remote connections.

patients may fail to describe elements that would be situated on the contralesional side for well-known settings or imagined scenes. Moreover, when asked to adopt a different perspective in their mind's eye (e.g. the view from the other side of a familiar city square), the previously omitted details may now be reported, while previously reported details now shifted to the neglected side become missed instead. In some cases, neglect in mental imagery can apparently arise without ostensible neglect for externally present stimuli, and vice versa.

ANATOMICAL CONSIDERATIONS

Neglect can arise after focal damage in a number of different brain areas, all reciprocally interconnected in a distributed network that is considered critical for the elaboration of high-level multimodal spatial representations, for the control of spatial attention, and for the spatial preparation of intentional motor responses. Although some aspects of neglect can be seen in the immediate aftermath of left hemisphere damage, neglect is more common and much more enduring after right hemisphere damage. Prototypically, severe neglect is seen after major strokes in the territory of the right middle cerebral artery, causing damage to numerous brain areas and also to underlying white matter that affects remote connections. Such large lesions (Figure 2a) may cause numerous deficits, each of which can potentially exacerbate the others to produce florid neglect symptoms. Severe neglect can also follow more focal damage centered around the sylvian fissure, involving right inferior parietal cortex (supramarginal and angular gyri, Brodmann areas 39 and 40; Figure 2b). However, even such relatively focal lesions may affect many distinct parietal areas, and also disrupt fiber connections in the paraventricular white matter. It has been suggested that the superior temporal cortex may have a critical role in spatial neglect, although this remains controversial.

Other areas implicated include the prefrontal cortex (either close to the frontal eye field or in the more ventral inferior frontal gyrus), medial frontal cortex (supplementary motor and cingulate areas), thalamus (anteromedial nuclei and posterior pulvinar) and basal ganglia. It has been suggested that subcortical lesions might produce neglect by disconnection or functional disruption of distant parietal areas. Parietal lesions themselves can cause remote dysfunction in frontal and cingulate areas, and this has been found to correlate with neglect

severity. Even though neglect is characterized by a dramatic loss of conscious perception and of goal-directed action towards the affected side of space, the typical brain lesions are quite remote from primary sensory and motor cortices. This further underlines the point that patients can exhibit severe neglect despite not being blind, deaf, insensitive or paralyzed. For instance, patients can show severe visual neglect despite primary (striate) and secondary (extrastriate) visual cortical areas in the occipital and temporal lobe remaining structurally intact.

Some aspects of neglect have been related to neurophysiological data on parietal, premotor or prefrontal cortex, as gleaned from single cell recordings in monkeys. Particularly relevant properties of certain intraparietal neurons include the following: convergence of spatial information from different modalities; modulation of sensory responses (e.g. to stimuli at a particular point on the retina) by current posture; some ipsilateral receptive fields in addition to a predominance of contralateral receptive fields; highly selective responses to currently attended or salient stimuli; and involvement in the initial translation of sensory information into particular spatial motor responses. Computational models have shown that all of these aspects of parietal neurons may help to explain seemingly disparate aspects of neglect (specifically, its often multimodal nature; its modulation by posture; its graded nature; its attentional aspects; and the combination of perceptual and motoric biases; see below). Nevertheless, it remains controversial whether brain lesions in monkeys can produce deficits closely mimicking human neglect. Extinction-like deficits, as well as biases in search and exploration, may follow unilateral destruction of structures associated with human neglect, or reversible chemical lesions within specific intraparietal subareas. However, these deficits seem relatively short-lived and less severe than the human syndrome, perhaps reflecting the much larger size of damage in stroke patients (see Figure 2) or some laterality of function that is unique to humans.

VARIETIES OF NEGLECT: DISSOCIATIONS AND SUBCOMPONENTS

The exact pattern of deficit can differ between patients with neglect, presumably in accord with differences in the lesion. Dissociations have been reported between different tests for neglect (e.g. cancelation versus bisection or extinction); between perceptual versus motor aspects of neglect; between perceptual versus imaginal neglect; and between neglect in different spatial domains (e.g. in near within-reach space, versus far in space; or within objects versus between objects). Bisection and cancelation tasks can indeed provide contrasting measures of neglect. Difficult cancelation tests may constitute the paper-and-pencil measure correlating best (to date) with clinical severity of neglect and with function in daily life, whereas bisection tests may show substantial influences from other deficits (e.g. coexisting visual field cuts). Extinction can dissociate from neglect in some cases, although as noted earlier, there is an analogous competitive aspect to many of the standard tests for neglect.

The issue of perceptual versus motor aspects arises because many tasks in which patients show neglect not only assess perception or attention for the affected side, but also require a spatial motor response to stimuli there (as in the cancelation task). In principle, pathological neglect behavior (e.g. failures to cancel contralesional targets) could either have a perceptual/attentional basis, or instead reflect some deficit in executing movements towards the affected side (perhaps even with the ipsilesional limb), or a combination of such deficits. Some studies have sought to disentangle such components with ingenious methods for opposing the spatial direction of sensory information versus the required motor response (e.g. by means of video systems, reversing mirrors, pulley systems, or spatially reversed mouse–cursor relations in computerized studies). Such work initially suggested a relatively clear-cut distinction between 'perceptual' neglect after posterior lesions and 'motor' neglect following more anterior prefrontal lesions. However, the apparent frontal involvement may primarily be due to the unusual requirement to move away from the direction indicated by target stimuli in many of these experimental situations. Frontal lesions are known to produce general impairments in such incompatible tasks. Further work has separated perceptual and motor requirements by changing the start position and hence the direction of movement, while still reaching directly towards the same visual target. In this situation, patients with inferior-parietal (but not frontal) lesions were not only impaired at perceiving contralesional visual stimuli, but over and above this were slower to initiate movement in the contralesional direction. Such a combined perceptual-motor deficit would accord with recent views of parietal areas as sensorimotor interfaces.

Nevertheless, with appropriate tests, purely sensory and purely motor aspects of the neglect

syndrome can still be identified. For instance, tests of perceptual extinction do not require spatially directed motor responses, yet can reveal clear deficits. On the other hand, purely motor neglect may be apparent in patients who fail spontaneously to use the contralesional hand, even when this is not paretic and can be moved skillfully when prompted. 'Motor extinction' can be observed for tasks requiring unseen bimanual action (e.g. raising both hands, or making repeated movements with both, either in or out of phase), with deficient contralesional movements during bimanual but not unimanual actions. Note that this may reflect competitive aspects analogous to those for perceptual extinction, but possibly arising within different neural structures. Motor extinction or underuse of a nonparetic contralesional hand have been observed after unilateral lesions to frontal cortex, supplementary motor area, parietal cortex, basal ganglia or thalamus.

Pioneering lesion work in monkeys showed that unilateral damage to different areas of premotor cortex could produce phenomena resembling neglect or extinction for different spatial domains: within space close to the head following damage to area 6, sparing behavior for more distant stimuli; and vice versa following damage to area 8 instead. Human studies have reported that neglect is sometimes more severe for stimuli in near space than in far space (in bisection tasks), or conversely worse in far space than near space for other patients across a variety of tasks. This dissociation between near versus far neglect suggest that it may affect different types of spatial representation independently, rather than arising only within some single 'master map' of space. A similar conclusion follows from demonstrations that neglect can arise either 'within' visual objects, or 'between' visual objects. Such a dissociation may actually arise within the same patient, but affect opposite sides of space. For instance, one patient with bilateral brain damage showed neglect of the left side of individual objects (e.g. missing the initial letters in words), but neglect of whole objects on the right side of space (e.g. missing whole words on that side of a page). Importantly, this pattern was not just specific to reading, but was found across a variety of different tasks and stimuli.

The various dissociations described above indicate that neglect is a multicomponent disorder, consistent with the anatomy reviewed earlier. In addition to the different types and different domains of neglect, some further components exist that might not produce neglect in isolation, but exacerbate symptoms when combined with the other deficits. One example of this is the bias towards 'local' rather than 'global' aspects of a visual scene, associated with damage to the right temporoparietal junction. Some patients with focal damage here may exhibit local biases without neglect, whereas patients with equivalent damage in the left hemisphere contrastingly show a global bias. Because the large right hemisphere lesions in neglect will often include the temporoparietal junction, such patients are likely to suffer from local biases in addition to their perceptual, attentional and motor biases towards the ipsilesional side of space. This may greatly exacerbate their deficit: because their attention tends to lock onto local rather than global aspects of complex displays, as in cancelation tasks, they may consequently neglect a much wider area of contralesional space.

Another deficit that might apply to all locations following right hemisphere damage, yet still exacerbate spatial neglect when combined with biases towards the ipsilesional side, concerns an impairment in tonic arousal. The noradrenergic alerting system, originating in the brainstem and projecting to frontal cortex, shows greater right lateralization cortically in humans. Extensive right hemisphere damage may cause many neglect patients to be chronically underaroused, with particular difficulties in maintaining self-arousal endogenously over lengthy periods. This might in turn aggravate their neglect. In apparent support of this, phasically alerting neglect patients with warning stimuli can temporarily reduce their abnormal ipsilesional bias.

A further deficit that might apply to both sides of space, yet exacerbate contralesional neglect, concerns a general reduction in perceptual capacity following right hemisphere damage. As described earlier, perceptual extinction is a failure to detect contralesional stimuli specifically in the presence of multiple competing stimuli. This may reflect reduced processing capacity in addition to the ipsilesional bias. Neglect patients may thus exhibit a degree of simultanagnosia (a difficulty in perceiving multiple stimuli simultaneously) in addition to their lateral bias. In support of this, patients with extinction following right parietal damage may show an impaired capacity for reporting more than one target even in vertical arrays briefly presented on the ipsilesional (i.e. supposedly intact) side. Moreover, if instructed to report any contralesional item first in brief bilateral displays, they may show paradoxical extinction of items on the ipsilesional side. Abnormally prolonged attentional dwell-time has also been observed in people with right hemisphere neglect, even when

all stimuli are presented at central fixation and in rapid succession. Finally, it has recently been proposed that, in addition to the lateral biases in attention, neglect may involve deficits in spatial working memory (or more specifically, in maintaining representations of locations already examined during search, across saccades). Spatial working memory tasks in the normal brain activate a predominantly right-lateralized network that is strikingly similar to the areas of typical lesions in neglect patients. If neglect patients fail to form a stable representation of previously searched locations across multiple saccades, then their search might return recursively to those locations most favored by their lateral attentional bias, without the patient realizing this, exaggerating the bias still further.

The possible involvement of local biases, deficits in alertness, general reductions in perceptual capacity, and impairments in spatial working memory, all as exacerbating factors, may provide some explanation for the strong association of neglect with right hemisphere damage. Further accounts for this asymmetry include proposals that in humans the right hemisphere is specialized for spatial cognition (perhaps as the flipside of left hemisphere specialization for language); or that some right hemisphere areas normally represent locations within both sides of space, while left hemisphere homologues primarily represent contralateral locations (so that a right hemisphere lesion would be more devastating in terms of the spatial locations whose representations are lost). None of these various explanations need be regarded as mutually exclusive. Analogous hemispheric specialization may not exist in other animals.

RESIDUAL UNCONSCIOUS PROCESSING

Despite escaping the patient's awareness, neglected or extinguished stimuli can nevertheless undergo residual unconscious processing. Such findings again underscore the fact that neglect or extinction can arise despite sparing of some basic sensory and motor processes. Much of the evidence for residual processing has stemmed from analogies between the fate of neglected and extinguished stimuli in the patients, and the fate of unattended information in neurologically healthy people. While normal people can show little or no explicit awareness for stimuli that are not selectively attended, some implicit processing of these can nevertheless be revealed by indirect measures such as priming. As a first approximation, the residual unconscious processing found in patients with neglect or extinction corresponds well with that thought to take place 'preattentively' in the normal brain. In people with or without brain damage, this processing can determine which information will attract attention and reach awareness, and which will escape awareness instead.

Residual unconscious processing for contralesional stimuli can manifest in different ways. Extinguished or neglected stimuli can influence the patients' responses to consciously detected ipsilesional stimuli (e.g. affecting the speed of such responses), revealing that the presence, color, shape, or even the semantics of a contralesional stimulus can sometimes be extracted despite unawareness of it. In some cases, particular relationships between concurrent contralesional and ipsilesional stimuli can influence the degree of extinction or neglect. For instance, extinction is reduced when bilateral stimuli can be linked into a single object through image-segmentation principles, connecting the stimulated spatial locations to yield a common perceptual event. Such effects imply that image-segmentation processes may operate normally on contralesional visual inputs, prior to the level at which extinction arises. Similar conclusions follow from the various manifestations of so-called 'object-based' neglect (i.e. neglect affecting segmented visual objects, rather than unparsed spatial regions of the retinal image). Extinction or neglect can also be influenced by the particular identity of the stimuli used, again suggesting that some residual processing occurs prior to stages where contralesional inputs become extinguished or instead detected. For instance, stimuli of particular emotional significance (e.g. angry faces) may undergo less extinction, in keeping with the fact that such stimuli can readily capture attention even in healthy people.

The anatomical basis of such residual processing has been studied using functional imaging and electrophysiological measures of neural activity in the patients' brains, in response to extinguished or neglected stimuli. To date, functional magnetic resonance imaging (fMRI) studies have confirmed that, although escaping awareness, such stimuli can still activate anatomically intact areas in striate and extrastriate visual cortex, including category-specific areas in temporal cortex (e.g. the fusiform face area for extinguished faces), plus more remote limbic regions (e.g. amygdala and orbitofrontal cortex for extinguished fearful faces). This supports prior proposals that residual unconscious processing in neglect and extinction may reflect preserved afferents into primary visual cortex (V1), and

thence along the ventral visual system into temporal lobe (typically spared by prototypical parietal lesions). On the other hand, even early visual responses to extinguished stimuli may not be entirely normal. Visual evoked potentials have shown that components around 100 ms after stimulus onset can be attenuated for extinguished compared with perceived contralesional stimuli. Functional MRI results have also shown greater visual activation associated with conscious perception versus extinction, together with a greater covariation of striate visual cortex with parietal and frontal areas in the intact hemisphere during conscious perception. These results may accord with proposals that such parietal and frontal areas control spatial attention in the normal brain, by modulating activity in early sensory areas.

REHABILITATION

Neglect is disabling and carries a poor prognosis for independent living after a stroke. Spontaneous recovery occurs in some cases, but is often partial and poorly understood, though it may correlate with improved cerebral blood flow in spared areas of both the damaged and intact hemispheres. There have been some encouraging demonstrations of plasticity in the adult brain from other research areas, but rehabilitation of neglect remains a major challenge despite considerable effort and some recent progress. The evidence described above of considerable residual processing, and of factors influencing the degree of deficit, suggests a potential platform to build on.

One approach has been to train patients to direct search or attention towards the contralesional side. Neglect is improved by this in the short term, but there is little generalization to daily life. Another approach has been to modulate arousal, but again the challenge is to generalize this successfully to self-arousal during daily life. Use of the contralesional limb (in nonparetic patients) on the contralesional side of space can reduce neglect. However, many patients may not use this limb spontaneously in daily life, favoring the ipsilesional limb instead. Ipsilesional arm restraint may be considered, since this can ameliorate mild contralesional paresis, and may also reduce neglect. Patching of the whole ipsilesional eye has produced inconsistent results. More recently, patching of the ipsilesional visual hemifield in both eyes has produced some encouraging results. The logic behind this intervention is to correct the asymmetrical spatial bias by inducing a reverse bias at the input stage.

Caloric stimulation of the vestibular system (by iced water in the left ear, or warm water in the right ear, to induce vestibular signals similar to those from actually turning left) has been shown to ameliorate perceptual and exploratory neglect, plus associated deficits such as imaginal neglect, or anosognosia for hemiplegia. Again, the asymmetric stimulation may oppose the pathological bias to the ipsilesional side caused by the lesion. Vestibular signals also contribute to coding of external space relative to the body, being integrated with other sensory signals within parietal cortex. Similar principles may explain the analogous beneficial effects of vibratory neck-muscle stimulation (inducing proprioceptive signals similar to a leftwards turn of the trunk relative to the head). Both vestibular and proprioceptive manipulations produce consistent reductions in neglect, but their effects dissipate when the stimulation ends. The same applies for optokinetic stimulation.

Longer-term benefits have been reported following prism adaptation. The patients wear prisms shifting visual information towards the ipsilesional side, so that their reaches to visual targets initially err in the ipsilesional direction. Following adaptation, the hand is directed further to the contralesional side for a given retinal position. Just 10 min of this procedure has been claimed to improve neglect over several days, although the exact basis for this remains unknown. Prism adaptation in the reverse direction has no analogous impact.

Finally, drugs such as dopamine agonists have been used to increase arousal and enhance contralesional exploration, but with only mixed success to date.

Research into the processes that are impaired or spared in spatial neglect, and into the underlying neural mechanisms, has uncovered many important new findings in recent years. It is hoped that these findings will contribute to improved rehabilitation procedures in the future.

Neural Basis of Memory: Systems Level

Introductory article

Arthur P Shimamura, University of California, Berkeley, California, USA

CONTENTS

A systems level approach to the neuroscientific investigation of memory looks at the ways in which different areas of the brain interact and communicate to achieve this function.

INTRODUCTION

What did you eat for dinner two days ago? What is the name of the mouse in the story *Dumbo*? How many turns do you need to make to get from your front door to your bedroom? How are you able to understand the visual symbols in this sentence? Memory – our remarkable capacity to learn and retain information – offers the answers to these questions. Across a lifetime, we encounter, store and retrieve an enormous amount of information. We have knowledge about ourselves, about world facts, and even about things that we do not usually associate with our memory, such as habits and skills. How does the brain accomplish such extraordinary feats of memory?

The study of memory has been approached from many scientific disciplines. Neurobiological approaches address the microstructure of memory, such as the biochemical mechanisms within neurons or the formation of synaptic connections between neurons. Such processes allow the brain to adapt to changes in the environment. At a more global level of analysis, or what is often described as a systems level, neuroscientists describe how brain regions interact and communicate to serve human memory. Take, by analogy, the levels at which one could understand how an automobile works: at a microscopic level, one could study how the fuel molecules, through combustion, react to make an automobile move, whereas at the systems level, one could study the function of specific components, such as the engine or the transmission, and then determine how these components work together. This article approaches human memory from a systems level, focusing on brain regions that contribute to various components of human memory.

Our understanding of human memory has been significantly advanced by integrating neuroscience with cognitive science – a field of research called cognitive neuroscience. Over the past century medical scientists have studied patients with brain injury as a way to understand the biology of human memory. Around 1970, cognitive scientists became interested in neuropsychological studies, because such studies often demonstrated modularity in cognitive function. For example, brain injury could severely impair an aspect of memory, but leave intact other cognition functions such as attention, language, and problem-solving skills. More recently, studies using neuroimaging techniques – such as functional magnetic resonance imaging (fMRI) or positron emission tomography (PET) – have led to finer analyses concerning the relationship between brain regions and memory function. In such studies, it is possible to show that specific brain regions become active when individuals engage in memory processes, such as learning a list of words or trying to remember a past event. The following sections will identify components of memory from a cognitive neuroscience perspective.

ORGANIC AMNESIA AND THE MEDIAL TEMPORAL CORTEX

A significant advance in understanding the biology of human memory occurred by chance through the study of a now-famous neurological patient known by his initials, HM. This patient underwent an experimental surgical procedure in 1953 to relieve severe epilepsy. The surgery involved removal of brain tissue in the medial temporal cortex, a region

of the cerebral cortex that encompasses the inner (medial) surface of the temporal lobe. The operation included removal of the hippocampus, a brain structure adjacent to the cerebral cortex. Following surgery, HM's epileptic seizures were reduced, but he was left with a profound organic amnesia – that is, he was unable to remember events and information encountered since his operation. For example, when HM was asked what he had had for lunch half an hour previously, he could not remember what he had eaten, or even if he had eaten at all. Despite this severe memory impairment, there was little impairment in intellectual ability or language skills. Indeed, HM had a normal IQ (intelligence quotient) and could communicate fluently with others. There was some memory impairment for information that occurred before his operation, a disorder called retrograde amnesia. For example, HM could not recall the layout of the hospital in which he was treated, or recall the death of a favorite uncle who had died three years previously. Yet HM's retrograde amnesia was not gross, as indicated by the fact that he performed as well as others on a face recognition test of celebrities who became famous prior to his operation. Also, he was capable of recollecting events and episodes from his childhood.

Clinical observations indicate that HM's memory for ongoing events is still severely impaired. He is somewhat aware of his condition, as indicated by the following quote:

> Right now, I'm wondering. Have I done or said something amiss? You see, at this moment everything looks clear to me, but what happened just before? That's what worries me. It's like waking from a dream; I just don't know. It's like waking from a dream.

Indeed, HM lacks the ability to acquire and retain events and facts encountered since his operation. The impairment affects information received from all types of sensory receptor and includes impairment of both verbal and nonverbal (e.g. spatial) memory. For example, HM has failed to add to his vocabulary new words such as 'jacuzzi', because such words have been added to the language since his surgery. He also exhibits severe impairment on laboratory tests in which he is asked to recall or recognize recently presented words and pictures.

Studies of neurological disorders that affect the medial temporal cortex have confirmed the importance of this brain region for memory. For example, tumors or strokes occurring in the medial temporal cortex can cause organic amnesia. Also, other neurological disorders – such as viral infections, ischemia (loss of blood flow to the brain) or hypoxia (loss of oxygen to the brain) – particularly damage the medial temporal cortex. In these cases, the inability to retain newly learned information is the outstanding cognitive disorder. Finally, in Alzheimer disease, organic amnesia is usually the most significant impairment in the early stages. However, this is a degenerative disease, and as more brain areas become affected more cognitive functions become disrupted.

Events in your life consist of a variety of psychological experiences, such as sensory inputs, ideas, feelings, and actions. Indeed, every moment is completely unique in that these experiences – perceptions, thoughts, emotions, actions – will happen together only once. If something significant occurs at any particular moment, such as a life-threatening or life-enriching event, it would be useful to be able to bind or associate the varied aspects of the event as one encapsulated 'episodic' memory. Likewise, if you are asked to take an examination, say a history test, it is important to be able to relate or associate a diverse set of facts into an encapsulated 'semantic' or conceptual memory. To form such encapsulated memories, it important to relate quickly many aspects of an event or concept.

A prominent view of medial temporal function is that it allows for the rapid linking of these experiences, sometimes called 'relational binding'. The medial temporal cortex is ideally situated for such relational binding to occur. Many parts of the cerebral cortex extend neural projections that converge onto regions within the medial temporal cortex, from which neural projections extend back to these cortical areas. It is believed that the medial temporal cortex enables neural activations in any given moment to be bound as an encapsulated set of associations. Without this ability, memory would dissolve into fragments unattached or unrelated to any particular time, place, or concept.

WORKING MEMORY AND THE PREFRONTAL CORTEX

Despite HM's amnesic disorder, he is able to think, communicate, and even retrieve childhood memories. In addition, he has the capacity to keep information in mind for brief periods: for example, he can hold in mind a short series of digits, such as a telephone number. Yet, as soon he is distracted, the information is lost. These findings suggest that organic amnesia does not affect the online processing of information, or what psychologists call 'working memory'. Working memory refers to the

processes that allow us to keep information in mind. These processes include the ability to select, retrieve, and maintain information in a short-term or transient manner. With respect to the example of holding a telephone number in mind, working memory is essential when it is necessary to maintain or use information after it has been presented. Animal studies have been invaluable in defining a brain region – the prefrontal cortex – that is essential for working memory. In such studies, neurons in the prefrontal cortex are activated when an animal must maintain information, such as the location of a food item after it has been hidden. Moreover, when this brain region is damaged, the ability to maintain information is disrupted.

The prefrontal cortex is part of the most anterior section of the frontal lobes. It is a large area, comprising 28 percent of the human cortex. Disruption of working memory is apparent in people with damage to the prefrontal cortex. Such individuals have difficulty paying attention and keeping things in mind. For example, people with frontal lobe lesions exhibit severe deficits in the ability to keep in mind a series of items, such as digits (telephone numbers), sounds or spatial locations. In neuroimaging studies using PET and fMRI, increased activation in prefrontal cortex occurs when individuals are asked to keep information in mind. The left prefrontal cortex is involved in holding verbal information whereas the right prefrontal cortex is involved in holding spatial information.

Working memory is important for efficient learning and retrieval. For example, try to learn the following series of words: sister, soda, milk, shoe, father, pants, juice, brother, hat. Maybe you used a strategy to help you organize the words. Perhaps you noticed that the words could be encoded or grouped into three meaningful categories: family relatives, drinks, and clothing. Learning is significantly benefited by the meaningful organization of information. Making new information meaningful to you enhances the integration of new information into your existing database. This strategy involves working memory, because it is necessary to manipulate and update the information in mind. That is, the more you think about the information and why it is meaningful to you, the more you actively integrate the new information with what you already know. Individuals with prefrontal damage exhibit problems in organizing their thoughts and memories. These people do not develop learning strategies or think deeply about what they need to learn. For example, they do not group words into meaningful categories. In neuroimaging studies, the prefrontal cortex is particularly active when individuals are asked to consider the meaning of words. Also, prefrontal activation during the learning of words is greater for words that are later remembered than for words that are forgotten. This finding shows that activity in the prefrontal cortex during learning increases the chances of retrieving the information at a later time.

Working memory is also important in retrieving information. Consider a fairly simple memory retrieval task – try to retrieve as many animals that you can think of in 60 s. This task requires you to search your memories and retrieve specific items. Perhaps you developed a strategy, such as retrieving animals within certain categories, such as pets, farm animals and animals one sees at the zoo, or maybe you went down the alphabet and used each letter as a cue to retrieve animal names. Such strategies are efficient because they facilitate the retrieval of different items and prevent repeating the same ones. Keeping track of which animals were already elicited requires you to keep in mind the animals and update this list each time you retrieve an item. Individuals with prefrontal damage have difficulty keeping track of previously retrieved items. It is as if these items get in the way, making it harder to retrieve others. Thus, these people report only four or five different animals in a minute and often repeat the same ones over and over. Neuroimaging studies have corroborated the importance of the prefrontal cortex during memory retrieval: when brain activity is measured while individuals are asked to retrieve information, the prefrontal cortex is particularly active.

Findings from studies of patients with prefrontal damage and findings from neuroimaging studies suggest that the prefrontal cortex enables efficient organization of information in mind. That is, when one is working with memories, it is necessary to select relevant information, update that information, and use it to respond. Cognitive scientists use the term 'executive control' to characterize the processes associated with the selection, control, and manipulation of information in working memory. Related issues include selective attention and response supervision. Selecting and using information in working memory is essential for efficient processing in many cognitive domains. Indeed, the prefrontal cortex, which is most closely tied to executive control, appears to be involved not only in the control of memory, but also in the selection of perceptual features, thinking, problem-solving, and response selection. Different areas of the prefrontal cortex appear to be responsible for the control of difference aspects of information processing.

REPRESENTING KNOWLEDGE AND PAST EXPERIENCES

So far, we have looked at how the medial temporal cortex binds experiences together to form new memories and how the prefrontal cortex monitors and controls memory activations. But what actually is stored in memory? This intriguing question has bemused scientists, philosophers and poets. Karl Lashley, the noted neuroscientist, argued that there was not a single location where a particular memory was stored. Instead, memories were distributed widely in the brain. To demonstrate this notion, Lashley trained rats to follow a particular pathway in a maze in order to obtain food. Lashley found that lesions of many brain regions, not just one region, impaired performance on this task; moreover, the severity of impairment was determined by the size of the lesion rather than its location. This idea – that memories were distributed in many parts of the brain – countered 'filing cabinet' views of memory in which specific memories were localized in specific areas in the brain.

Today, most cognitive neuroscientists take a middle-of-the-road position between distributed and localized views of memory storage. It is not likely that any memory, such as memory of a past birthday party or your knowledge about a particular historical event, is stored in a small, localized area in your brain. Indeed, there is no evidence that a brain injury would produce an absence of a specific piece of information in one's memory, which would be akin to throwing out a specific folder in your filing cabinet. Thus, memory storage appears to be distributed or represented in many parts of the brain. However, certain features of a memory, such as memory for faces, can be disrupted by specific brain damage. In many cases, these aspects are tied to the way the brain uses or processes such information. Thus, although memories may be distributed widely in the brain, each area may contribute to the memory in a different way. For instance, memories of the sights, sounds, feelings, and actions experienced during a birthday party are likely to be stored in different parts of your brain. When you recollect such past events, you draw on many of these different aspects of your memory, not just any localized one.

Episodic and Semantic Memory

Episodic memory refers to memories that are tied to one's autobiography. These memories are embedded within a context of time and place. Semantic memory refers to the vast database of factual knowledge stored in memory. Such knowledge is usually learned on many occasions and thus not tied to any specific time in one's life. For example, your knowledge of how memory works comes from many experiences (hopefully one of which is from reading this text). The distinction between episodic and semantic memory was first developed by Endel Tulving in 1973. It has been useful in denoting two major divisions of memory representation.

There are both similarities and differences in the manner in which episodic and semantic memory are represented in the brain. One similarity is that the acquisition of new episodic and semantic memory is dependent upon the integrity of the medial temporal cortex. That is, people with organic amnesia have difficulty remembering autobiographical events experienced since the onset of amnesia as well as learning new factual information. Indeed, the outstanding feature of organic amnesia is a deficit in forming new episodic memory. However, these people also fail to learn new semantic knowledge. As mentioned earlier, HM has no knowledge of words that entered his culture after the onset of his amnesia. In another example, a patient with amnesia had been vice-president of an optical firm and was very knowledgeable about the field of optics. However, when he became amnesic, this knowledge did not grow as he was unable to add to this knowledge base. Thus, the acquisition of both episodic and semantic memories depends upon the medial temporal cortex.

One difference between episodic and semantic memory is the extent to which they are represented in the two cerebral hemispheres. It has been known for over a century that the left hemisphere in most individuals is specialized for language processes. Much of our verbal processes and verbal knowledge, such as knowledge about phonology and word definitions, are largely represented in the left cerebral hemisphere. The right hemisphere in most individuals is specialized for spatial processes. For example, damage to the right hemisphere often produces spatial disorders, such as a 'neglect' syndrome in which individuals fail to attend to stimuli on one side. As a large proportion of episodic memory is spatial in nature, damage to the right hemisphere tends to produce greater disruption of episodic memory than semantic memory. As semantic memory is often more tied to verbal processing, such as factual knowledge read in books, it is often the case that semantic memory is more disrupted by damage to the left cerebral hemisphere. As mentioned earlier, such

memories are widely distributed. Thus, extensive damage to one hemisphere is needed to observe disruption in episodic or semantic memory. Moreover, such damage does not appear to reflect a loss of a specific memory, but instead impairment is indicated by diffuse or fuzzy memories.

Category-specific Knowledge

The notion of a widely distributed memory system suggests that memory is multiply represented in many brain regions. This kind of memory representation is efficient because damage to one region may degrade memory but it is unlikely that it will totally abolish it. Yet, as mentioned above, there appear to be features or categories of knowledge that are grouped together. Interestingly, in rare cases of brain injury, there appear to be category-specific deficits of semantic knowledge. That is, some affected individuals exhibit greater problems in recollecting certain features of knowledge than others. One outstanding impairment involves a disorder in remembering faces. This impairment (prosopagnosia) is often caused by damage to ventral–posterior regions of the cerebral cortex; it affects visual recognition of all faces, including the patient's own face. Recent fMRI studies have identified an area within this region, called the fusiform gyrus, that is highly active during the viewing of faces. Although this area is involved in the visual memory of faces, it does not disrupt all memories for people. Patients with prosopagnosia can recognize familiar individuals, such as friends and family, by their voices.

In rare cases, specific loss of a semantic category can occur. For example, a person can exhibit a severe loss in the ability to recognize drawings of common animals, whereas the same individual can recognize drawings of manufactured objects, such as common tools. Interestingly, other affected individuals may exhibit exactly the opposite pattern – an inability to recognize common tools while retaining the ability to name common animals. Such cases suggest that the representations of certain aspects of knowledge are localized in different brain regions. In these people it is difficult to ascertain the brain regions responsible for such category-specific deficits, because it is often the case that the brain injury is large or diffuse.

Do category-specific deficits in semantic knowledge suggest that our memories are stored in a localized rather than a distributed manner? It is unlikely that a specific memory, such as memory of a pet you once owned, is represented in a specific location in the brain. How, then, can one interpret findings of a separation of the concept of animals from that of tools? Neuroimaging studies have shed some light on this issue. In one PET study, participants viewed drawings of animals, tools, or nonsense forms. The nonsense forms were used as control stimuli, and PET activation in response to drawings of animals and tools was compared with activation to these control stimuli. The study showed that both animals and tools activated bilateral areas in the ventral temporal cortex, suggesting that semantic knowledge of animals and tools has broad and overlapping (i.e. distributed) representation.

There were, however, some category-specific activations. Drawings of animals but not tools activated areas in the occipital cortex, an area of the brain associated with visual processing. Drawings of tools but not animals activated premotor areas in the frontal cortex, an area that is also activated during imagined hand movements. Such findings suggest that category-specific knowledge may be tied to the manner in which such information is encoded or used. Animals tend to be encoded and encountered visually, whereas tools are manipulated. It appears that our memories are not stored as purely abstract, semantic representations. Instead, they are associated with the manner in which they have been encoded and used. Apparently, the distribution of our semantic knowledge is related to the distribution of other cognitive processes in the brain, such as visual, auditory, verbal, spatial, emotional, and motor processes.

Procedural Memory: Habits and Skills

The ability to read, drive a car or swim certainly requires memory. This kind of memory, however, is not represented in the same manner as other forms of memory, such as semantic or episodic memory. Skills involve the tuning or coordinating of sensory and motor associations. Procedural memory refers to the processes and representations associated with habits and skilled behavior. Thus, procedural memory is linked specifically to neural circuits associated with the modification of perceptual and motor function. For example, a skilled behavior such as throwing a ball or playing a musical instrument involves the modification and tuning of various perceptual-motor circuits. It is inherently 'procedural' in that skilled behavior is expressed as a sequence of finely tuned movements. Procedural memory can occur without explicit or conscious knowledge of the training session. Indeed, it is often the case that conscious intervention or feedback can disrupt the expression of skills.

Procedural memory is unique in that it appears to be independent of the medial temporal cortex. One of the most striking findings is that people with amnesia can learn simple skills in an entirely normal fashion. For example, HM showed learning and retention in a mirror-drawing task in which he was required to trace the outline of a star while viewing the star through a mirror. The task is difficult at first but then becomes easier with practice. HM exhibited normal learning and retained this skill over days of practice. Another skill learning task, the pursuit-rotor task, has been used to test people with brain injury. In this task, the patient learns to keep a stylus on a rotating target. In these tests, HM and other amnesic patients perform well, even when tested the next day. However, such patients have no memory of having performed the task before.

Habits or dispositions are forms of procedural memory that can be acquired without conscious awareness. For example, during an interview with an amnesic patient, a neurologist hid a pin between his fingers and surreptitiously pricked the patient on the hand. At a later time during the interview, he once again reached for the patient's hand, but the patient quickly withdrew her hand. The patient did not acknowledge the previous incident, and, when asked why she withdrew her hand, she simply stated, 'Sometimes pins are hidden in people's hands.' This anecdote is an example of stimulus–response habit learning without awareness, or what is called 'fear conditioning'.

Other habitual forms of learning can be demonstrated in studies of Pavlovian classical conditioning, in which a tone is paired with a puff of air to the eye, causing the subject to blink. After several trials, the person will blink on hearing tone by itself. This kind of habit conditioning is normal in individuals with amnesia. These people retained the eyeblink response for as long as 24 h, even though they did not recognize the test apparatus.

Such examples of habits and skill learning have been used to study subcomponents of procedural memory, such as timing, sequencing, and storing of perceptual-motor associations. Procedural memory is presumed to involve both cortical and subcortical circuits. At the cortical level, procedural memory is assumed to depend significantly upon unimodal sensory systems in posterior cortex, and motor and premotor systems in frontal cortex. At the subcortical level, the cerebellum and basal ganglia appear to be significantly involved in skilled behavior.

Functional imaging studies have provided some additional support for the participation of the basal ganglia in motor skill learning. In one study, participants underwent PET scanning while learning a finger-tapping skill. Comparisons between activations seen during initial stages of learning and skilled performance revealed reductions in basal ganglia activation over the course of learning, perhaps reflecting increased processing efficiency. Changes in activation over the course of motor skill learning have also been observed in motor cortex, somatosensory processing areas of thalamus and cortex, and the cerebellum – indeed, in all areas thought to be involved in sensorimotor behavior. These findings suggest that the products of skill learning are represented in widely distributed networks involving many, if not all, of the brain areas that contribute to performance of the skill.

CONCLUSION

Findings from both neurological patients and neuroimaging studies have suggested that certain brain regions contribute to human memory. The medial temporal cortex is essential for the learning of new information. People with organic amnesia following damage to this brain region have difficulty learning new episodic and semantic information. Conceptually, the medial temporal cortex appears to be involved in relational binding, which enables new information to be linked or associated with existing knowledge. The prefrontal cortex is critical for the selection and control of activated memories. The notion of executive control is used to describe the role of the prefrontal cortex in activating memories.

We know less about the manner in which memories are actually stored. Cognitive scientists suggest that memories are stored as a widely distributed network of knowledge. Neuroimaging studies suggest that our memories are not simply abstract concepts but are instead stored with respect to the way they were encoded and used. Thus, some memories are tied to sensory processes whereas others are tied to motor functions. Moreover, procedural memory appears to be represented in a different manner from episodic or semantic memory. That is, our memory for skills and habits is less available to conscious awareness and appears to be represented as the tuning of associations between sensory and motor functions.

Based on this analysis, cognitive neuroscience provides a useful framework in which to conceptualize the intricacies of human memory. It has been possible to identify components of memory function, such as relational binding, working

memory, episodic memory, semantic memory, and procedural memory. Just as one component of an automobile, such as the engine or transmission system, cannot completely define its working, it is impossible to identify one component or region of the brain that completely defines the workings of human memory. It is the interplay of these components that provides us with the rich and seemingly endless experience of memories.

Neural Correlates of Consciousness as State and Trait

Intermediate article

Petra Stoerig, Heinrich-Heine-University, Düsseldorf, Germany

CONTENTS

INTRODUCTION

Consciousness, filed as 'unmentionable' for many decades, 'both the most obvious and the most mysterious feature of our minds' (Gregory, 1987, p. 160), came back into the scientific arena with a vengeance in the 1990s. As there is still no accepted scientific definition in sight, the general definition has been circumscribed as what you lose when you become comatose or anesthetized, and what you regain upon recovery (Searle, 1992). In this sense it is a state of an organism, and by studying the differences between conscious and unconscious states, insights into the neuronal basis of consciousness, as well as its function(s), can be gained.

If all losses of consciousness were to result from damage to the same structures of the central nervous system (CNS), one could regard these structures as hypothetical correlates of conscious states. The alternative view, which regards consciousness as an emergent property of the overall activity of the brain, could then be relegated to the back burner. However, 'consciousness' is not only a state of an organism, it is also a trait of a perception, a thought, a wish, a memory or an intention. How does the brain effect this 'consciousness of something'? How does it effect the conscious representation of one piece of information but not another at any one point in time? Do particular macroscopic structures of the CNS (nuclei, pathways, cortical areas) need to be activated? Or is consciousness an emergent property of particular CNS functions? Does it entail coherent patterns of activation, possibly involving recurrent loops between cortical areas? Since, in order to have consciousness of anything, the organism needs to be in a conscious state, should the neural correlate of conscious representations involve the same substrate as the conscious state, or a different one, or an interaction between the two? Or is any neuronal pattern in principle accessible to conscious representation so long as the organism is in a conscious state?

This article will deal with empirical findings that bear on these questions, focusing on consciousness in these two senses of the term, namely conscious as opposed to unconscious (as an attribute of an organism), and conscious as opposed to implicit (as an attribute of a representation).

CONSCIOUSNESS AS A STATE OF ORGANISMS

Consciousness is a graded state, with levels ranging from somnolent and drowsy to alert and hyperactive. These correlate with different levels of perceptiveness and attention, speed and complexity of behavior, and electroencephalographic (EEG) activity (which is of lower amplitude and higher frequency the more awake the subject) (Moruzzi and Magoun, 1949). A characteristic feature that may help to target the system that regulates the state of consciousness is its lack of specificity: an organism is conscious regardless of the specific content of that consciousness.

Coma and Vegetative State

Of the unconscious states, the rarest and least reversible is that of coma, which can result from toxic, metabolic, degenerative, vascular, or traumatic causes. It probably comes closest to what most people intuit unconsciousness to be – something akin to a state of deepest sleep. Reflexes such as the pupil light reflex may be present, flexor or

tensor muscle activity is absent, verbal behavior (if present) is restricted to grunts, and brain metabolism is reduced by approximately 50%. If the coma does not end in recovery or death, it develops into a more or less persistent vegetative state (PVS) (Jennett and Plum, 1972). This state differs markedly from coma in that the sleep–wake cycle is resumed, and during the waking phases the eyes open spontaneously and in response to stimulation. In addition, the patients may move limbs, grimace, smile, cry, utter words, and briefly follow a moving object with gaze or head. Although overall brain metabolism is still as reduced as in coma, islands of relatively preserved functional cortical tissue have recently been found using brain imaging techniques (Menon *et al*., 1998; Schiff *et al*., 1999, 2002). If in contrast to the 'locked-in syndrome' in which the patient is conscious but, due to paralysis, almost incapable of expressing him- or herself, the patient in the vegetative state is indeed fully unconscious, then it follows that wakefulness is not sufficient for consciousness.

It is still uncertain whether, despite the wide range of pathology that causes coma or PVS, a common anatomical substrate exists that needs to be impaired for consciousness to be abolished. On the one hand, very widespread cortical degeneration as well as diencephalic, mesencephalic, and brainstem lesions may all cause loss of consciousness (Plum and Posner, 1980). On the other hand, massive bilateral lesions of the frontal, temporal, parietal, or occipital lobes do not cause unconsciousness (Bogen, 1997), nor does even a very extensive hemispherectomy (Austin and Grant, 1955). Therefore the substrate necessary for consciousness cannot reside in any one pair of the cortical lobes, and must be present in both hemispheres.

The major contenders at present differ primarily in their delineation. The wider concept (Penfield, 1938) postulates a centrencephalic network consisting of the ascending reticular activating system (ARAS) of the brainstem, the diencephalic nuclei that it targets, and the diffuse thalamocortico-thalamic projections that it receives. The narrower hypothesis focuses on the nonspecific thalamic nuclei, specifically the intralaminar nuclei of the thalamus (ILN) (Bogen, 1995, 1997). The latter theory has gained some support from the neuropathological findings in the famous PVS case of Karen Ann Quinlan which, despite the common widespread lesions that develop in the course of longlasting vegetative states, showed disproportionately dense bilateral destruction of the thalamus (Kinney *et al*., 1994).

Anesthesia

It was only very recently that general anesthesia was first reported to target these same structures preferentially. Previously, a homogenous overall reduction in brain metabolism was regarded as characteristic of the anesthetized state (Alkire *et al*., 1995). However, analysis of functional brain imaging data recorded under widely used anesthetics (isoflurane, halothane, and propofol) has revealed a disproportionate deactivation in both narcotic-specific and (at least for the small number of substances tested so far) narcotic-independent foci of selective depression (Fiset *et al*., 1999; Alkire *et al*., 2000). In addition to frontoparietal structures, the latter include the thalamus, forging the first link between anesthetically and pathologically induced unconsciousness.

Sleep

The neuroanatomy of dreamless sleep which is often counted among the unconscious states (e.g. Rees *et al*., 2002), involves the ARAS of the brainstem, the pontine nuclei, the locus coeruleus, the raphe, and the dorsal tegmental nuclei (Moruzzi and Magoun, 1949; Hobson and Steriade, 1986). Neurons within these structures defacilitate thalamic neurons (Steriade and McCarley, 1990) and, via the reticular thalamic nucleus (RTN) that mediates between the thalamus and the cortex, entrain the thalamocorticothalamic network into the spindle and delta rhythmicity that is expressed in the spontaneous EEG characteristics of sleep stages 2 and 3–4, respectively (Steriade *et al*., 1994). In contrast, rapid eye movements occur predominantly in stages characterized by a low-amplitude, high-frequency EEG resembling the waking pattern, the 'REM' phases. As dreams are reported more often when subjects are woken during REM rather than non-REM sleep, neuroimaging studies revealing a regional decrease in the thalamus during slow-wave sleep (SWS) that covaried with the delta activity simultaneously recorded for sleep-stage assessment (Maquet *et al*., 1990, 1992) again point to a central role for the thalamus in regulating the level of consciousness. However, dreams and other more thought-like forms of mentation have also been sufficiently often reported by subjects woken from non-REM sleep (Foulkes, 1962; Bosinelli, 1995) to forbid a simple equation of SWS with an unconscious state; indeed, any differences between dream and non-dream sleep may thus be obscured. After all, getting a dream report necessitates waking the subject, which abolishes the

sleeping state one would like to study, and relegates whatever mentation may have occurred before to memory, which in turn may be differentially affected by different sleep stages. In view of these unsolved methodological issues, it is in fact uncertain whether any truly unconscious phases are part of normal sleep at all. Even if sleep entailed a switch more in what one can be conscious of than in whether one is conscious, it is still noteworthy that, like the vegetative states and anesthesia, SWS appears to be associated with disproportionate deactivation of thalamic and dorsal brainstem structures. (*See* **Sleep and Dreaming**)

CONSCIOUSNESS AS AN ATTRIBUTE OF REPRESENTATIONS

Loss of a conscious representation can be induced in conscious organisms either by non-invasive experimental manipulation, or following lesions in the central nervous system. The advantage of the former approach is that pathology does not interfere with the conclusions that can be drawn from the results, but this is balanced by two disadvantages. First, the effects are transitory, and secondly, the differences in the neuronal activation patterns are difficult to assess. The reverse is true for the neuropsychological approach. Here the lesion prevents the conscious representation permanently, allowing extensive prompting of the implicit faculties remaining in its absence. However, conclusions about the neuronal basis are restricted by the fact that a CNS lesion that causes loss of a conscious representation both anatomically and functionally also affects neurons that are distant from the lesion itself and/or unrelated to the loss.

To date, the majority of both types of study have concentrated on the visual system, but the findings agree with those obtained from other modalities.

There are several types of experimental manipulation that transiently block a particular conscious visual representation. In visual masking, a second stimulus is presented in close temporal conjunction with the target (Alpern, 1953; Breitmeyer, 1984), or a transcranial magnetic impulse is applied (Amassian *et al*., 1989). In change blindness, there is an impaired capacity to detect the position or identity of a changing item in a complex visual pattern when the original and altered image are successively presented and separated by brief blanks (Simons and Levin, 1997). In binocular rivalry, two incompatible patterns (e.g. an upward and a downward moving grating) are presented simultaneously, one to each eye, and the observer's perception, instead of fusing the patterns, alternates between them (Blake, 1989). In all of these paradigms, a transient blindness is induced for a stimulus or change that would be easily detected in isolation. How does the manipulation interfere with the processes that are necessary for conscious vision? And how is the neuronal response to unseen targets different from that to seen targets?

Both backward and forward visual masking and binocular rivalry have been amply studied psychophysically and physiologically in order to determine the most effective conditions and learn how the neuronal coding of seen and unseen information may differ. The results of the latter approach show that backward and forward masking stimuli interfere with different aspects of the neuronal response to the masked target in the primary visual cortex (V1). The mask that precedes the target obliterates the early part of the discharge, whereas the mask that follows the target obliterates its late components (Bridgeman, 1980; Macknick and Livingstone, 1998). (*See* **Neural Correlates of Visual Consciousness**)

Neuronal activity both in V1 and in higher extrastriate visual cortical areas has been studied during rivalrous dichoptic stimulation while a monkey behaviorally indicated which pattern it perceived at any one point in time (Logothetis, 1998). The results showed that some neurons responded to their preferred stimulus only when the monkey reported seeing it (although it was always present), while others responded independently of the perceptual status. Interestingly, the proportion of neurons that followed the percept increased markedly from V1/V2 (*c*. 20%), to high extrastriate visual cortical areas in the temporal lobe (90%). This increase may indicate that the higher the visual cortical area, the more its activity reflects what the animal is aware of. But why do some neurons in earlier areas already follow the percept? Do they decide what will happen at the later stages? Or do they receive the output of the higher areas via re-entrant connections?

The latter possibility is more consistent with recent functional magnetic resonance imaging (fMRI) data which demonstrate that activity in areas V1, V2, and V3 covaries with the percept when stimuli that differ in contrast and are thus tuned to the properties of the early areas are used (Polonsky *et al*., 2000). The cause of the characteristic time course of the perceptual switch, which is approximately of the order of 1–3 s, was addressed in an fMRI study that compared activity during rivalry with that seen during successive presentation of the same stimuli, mimicking the rivalry percept. The results revealed that only

frontoparietal areas in the right hemisphere responded preferentially in the rivalrous condition, which suggests that the perceptual switch may be initiated outside the visual system proper (Lumer *et al*., 1998). The view that awareness may be mediated by a special module outside the visual system, and not by particular types of neuronal response patterns within it, is also championed by Crick and Koch (1998). Like J. H. Jackson (Taylor *et al*., 1931), they focus on prefrontal areas, surmising that sensory awareness needs to be directly accessible to executive functions.

However, even if that is indeed the major purpose of conscious representations, neuropsychological evidence demonstrates that while frontal lesions can impair the appropriate use of consciously represented information, it is only destruction of the primary retino–geniculo–striate cortical visual system that causes blindness (e.g., Wilbrand and Sänger, 1900). Neither circumscribed prefrontal lesions (complete destruction of both prefrontal lobes has not been reported, and would impair a multitude of cognitive and executive operations) nor lesions confined to higher visual cortical areas cause a loss of conscious vision. The latter type of lesion instead affects selective aspects of conscious vision. Destruction of the cortical color complex causes cerebral color blindness (Meadows, 1974), lesions in the human motion complex cause motion perception deficits (Zeki, 1991), and extensive damage that predominantly affects the higher occipitotemporal areas produces the visual agnosias (inability to recognize objects, faces or scenes as what they are or mean) (Benson and Greenberg, 1969; Grüsser and Landis, 1991). Conscious phenomenal vision (the ability to see color and brightness), although impaired in these conditions, remains so long as the lesion does not completely disconnect the higher cortical areas from areas V1 and V2. The intrinsic architecture of conscious vision that is expressed in the way in which the deficits map on to the lesioned areas (Stoerig, 1996), together with the loss of conscious vision caused by V1/V2 damage (although higher extrastriate areas can still be activated via non-geniculo-striate cortical pathways), points to a pivotal role for V1 and V2. Whether this is due to their providing a necessary input, to their receiving the results of the processing in higher areas via reentrant projections, and/or to their allowing the establishment of reverberating inter-areal circuits is still unknown.

These possibilities relate to computational aspects of the neuronal processing that mediates awareness (Cariani, 2000; Atkinson *et al*., 2000). What structures are involved in the process of making neural information conscious is one question, and whether neurons in these structures need to fire or interact with others in a particular fashion is another. Synchronization of neuronal firing in neurons that code for similar features or objects (Singer, 2000), stability (O'Brien and Opie, 1999) or strength (Greenfield, 1995) of responses, and the duration of the spike train may have important roles.

The latter was demonstrated in a pioneering series of experiments on human subjects performed by Libet *et al*. (1964). These researchers studied the time period required for peripherally and (via electrodes applied to the subject's brain) centrally applied electrical stimulation to evoke a reportable sensation. They found this duration to be at least 100 ms, a value that could increase to several hundred milliseconds with low-intensity stimuli. Although these findings could be seen to indicate that the duration of the spike train is more important than the type or position of the stimulated neuron (so that if the timing was right, any neuron could contribute to conscious experience), the fact that a very large proportion of neuronal processing is in principle inaccessible to direct conscious representation renders this possibility unlikely. The regulation of our hormonal status, blood sugar level, digestion, and sleep, and also the concerted action of the muscles that underlie our every action, are not consciously representable. This indicates that a combination of anatomical and computational features is ultimately more likely to explain the way in which information is consciously represented.

CONSCIOUSNESS AS STATE AND TRAIT

Implicit Functions in the Absence of Consciousness

To a varying degree, information can be processed in unconscious states. Comatose patients may show reflexive responses. PVS patients may, in response to sensory stimulation, show regional increases in cerebral bloodflow which reflect the particular rudimentary behavior patterns that these patients exhibit (Menon *et al*., 1998; Schiff *et al*., 1999, 2000). Anesthetized subjects who are presented with lists of spoken words via headphones during surgery may score well above the levels expected by chance in postoperative tests of implicit recognition (Andrade, 1995; Bonebakker *et al*., 1996). It is common knowledge that information is also processed during sleep. Examples of this include the

phenomenon of sudden awakening in response to small sounds of distress from one's child, while sleep continues undisturbed by much louder but irrelevant noises on the street outside. External information is also processed during sleepwalking and other forms of sleep activity, which include sensory-guided navigation and fixed-action patterns such as walking and eating. As pointed out earlier, proof that normal sleep is unconscious is still outstanding, and it is safer to assume that this kind of complex behavior occurs in altered states of consciousness rather than in its absence.

More evidence for information processing in the absence of a conscious representation comes from studies of conscious subjects who were rendered incapable of seeing a stimulus either by an experimental manipulation or because of a circumscribed visuocortical lesion. Using forced-choice procedures that make the subject guess whether or not they are or have previously been confronted with a stimulus, and indirect procedures, such as the measurement of reaction times as a function of presenting unseen stimuli in addition to seen ones, evidence has been found for the processing of information that is neuronally but not consciously represented. Examples from neuropsychology show that prosopagnosic patients respond differently to familiar and unfamiliar faces (Bruyer *et al*., 1983), colorblind patients can see borders or movement, although these features are defined solely by 'unseen' chromatic information (Heywood *et al*., 1991), and patients with fields of cortical blindness can guess the presence, position, and identity of stimuli in their blind field.

The latter phenomenon, termed 'blindsight' (Weiskrantz *et al*., 1974), is one of the best-known examples of implicit functions. It demonstrates that a visual input processed in the extra-geniculostriate cortical system can be put to behavioral use even when it is not consciously represented (Stoerig and Cowey, 1997). Whether the dissociation between visually guided responses and consciously acknowledged vision that characterizes 'blindsight' also occurs in monkeys with hemianopia due to unilateral V1/V2 lesions has been tested using a combination of two forced-choice paradigms (Cowey and Stoerig, 1995). In a first step, the monkeys learned to almost perfectly localize targets in their blind field, as was expected from extensive previous research (Weiskrantz and Cowey, 1970; Pasik and Pasik, 1982). In order to then 'ask' them whether they had seen the targets to which they had responded (something that is usually done verbally with human subjects), in addition to localizing a target wherever it had appeared by pressing its position, as before, they had to respond to newly introduced blank trials by pressing a no-stimulus response area on the monitor whenever no stimulus was given under otherwise identical conditions. Once they had mastered this new signal detection task in their normal visual field, stimuli that they could localize well in the blind field were presented there, interspersed with blanks and stimuli in the normal hemifield, in order to determine whether they would touch them or whether they would touch the no-stimulus field instead. As they consistently chose the latter option, it seems that monkeys also have blindsight, and not some type of reduced but conscious vision in their visual field defects (Stoerig *et al*., 2002).

Consciousness in Animals

The results obtained for blindsight in monkeys suggest that they, like humans, lose conscious vision when their primary visual cortex is lesioned. They do not show that monkeys normally have conscious vision, but instead they posit that this is the case. The same is true for the experiments on binocular rivalry in monkeys, which do not demonstrate that the stimulus the monkey indicates as seen is indeed consciously represented, but which assume that this is so and then attempt to elucidate the difference in the neuronal processing of the dominant and suppressed stimuli. Old World monkeys in particular have a visual system whose function and architecture are very similar to ours. Although this does not prove that they have conscious vision, it makes it likely for those who assume that conscious vision is but one of the functions performed by the system.

Studies that explicitly address the question of consciousness in animals have largely focused on demanding cognitive tasks, and then discussed whether the ample evidence for communication, scheming, planning, and abstracting thus revealed is sufficient to allow the conclusion that their subjects need to be conscious of the task at hand (Griffin, 1976; Ristau, 1991). It is obvious that the answer will depend on what one takes the function of consciousness to be; if it had none, obviously every cognitive task could be solved without consciousness ('Zombie-hypothesis'); if it was necessary for creative problem solving, then all animals capable of complex behavior need it (Stamp Dawkins, 1998). As all consciousness *of* requires the organism to be in a conscious state, and mammals, birds, fish, and even insects lose consciousness just like humans as a result of appropriate brain lesions or under general anesthesia, it seems

straightforward to assume that they are conscious when brain-normal and not anesthetized; after all, this reasonable assumption is the rationale for using general anesthesia during surgery on animals. What they are or can be conscious of when in a conscious state should depend on their sensorium as well as their capacity to deal with the information in terms of planning, memorizing, problem-solving, abstraction, attribution, enjoyment, and so on. Animals whose sensorium includes echolocation and sideline organs will have sensations that we cannot imagine, but this in no way precludes the sensation's conscious representation. In view of the limited behavioral repertoire that we see in our unconscious conspecifics, animals that are able to communicate and respond to challenges in a creative manner are very likely to be conscious in both senses of the term.

It seems obvious that an organism needs to be in a conscious state in order to be conscious of anything, but the reverse dependence – that is, the state depending on a conscious content of whatever denomination – appears to be less certain. However, the effects first on content (in the form of hallucinations), and later on the conscious state, caused by both sensory deprivation and the anesthetic ketamine may indeed be indicative of an interdependence. If the state and content of consciousness were indeed mutually interdependent, the function of the specific systems that furnish the content would depend on the nonspecific system mediating the state, and equally the nonspecific system's function would depend on some specific system's ability to produce a conscious sensation. Evidence for such interaction (e.g., between the ILN and the reticular formation on the one hand, and specific thalamic and cortical responses on the other hand) shows that stimulation of nonspecific nuclei has a substantial influence on the processing of sensory information (Jasper, 1949; Munk *et al*., 1996). Furthermore, recent research has revealed that nonspecific and specific neurons are quite intermingled, and do not respect the traditional boundaries of the nuclei that are attributed to one or the other system (Jones, 1998), suggesting that interaction between the specific and nonspecific systems is much more common than was previously suspected.

CONCLUSION

Consciousness is a state that is lost in coma and general anesthesia, and altered in sleep. It enables the organism to have conscious experiences, communicate purposefully, and respond in a novel, adaptive fashion to unexpected events. In mammals, it appears to be mediated by a nonspecific system of neurons distributed in the brainstem, thalamus, and cortex, which interacts with the specific systems that mediate the content of consciousness. Thalamocortical structures are currently the most likely site both for making the conscious representation (visual or otherwise) and for the interaction between the systems. To date, the evidence indicates that the correlate of an individual conscious representation consists of a network of activated neurons which may require a minimum number of participants, a minimum duration, and a cortical component with a minimum level of activation and complexity.

CONTENTS

As adult neurons generally do not divide, dysregulation or unwanted induction of apoptosis at an adult stage can have dramatic consequences for brain function.

INTRODUCTION

During the early development of the central nervous system (CNS), new cell generation and cell division are widespread phenomena. Notably, they often occur in close association with massive cell death. Many of the initially generated cells extend protrusions into their surroundings which contain growth cones; these structures enable subsequent nerve fiber migration by which new cells search for contacts with protrusions from other cells close by. Competition for growth promoting factors (neurotrophins), which are secreted by the target cells, eventually determine the establishment and maintenance of functional neuronal connections. In this way, a myriad of interconnected neurons is formed which is the basis for our brain.

It is during this phase of extensive migration that many of the immature cells either fail to make contact, or establish nonfunctional, unwanted connections. These cells are rapidly eliminated by activation of an intrinsic death program present in every cell, which kills the cell in a well-controlled and orderly manner. This cellular 'suicide' consists of various intermediate steps and is known as 'programmed cell death'. Its morphological appearance is referred to as 'apoptosis', which is different from the more passive, necrotic type of cell death, both of which are discussed below.

A neuron's chance of survival during development depends on the extent of its connections, the neurotrophic support it receives from other neurons and glia cells, and in adulthood, also on the presence of steroid hormones.

ROUTES OF NEURODEGENERATION: APOPTOSIS AND NECROSIS

Traditionally, a cell anywhere in the body had only two ways to die: through apoptosis or necrosis. For over 125 years 'necrosis' was the main term used to describe pathological degeneration such as that following physical injury (i.e. cell 'murder'). This usually involved the death of large groups of cells within a specific region. Necrosis is characterized by initial swelling of the cell, modest condensation of the deoxyribonucleic acid (DNA), occurrence of holes, or vacuoles, in the cytoplasm, breakdown of cell organelles, and rupture of the outer cell membrane. This causes the release of cellular contents in the space surrounding the neurons and often elicits a local inflammatory response.

Although apoptosis (the name is derived from an ancient Greek term for the seasonal dropping of leaves from trees) was recognized in 1885, when specific morphological alterations were observed during egg development, the process went relatively unnoticed for decades. Only in the early 1970s, when apoptosis was described in extensive detail and in relation to pathology, did the term became widely adopted. Subsequently, in the early 1990s, specific histological techniques (*in situ* end labeling, ISEL) were developed that allowed identification of dying cells in tissue sections. Together with the clarification of the molecular pathways of the apoptotic cascade, this has greatly facilitated the study of apoptosis in various disciplines, such as development, immunology, oncology and neurodegeneration.

Apoptosis denotes a 'suicidal' type of cell death that involves the sporadic and self-chosen loss of primarily individual cells, without any tissue inflammation. Although preparation for apoptosis may take days, the actual execution is rapid and

dying cells are detectable only for minutes to hours. Consequently, if massive loss occurs over a few days, only a small minority (< 1%) of apoptotic cells will be visible at any one moment. The chance of 'trapping' ongoing apoptosis in thin tissue sections, taken for example from a person with a chronic brain disorder, is hence very low. This may explain why the magnitude and importance of apoptosis in many conditions has gone unnoticed for so long. Necrosis received much more attention because it was present in larger quantities and for longer periods of time, and hence was more easily detectable in tissue.

An additional feature that distinguishes the two types of cell death is their pattern of DNA fragmentation. The highly condensed and supercoiled DNA that is wrapped around specific nuclear proteins, the nucleosomes, is fragmented during apoptosis. This DNA fragmentation involves the activation of specific enzymes that cut DNA particularly between these nucleosomes. This gives rise to characteristic DNA fragment sizes that are multiples of 200 base pairs, i.e fragments of 400, 600, 800 bp and so on. When separated on agarose gels these produce characteristic DNA 'ladders', whereas in necrosis a 'smear' is found, due to the presence of randomly cut DNA which yields all kinds of different fragment sizes.

Furthermore, a neuron undergoes extensive structural reorganization during apoptosis as it dismantles its nucleus, membranes and dendrites. Under the microscope, the hallmarks of apoptosis are: shrinkage in cellular and nuclear size, membrane blebbing, DNA fragmentation, pycnotic chromatin condensing against the nuclear membrane, and cytoplasmic organelles that remain intact as the cytoplasm and nucleus break up into characteristic apoptotic bodies, which are subsequently cleared by macrophages or neighboring cells (Figure 1). Although initially strictly separate, the morphological distinction between apoptosis and necrosis has gained in nuances over the past years, and intermediate forms also have been observed, with (for example) nuclear enlargement rather than condensation in the very early phase of apoptosis, accompanied by DNA fragmentation.

Initially considered to be 'wasteful', the massive cell death during development is now seen as a fundamental mechanism for controlling cell number. The ability to ablate cells at will is as essential for an organism's survival as the ability to replicate and differentiate them. For example, during brain development, apoptosis eliminates transient brain structures that are only there to support additional cortical layers built on top of them, after which they are no longer needed. As such, apoptosis shapes and sculpts the first structural blueprint of the brain. Moreover, it serves as an important quality control and error correction mechanism, removing cells with inappropriate phenotypes and thus preventing the transmission of genetic errors.

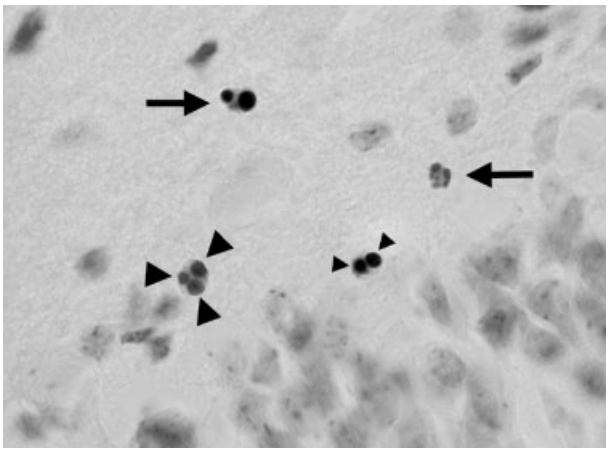

Figure 1. Apoptotic cells (arrowed) in the rat hippocampus. Note the different morphological stages of apoptotic cell death. All include shrinkage in size, dark staining due to *in situ* end labeling, indicating extensive DNA fragmentation, as well as the clear presence of two, three or more apoptotic bodies (arrowheads).

The incidence of apoptosis in the brain rapidly decreases postnatally, making cell death virtually absent in the adult central nervous system, where neuron number, and the network derived from it, remain fairly constant. As adult neurons generally do not divide anymore (with some exceptions), dysregulation or unwanted induction of apoptosis at an adult stage has dramatic consequences for brain function. The underlying molecular mechanisms that control apoptosis appear quite similar in different models and situations. Therefore, knowledge of the factors that regulate developmental apoptosis might improve our understanding of possible ways to attenuate pathological apoptosis in adult neurodegenerative disorders.

MOLECULAR MECHANISMS OF NEURONAL APOPTOSIS

Molecular Mediators

Several gene products have been identified in the pathways that (a) prepare for and (b) eventually execute the apoptotic death of a cell. Initial genetic studies in the worm *Caenorhabditis elegans* have

revealed three genes, *ced-3*, *ced-4* and *ced-9*, whose products were implicated in the developmental cell death in these animals. Later, several mammalian homologs such as interleukin-1 converting enzyme (ICE), with analogous functions, were identified. In contrast, *bcl-2*, a human oncogene overactive in a tumor named follicular lymphoma, was found to block apoptosis. The product of this oncogene, Bcl-2, allows the survival of cells for which death would have been more appropriate, and is therefore generally considered to be a neuronal survival factor. It belongs to a larger protein family with many other members, such as those encoded by *bcl-Xl*, *bcl-Xs*, *bid* and *bax*, each exerting either a specific proapoptotic or antiapoptotic action. The balance between these factors determines whether a cell lives or dies (Figure 2).

This is demonstrated by inducing alterations in specific *bcl-2* family members in a model of neuronal damage. These determine the extent of neuronal death occurring after nerve fiber transsection (axotomy) in a motor system. Increasing the endogenous levels of Bcl-2 reduced motor neuron death after axotomy, as the ratio of Bcl-2 to Bax and other proapoptotic family members is tilted, favoring cell survival. An opposite effect is accomplished in mice lacking the proapoptotic death factor gene *bax*, where approximately 90% of the motor neurons survive the axotomy. This confirms that the balance between specific mediators of the apoptotic cascade strongly influences cell death.

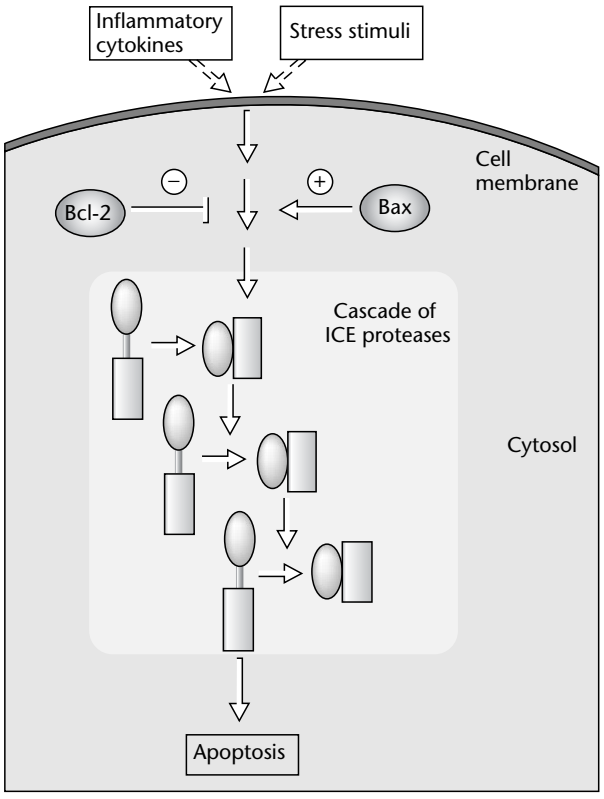

Figure 2. The apoptotic cascade. ICE, interleukin converting enzyme. Redrawn from: Cosulich S and Clarke P (1996) Apoptosis: does stress kill? *Current Biology* **6**: 1586–1588. Copyright 2002, with permission from Elsevier Science.

Apoptosis Signaling Routes

Elucidation of the molecular biology of apoptosis has, so far, revealed a complex suicide program. However, although apoptosis can be triggered by a wide variety of cellular stresses, including DNA damage, ultraviolet radiation, ionizing radiation, heat shock and oxidative stress, as well as by extracellular stimuli acting through activation of specific receptors at the cell surface, most cells undergoing apoptosis go through a similar series of changes that are well conserved across different cell types and models. Interestingly, various apoptotic triggers all converge to activate a single group of enzymes, which cleave their substrates after specific aspartic residues and are named 'caspases'.

All the biochemical and morphological alterations occurring during apoptosis, such as DNA fragmentation, membrane blebbing and the formation of apoptotic bodies, are the direct consequence of the activation of one or more of these caspases. In living cells caspases are generally inactive, but they can be activated by specific death receptors, such as the Fas receptor or tumor necrosis factor (TNF) receptor at the cell surface. The Fas ligand and TNF together form a complex that eventually recruits procaspase 8 in the cell. The subsequent activation of this enzyme activates other downstream caspases, such as caspase 3, caspase 6 and caspase 7, which are involved in the actual execution of cell death.

Another apoptotic route through which caspases can be activated is by the release of cytochrome C (CytC) from the mitochondria. This molecule is involved in electron transfer important for energy metabolism, and is exclusively located in the intermembrane space of mitochondria. During apoptosis, the outer membranes of the mitochondria become permeable to CytC, which can then bind a cytosolic factor called Apaf-1. This CytC–Apaf-1 complex recruits and activates procaspase 9, which in turn activates the downstream caspases 3, 6 and 7. Interestingly, CytC release not only initiates caspase activation, but also disrupts mitochondrial function, diminishing the energy essential for neuronal function and generating more

damaging oxygen species, further contributing to the neurons' demise. The CytC pathway in particular is regulated by various members of the Bcl-2 protein family.

Calcium Signaling

Another signaling mechanism that is particularly relevant to neuronal degeneration involves the redistribution of intracellular calcium ions (Ca^{2+}). Various physiological stimuli increase intracellular Ca^{2+} levels in a transient way. Under pathological stimulation conditions, however, Ca^{2+} levels can become elevated for prolonged periods. Although neurons are equipped with various Ca^{2+} buffering systems, high Ca^{2+} levels increase neuronal vulnerability, reducing neuronal function as well as viability. Extrusion of calcium ions is necessary, yet costly in terms of energy demand. Chronic calcium overload therefore leads to exaggerated energy expenditure. Furthermore, excess calcium ions can activate damaging enzymes that attack the cytoskeleton and DNA. Interestingly, steroid hormones also have an important role in maintaining neuronal Ca^{2+} levels (see below).

APOPTOSIS IN NEURODEGENERATIVE DISEASE

In several human neurodegenerative disorders, neuronal loss is obvious. Not surprisingly, in many of them a causal role for apoptosis has been suspected, either in selected neuronal populations, or in relation to genetic defects affecting the entire brain or spinal cord. An example of the latter is the most severe form of human spinal muscular atrophy, Werdnig–Hoffmann disease. This disorder is caused by an autosomal recessive mutation in a neuronal apoptosis inhibitory protein (NAIP). Under normal conditions this gene product inhibits apoptosis in vertebrate cells. In Werdnig–Hoffmann disease, however, the mutation in this protein induces failure to inhibit apoptosis in early development, and the consequent massive death of motor neurons during the perinatal period results in respiratory failure and death at a young age.

In many other neurodegenerative disorders, aberrant apoptosis is, however, not linked to such a gene mutation. Although end-stage diseased human brain tissue often shows increased expression of apoptosis-associated genes, it is difficult to prove a causal role for apoptosis, owing to its rapid time kinetics, and its probable early occurrence in the disorder. Nevertheless, apoptotic neurodegeneration is also suspected in other systems and disorders as diverse as the spinal cord in amyotrophic lateral sclerosis, the nigrostriatal system in Parkinson disease and the basal ganglia in Huntington disease. Disturbances in memory and higher cognitive functions have been linked to apoptosis, involving brain areas such as the hippocampus and cortex in Parkinson and Huntington disease, acquired immune deficiency syndrome (AIDS) dementia complex, stroke, prion diseases and Alzheimer disease.

Stroke

Stroke or cerebrovascular accident (CVA) is a major cause of death and physical impairment. It can be caused by occlusion, rupture or bleeding of one of the cerebral vessels, resulting in cerebral ischemia. Stroke may be of ischemic or hemorrhagic origin: ischemic CVA is caused by occlusion of one of the major arteries or small perforating vessels, which occurs in 80% of all CVA cases; bleeding from one of the intracerebral or the subarachnoidal arteries results in hemorrhagic CVA. (*See* **Stroke**)

The incidence of stroke is between 150 and 250 per 100 000 persons. This incidence rises sharply with increasing age (up to 2000 per 100 000 in those aged 80 years and over). About 60–80% of people who have suffered a stroke die within 30 days, while of those who survive, many remain disabled. Extensive research is therefore carried out to explore possible therapeutic interventions.

In primates, the normal cerebral blood flow is 50–60 mL per 100 g per minute. Profound reduction of cerebral blood flow (below 10–15 mL min^{-1}) produces rapid neuronal cell death. Importantly, between this ischemic core and the normally perfused brain there is tissue in which blood flow is moderately reduced, which forms a target for acute therapeutic intervention. The amount of blood flow in this zone (the penumbra) depends largely on the collateral blood supply from surrounding arteries. Ultimately, oxygen delivery becomes insufficient in the penumbra to allow normal energy metabolism. This results in lactic acidosis and further reduces the production of the main energy source of ionic pumps, adenosine triphosphate, in turn disturbing the homeostasis of cellular ionic processes, and the ensuing rapid loss of neuronal potassium ions triggers massive depolarization. This opens voltage-sensitive Ca^{2+} channels in the cell wall and leads to a sustained influx of calcium ions (Figure 3).

Prolonged periods of elevated intracellular Ca^{2+} levels can lead to the generation of reactive oxygen species, free radicals. They can cause severe

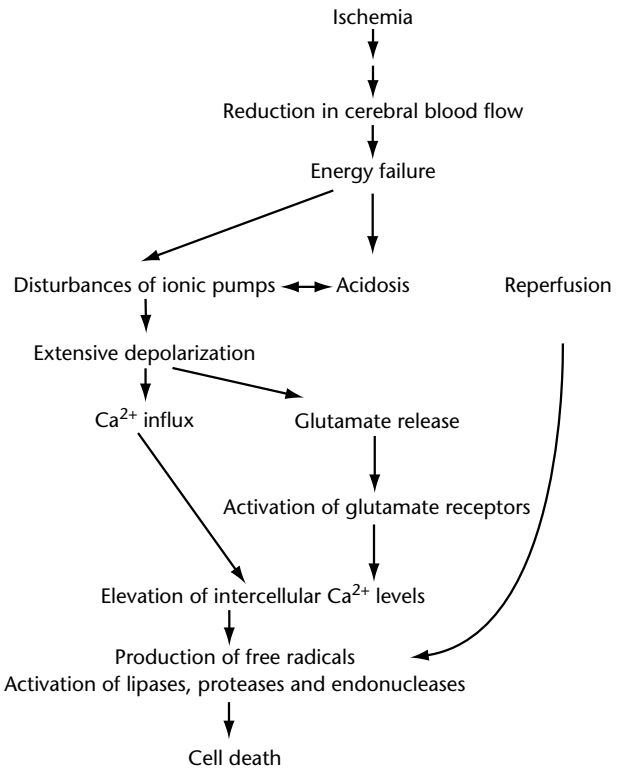

Figure 3. Sequence of events that might ultimately result in neuronal degeneration.

damage to membrane proteins, impairing membrane integrity which results in leakiness to substances that do normally not cross the cellular membrane. A second cytotoxic pathway activated by excessive intracellular Ca^{2+} levels involves Ca^{2+}-dependent phospholipases, proteases and endonucleases, all of which have deleterious consequences for cellular function. After ischemia necrotic cell death is accompanied by apoptosis in the penumbral area. When blood flow is restored (reperfusion), enhanced free radical production may further increase the oxidative damage.

Alzheimer Disease

Alzheimer disease (AD) is a well-known type of progressive dementia with a high incidence in the elderly population. Patients suffer from severe memory and cognitive disturbances, which involve selective neuronal circuits in the neocortex, hippocampus and cholinergic system. Conclusive diagnosis depends on postmortem histopathological findings, on the basis of quantitative rather than qualitative scoring of the main neuropathological hallmarks: these are extracellular (senile) plaques, associated with an amyloid protein, and dystrophic neurites and neurofibrillary tangles composed of an altered cytoskeletal protein, tau. (*See* **Alzheimer Disease**)

The early-onset forms of AD are mostly familial and show an autosomal dominant inheritance pattern. This small group (2–3% of all cases) involves mutations in three identified genes: those encoding the amyloid precursor protein (APP), presenilin 1 (PS-1) and presenilin 2 (PS-2). These mutations all induce an altered processing of APP, which gives rise to aberrant levels of amyloid beta (Aβ) protein. The normal biological function of APP, the presenilins and how they cause AD remains so far elusive, but most PS-1 mutations alter APP processing and increase the relative Aβ levels, which may stimulate apoptosis through oxidative damage or through modulation of apoptosis mediators.

A fourth gene important in AD (*APOE*) encodes apolipoprotein E, which has three isoforms: ε2, ε3 and ε4. Apolipoprotein E is involved in lipid transport in the periphery and has a separate pool in the brain. Epidemiological studies have shown that people with one or two copies of the ε4 allele have increased risks of developing AD earlier and in a more severe form. Another new and interesting aspect to AD is the possible contribution of frame shift mutations at the ribonucleic acid level which can give rise to toxic, or aberrant, proteins.

Early studies *in vitro* pointed to a neurotoxic and primary role for Aβ. This would induce massive cell death, which could explain the considerable weight loss in the brain observed in AD. Indeed, altered expression of apoptosis-related proteins, such as Bax, Bcl-2 and Par-4, has been found in AD brain. The observation in AD of many cells containing fragmented DNA has also been interpreted as evidence for apoptosis. However, necrosis and DNA damage were also detected with these techniques, and so far, no morphologically convincing evidence for apoptosis in AD has been observed.

Detailed morphometric studies have now revealed that cell loss in AD is certainly not massive, but takes place only in a few limited yet important brain areas: the locus coeruleus, the CA1 area of the hippocampus, and layer II of the entorhinal cortex. Specific unbiased counting techniques have failed to demonstrate any difference in total neuron number between the neocortex of control and AD cases. Massive cell loss due to apoptosis is thus unlikely in AD. More and more research contradicts the notion that Aβ is an early and toxic factor in AD; not only is there a poor relation between amyloid deposits and cognition, many studies *in vitro* have even established

growth-promoting capacities of amyloid fragments. Also, in various mouse models in which Aβ levels are increased, learning deficits do indeed occur, but do so months prior to the formation of Aβ deposits, and in absence of massive hippocampal cell loss in most models. This suggests that Aβ is not acutely neurotoxic, and at least not sufficient to cause pathological changes or apoptosis in AD on its own. The considerable weight loss is now attributed to atrophy and shrinkage of neurons rather than to neuronal loss.

HORMONAL CONTROL OF NEURONAL APOPTOSIS

Hormones, in particular steroid hormones, affect various processes in the brain, such as learning and memory, and notably also neuronal viability. In the adult vertebrate nervous system there are several examples of steroid-related neural degeneration. One example is the seasonal turnover of specific neuronal populations in the adult canary brain. These populations are considered to be a neural substrate for learning specific song patterns. During spring, when circulating levels of testosterone are highest, canaries sing frequently and the turnover rate of projection neurons in the song control region – the high vocal center (HVC) – is relatively low. In contrast, in autumn when testosterone levels drop and song patterns are modified, considerable numbers of older neurons in the HVC die, in parallel with incorporation of new neurons into the HVC.

In another example, steroids have been shown to be crucial for neuronal viability and function in the adult rat. This is apparent in the hippocampus, a brain structure involved in learning and memory. In intact animals, the steroid hormone corticosterone (Cort) is released from the adrenal gland in response to stress. Cort readily occupies two types of nuclear receptors which are present in large densities in the hippocampus and brain: the high-affinity mineralocorticoid receptor (MR) and the lower-affinity glucocorticoid receptor (GR). Owing to the difference in affinity the MR is almost always occupied, whereas the GR is only occupied during stress. Upon binding of Cort, the ligand–receptor complex translocates to the nucleus, where it binds to DNA and interferes with gene transcription for prolonged periods. After a rise in Cort, hormone binding in the brain causes adrenal Cort production to shut off again. This feedback inhibition of the stress system helps maintain Cort levels within physiological boundaries: this is important as both too high and too low corticosterone levels affect neuronal viability. Depletion of Cort by removing the adrenal glands induces massive apoptosis in the hippocampus three days later (Figure 1). This apoptotic cell loss directly affects hippocampal function and memory and, interestingly, can be completely prevented by replacing adrenalectomized animals with low levels of Cort just sufficient to occupy MR. Cort and MR are thus essential for neuronal survival in the rat hippocampus. (*See* **Hippocampus**; **Apraxia**)

Over-exposure to steroids too can affect neuronal function and viability. As the hippocampus exerts an (indirect) inhibitory control on Cort secretion, hippocampal damage or cell loss can disrupt the feedback inhibition and induce a feedforward cascade of cumulative hormone exposure. In rat, prolonged stress or overexposure to Cort impairs memory and learning as well as electrical activity of the hippocampus. Also, transient (but still reversible) atrophy of neurons is induced. Following prolonged Cort exposure, even massive neuronal loss has been reported, in rat and monkey hippocampus in some but certainly not all studies. This suggested that chronic stress or steroid overexposure kills neurons through apoptosis. This seemed relevant to human aging and AD, where the extent of hippocampal atrophy and disease correlate well with the moderately elevated Cort plasma levels.

A human condition even more relevant for steroid overexposure is major depression, in which plasma levels of cortisol and other indications of enhanced stress axis activity are much more pronounced – indeed, decreased hippocampal volume and adrenal enlargement are commonly observed. Hence, hippocampal damage would be expected. However, little (if any) neuropathological change, or evidence of massive cell death could be found in the hippocampus of people with major depressive disorder or steroid-treated patients. This agrees with the general clinical experience of depression, that treatment can relieve both the depressive symptoms and hippocampal atrophy, which would be unlikely if many cells had indeed been lost. In conclusion, although hippocampal function can certainly be affected by steroid overexposure, hippocampal structure shows reversible and adaptive rather than neurotoxic phenomena, particularly in the case of primates, including humans. (*See* **Affective Disorders: Depression and Mania**)

Modulation of Ischemic Neurodegeneration by Corticosteroids

Neurological insults such as ischemia activate the hypothalamic–pituitary–adrenal axis, with a

subsequent rise in Cort levels that bind MR and GR in brain. Considerable evidence indicates that Cort increases cellular vulnerability in the hippocampus when combined with additional challenges such as ischemia. This glucocorticoid endangerment potentiates the rise in extracellular glutamate levels after an insult and enhances intracellular Ca^{2+} levels. In contrast, low levels of Cort have been shown to reduce neuronal damage after ischemic insults, promoting neuronal viability.

In animal studies this has stimulated research to assess whether therapeutically relevant interventions might exert neuroprotective actions. Using the steroid synthesis inhibitor metyrapone it was shown that preventing the rise in Cort concentration during or after ischemia reduced neuronal damage and preserved hippocampal function. This was accompanied by attenuation of ischemia-related changes. However, metyrapone is likely to have more effects than reducing Cort levels alone. For example, other steroids with potential neuroprotective actions are found to have elevated levels after treatment with metyrapone. In addition, since activation of GR is considered to enhance neuronal vulnerability, one might speculate that GR antagonists such as RU 38486 would have neuroprotective properties. However, RU 38486 appears to be ineffective *in vivo* in preventing neuronal damage after ischemia. Thus, while elevated corticosteroid levels are generally believed to increase neuronal vulnerability, it is far from clear whether interventions that reduce Cort levels or prevent Cort from binding GR are of therapeutic importance.

CONCLUSION

In at least some neurodegenerative disorders, neuronal apoptosis is likely to be involved. More important than the question of whether or not apoptosis is involved (or detectable) is the question of which factors induce cell death and degeneration. For many conditions this is not known, but may be related to an enhanced vulnerability to triggers of apoptosis, or to a tissue-specific environment that favors apoptosis. However, neither of these have been proved. Also, cell death in postmitotic systems in neurodegenerative progressive disorders may in this respect be different from classic developmental apoptosis.

Steroids can interfere with and modulate the extent of neuronal damage in specific models. However, as yet there is no effective way to prevent neuron loss in neurodegenerative disorders such as stroke and AD, even though several candidate therapeutic agents have been developed based on interference with the apoptotic cascade. However, it is important to realize that these treatments can only be effective when administration is possible at the right time (i.e. early in the disorder) and in the right place (i.e. in a selected brain area), and preferably only when the factors that initially induced cell death (whether intrinsic, like local tissue environment conditions, or extrinsic, like free radicals), have been identified and are no longer operative. Furthermore, systemic inhibition of apoptosis throughout the body, affecting for example the immune system, should for obvious reasons be prevented. As apoptosis outside the adult brain is often highly functional, inhibition might have serious consequences for normal physiology.

Despite considerable progress in the clarification of the mechanisms of programmed cell death, the entire intracellular cascade leading to neuronal death in chronic progressive neurodegenerative disorders remains to be elucidated. Understanding these mechanisms in detail is crucial for the rational development of protective strategies and novel therapies for these devastating disorders.

Neural Development, Models of

Introductory article

Geoffrey J Goodhill, Georgetown University Medical Center, Washington, DC, USA

CONTENTS

Models of neural development attempt to produce precise mathematical and computational descriptions of the biological mechanisms that regulate the formation of the nervous system.

INTRODUCTION

Neural development is the process whereby the nervous system of a developing animal is formed. It involves several stages, each of which is regulated by different types of mechanisms. At each stage a complex interaction of genetic and environmental influences determines the final outcome. The effect of the environment becomes especially important in later stages of development, so that the mature nervous system is specifically adapted to the environment in which it must survive. Mathematical/computational models (hereafter referred to as 'models') have been formulated for several stages of development. As with all modeling, the goal is to take qualitative hypotheses about possible mechanisms and make them quantitatively precise. This rigorously defines the conditions under which such qualitative hypotheses are indeed plausible candidate mechanisms, and makes explicit the implicit assumptions that often underlie them. A desirable result of such modeling is that it makes novel and testable predictions about the outcome of experiments.

Neural development can be conceptually divided into four stages, although they overlap temporally to some degree. These stages are neural induction and neural-tube formation, pattern formation and regionalization, establishment of connectivity, and activity-dependent refinement of connections. The majority of modeling research has concentrated on the last of these stages, attempting to understand the principles by which connection strengths between neurons are adjusted in response to specific patterns of neural activity from the sense organs. This article will consider these stages sequentially.

NEURAL INDUCTION AND NEURAL-TUBE FORMATION

The first stage of neural development is the specification of neural ectoderm by the notochord, which occurs within the first few weeks of gestation in humans. This region, which is called the neural plate, then folds in on itself to form the neural tube. The neural tube gives rise to the peripheral and central nervous systems. As the neural folds come together to form the neural tube, neural-crest cells migrate from the neural folds away from the neural tube. The neural crest forms the peripheral nervous system, while the rest of the neural tube forms the central nervous system. The molecular interactions that lead to the specification of one region of the gastrula as the neural plate have been extensively investigated experimentally. Diffusion of certain molecules from the organizer region is crucial, and mathematical modeling of diffusion processes in general is very well understood. However, application in this area is complicated by the fact that these molecules may be transported by mechanisms other than free diffusion. Furthermore, as yet there are virtually no models of the mechanical forces that drive the formation of the neural tube.

PATTERN FORMATION

In the second stage of neural development, the neural tube expands and changes shape as new cells are generated and migrate to new locations. In conjunction with this, certain regions start to become specialized for particular fates. Moving from anterior to posterior, boundaries begin to form between the prosencephalon (embryonic forebrain), mesencephalon (embryonic midbrain) and rhombencephalon (embryonic hindbrain). Further subdivisions then occur as the prosencephalon divides into the telencephalon and diencephalon, and the rhombencephalon divides into the

metencephalon and myelencephalon. Within these general regions discrete structures are constructed, such as the hippocampus and cerebrum from the telencephalon, the retina and thalamus from the diencephalon, and the cerebellum and pons from the metencephalon. The main question that modeling can attempt to address at this stage of development is how such a spatially non-uniform structure can emerge from an apparently spatially uniform tube.

Reaction–Diffusion Systems

One way to approach this question is to treat it as a very general one. Pattern formation occurs in many other biological systems, such as the spatially regular pattern in which leaves are added to a plant stem, and the division of a fly embryo into individual body segments. In fact, evolutionary conservation of genetic programs has led to some of the same genes controlling regionalization of the nervous system as control fly body segment formation. Pattern formation has also been studied in many physical systems, such as convection patterns in heated liquids and certain types of chemical reactions. The most influential class of mathematical models in this area has been that of reaction–diffusion systems, first proposed by Turing in 1952 and subsequently developed in specific biological contexts by Meinhardt. The principal assumptions are that cells in an initially spatially uniform array produce several chemicals or 'morphogens' that diffuse at different rates from cell to cell through the array. In its simplest form there is one 'activator' chemical and one 'inhibitor', often called an activator–inhibitor system. The activator diffuses slowly and stimulates its own production, while the inhibitor diffuses more rapidly and suppresses production of the activator. In any real system some noise will be present, which means that each cell in the array will not initially have exactly the same concentrations of morphogen. The activator–inhibitor system amplifies such small fluctuations dramatically, leading to a stable state of regularly spaced regions dominated by either the activator or the inhibitor. This elegant mathematical idea has been developed in numerous ways to model biological pattern formation. One aspect of neural development where such algorithms may operate is the selection of just one cell in a proneural cluster to become a neuroblast. The ligand Delta, operating through its receptor Notch, acts as a lateral inhibitor, so that if one cell is specified as neural, then neighboring cells are inhibited from assuming that fate.

Morphogen Gradients

However, there is no evidence that reaction–diffusion mechanisms underlie the formation of overall regionalization in the embryonic nervous system. Rather than asking how symmetry is broken in a spatially uniform array, the key question seems to be how patterns arise from an initial gradient of some morphogen over the array. This initial polarization is created by the positioning of the egg inside the mother. Wolpert first framed this question in 1969 as the 'French flag' problem, and subsequently discussed how various types of chemical reaction kinetics could transform an initially smoothly varying morphogen concentration into sharply defined regions of different concentrations. The fundamental process by which the nervous system becomes initially regionalized seems to be a biochemical cascade, whereby initial gradients of maternal gene products turn on genes in a concentration-dependent manner, creating gradients of new proteins and so on, to form structure at ever finer levels of detail. One of the first signs of patterning along the anterior–posterior axis of the embryo is the expression of homeobox genes of the Pax family in different regions. These gene products then control the regional expression of other genes. As yet there has been no theoretical research addressing the structure and outcome of these complex networks of interacting proteins in the context of nervous system regionalization. However, some models have recently been proposed for fly segment formation, which may turn out to be relevant to the nervous system of vertebrates as well. In such models, certain gene products are assumed to regulate the expression of other genes in a network, somewhat akin to an artificial neural network with weighted connections. Gene products also diffuse within the embryo. Starting initially with a network of random weights (strength of regulatory influences), the outcome of the developmental process for this network is calculated. Using methods such as gradient descent and simulated annealing, weights are then incrementally updated until the developmental outcome matches that which is seen biologically. These optimal weights represent quantitative predictions of the strengths of the regulatory influences that exist in the real biological system, and predictions can be made about the effect of specific gene deletions.

ESTABLISHMENT OF CONNECTIVITY

The task that is achieved in the third stage of neural development is the establishment of initial patterns

of connectivity between neurons. Structures such as the retina send out axons which navigate through a complex environment to find appropriate targets (e.g. the superior colliculus and lateral geniculate nucleus). On their journey, they often have to make many guidance decisions, where for instance some axons in a group are routed in one direction and other axons are routed in another direction (e.g. the split between axons originating from the nasal and temporal halves of the retina that occurs at the optic chiasm). On reaching the correct target region, both the tip of the axon and the target have to change their structure in order to form a specialized synapse. The principal way in which the growing axon senses its environment is via the growth cone (a specialized structure at its tip). The growth cone continuously extends and retracts thin filopodia which sample the local region. The types of molecular guidance cues that can be detected include pathways of growth-permissive factors (e.g. laminin), barriers of growth-inhibitory factors (e.g. myelin-associated glycoprotein) and concentration gradients of molecules (e.g. netrins and semaphorins) which can be attractive or repulsive. These cues can be bound to or expressed by the substrate, or they can diffuse more or less freely. This type of diffusion process (e.g. from a target region) is one way in which a concentration gradient can be established.

Models of Growth-Cone Guidance

Models have been proposed that address several different types of questions at this stage of development. One class considers the types of gradient shapes that axons might encounter *in vivo* or *in vitro*, and how this shape constrains the maximum distance over which it is possible for an axon to be guided. Such models assume that gradient detection can only occur when two principal constraints are satisfied. First, the absolute concentration of the guidance factor at the growth cone must exceed a certain minimum, and secondly, the fractional change in concentration across the growth cone must exceed a certain steepness. Such models predict that the maximum distance over which a growth cone could be guided *in vivo* is about 1 mm for a target-derived diffusible factor, and about 1 cm for a substrate-bound gradient with shape optimized for maximum guidance length. Both of these are reasonably consistent with experimentally measured values. Another class of models attempts to understand how growth-cone gradient detection is limited by noise. The external ligand gradient causes different numbers of receptors to be bound on one side of the growth cone than the other. However, since receptor binding is a stochastic process, at each instant a small difference from the mean level of binding will be measured. One influential hypothesis has been that the threshold for reliable gradient detection occurs when the average size of these small differences becomes comparable with the true difference in concentration between the two sides of the growth cone. Such models can produce numerical values for growth cones of about 1%, which is similar to experimentally measured values. Another class of models focuses on the role of filopodia in growth-cone guidance. Such models propose rules (usually stochastic) with regard to the way in which filopodia are generated in response to environmental cues. Complete axonal trajectories can then be simulated, and both short-term and filopodial dynamics and overall trajectories can then be compared with reality. The mechanisms whereby a difference in receptor binding is internally amplified to give a turning response toward or away from the direction of higher concentration have not yet been considered for growth cones. This is partly because the signal transduction pathways in the growth cone that cause this response are only how beginning to be revealed experimentally. However, several models which may be applicable have been proposed for analogous signaling pathways in bacteria, white blood cells and slime molds. One hypothesis is that the polarization of a cell in response to the gradient may occur by a similar type of reaction–diffusion mechanism previously described in the context of spatial regionalization.

Retinotectal Map Formation

Perhaps the most popular area for theoretical modeling at this stage of development is the formation of topographic maps. There are numerous examples in the brain, such as the retina and superior colliculus (optic tectum), where the connections between two structures form a continuous map, so that neighboring neurons in one structure connect to neighboring neurons in the target structure. Although, as will be discussed later, neural activity plays an important role in fine-tuning the structure of such maps, their initial formation is probably governed by gradient-directed axon-guidance mechanisms. The basic idea, first proposed by Sperry several decades ago, is that gradients of some molecules in the input structure give each neuron in that structure a unique regional identity. Analogous gradients are postulated to exist in the target structure, and the map forms because each

axon follows the gradients in the target structure to a topographically appropriate location. During the past few years, direct evidence for this type of process has been discovered in the form of gradients of Eph receptors in structures such as the retina, and their ligands (the ephrins) in target structures such as the optic tectum. Starting in the 1970s, theoreticians proposed models that made the qualitative ideas of Sperry and others more precise. An early model suggested that, for retinal and tectal gradients of 'labels' (receptors and ligands) that run in the same direction, all retinal axons seek to connect to tectal regions with the highest level of tectal label. Competition for tectal space ensures that only those retinal axons with the highest available level of retinal label can connect to any particular region. A map forms because the 'best' retinal axons occupy the 'best' regions of tectum, and so on down the line. In more abstract multiple constraint models, systems matching arises as the optimal balance between the opposing forces of competition for tectal space and matching by stable gradients. Other models address retinal axon navigation over a continuous substrate in response to gradients running in opposite directions. In the future it will be important for such models to take into account the rapidly expanding experimental literature on Eph/ephrin gradients and their interactions.

ACTIVITY-DEPENDENT REFINEMENT OF CONNECTIVITY

In the fourth stage of neural development, the initially crude patterns of connections that were established by molecularly based axon-guidance mechanisms are refined by neural activity. Patterns of firing among groups of neurons, generated either internally or by sensory transduction of signals from the environment, help to mold the architecture of the nervous system for optimum matching with the structure of the external world. This process of continued refinement continues throughout life, and it is generally believed that the mechanisms of synaptic plasticity that operate during development are similar to those that govern adult learning. Recently it has also become clear that as well as refinement there is also growth (i.e. the generation of new neurons and new connections), and that this continues throughout life.

Hebbian Learning

The most basic principle of activity-dependent synaptic plasticity is the rule proposed by Hebb in 1949, which can be paraphrased as 'cells that fire together wire together'. That is, the connection between a presynaptic neuron and a postsynaptic neuron is strengthened when their activity is correlated. This is directly illustrated experimentally by the phenomenon of long-term potentiation (LTP). This was first discovered in the hippocampus, but has now also been observed elsewhere (e.g. in the visual cortex). Here synaptic strengths can be increased when an input pathway is strongly stimulated, causing a correlated depolarization of the postsynaptic cell, or when weaker stimulation of the input pathway is paired with direct depolarization of the postsynaptic neuron. A related phenomenon is long-term depression (LTD), where under certain circumstances synaptic strengths can decrease due to a lack of correlation between pre- and postsynaptic activity. Further experimental evidence for Hebbian learning mechanisms comes from the development of the neuromuscular junction and the visual system, which will be discussed below.

Hebb's qualitative statement of his rule can be made mathematically precise in a number of different ways. Each of these versions leads to different outcomes when the same series of input patterns is presented. Since postsynaptic activity is crucial, one important source of variability in the mathematical statements of Hebb is how this activity is calculated as a function of the activity of presynaptic neurons and the strengths of connections ('weights'). One common assumption is that the output is just a linear weighted sum of activities multiplied by weights. The change in the weight vector at each time can often then be expressed as the covariance matrix of the presynaptic input patterns multiplied by the current weight vector. The final weight pattern that then emerges is the principal eigenvector of the covariance matrix. This is computationally useful, since this weight vector is the principal component of the input patterns. This is the direction of maximum variance in the input data, which in one sense is the most 'interesting' projection of the input data.

An alternative common assumption with regard to how the output of postsynpatic neurons is calculated is that some form of nonlinear competition exists between these neurons. This is considered (either explicitly or implicitly) to arise via lateral connections between postsynaptic neurons. In the simplest case this is implemented computationally by a 'winner-takes-all' mechanism, whereby the postsynaptic neuron in the group that has the largest initial activity in response to an input pattern is the only one that has its weights updated. What

tends to emerge from this type of rule is weight vectors that point to the centers of clusters of input points. This is computationally useful since such cluster analysis can help to divide the input patterns into useful categories based on the degree of overlap of different patterns.

In both of these linear and nonlinear cases an important component is often competition in the form of normalization. Since Hebb's rule specifies only increases in synaptic strengths, without some such mechanism for decreasing weights they would all increase without limit. Therefore the total weight impinging on a postsynaptic neuron is often constrained so that when some weights are increased, others are decreased.

The Neuromuscular Junction

One particular process in neural development that has been modeled using Hebbian learning is synaptic elimination at the neuromuscular junction. When growth cones first encounter their targets, molecular signals are passed back and forth which induce the development of the presynaptic and postsynaptic specializations that form a synapse. This has been most extensively studied in the development of synapses of motor neurons on muscle fibers. Initially, several motor neurons contact each muscle fiber (polyneuronal innervation). However, by a process of activity-dependent competition all but one of these connections is eliminated. Several Hebbian-based models of this process have been proposed, and again an important component is normalization. In fixed-resource models, terminals (e.g. measured by synaptic strength or arbor size) compete for a fixed amount of a resource (e.g. total synaptic strength or space). In fixed-rate models, terminals compete for a resource that is generated at a fixed rate (e.g. neurotrophins). In these models a critical variable is the function which describes the dependence of receptor production rate on the amount of neurotrophin that is bound. Such models make testable predictions with regard to experimental perturbations such as a reduction in the supply of neurotrophin or a change in the level of activity.

Visual System Development

Processes of activity-dependent development have been most extensively modeled in the visual system, due to the large amount of experimental data that is available to constrain and inspire theories. As mentioned previously, the map from the retina to the optic tectum is topographic. If neural activity in the retina is blocked, a topographic map forms that is cruder than normal, indicating that activity is important for map refinement. This refinement can be modeled using Hebb-type rules, with two important assumptions. The first assumption is that 'neighborliness' between neurons in the retina is encoded by spatially correlated activity, so that nearby neurons are more highly correlated than more distant neurons. This is true of natural images – the correlation between pixels tends to drop off smoothly with distance. Similar correlations can also be generated earlier in development, before eye opening, by spontaneous activity of retinal neurons in the form of waves or blobs of activity that sweep periodically across the retina. The second assumption is that neighborliness between neurons in the tectum is encoded by lateral connections, so that nearby neurons have stronger connections and are thus more highly correlated than more distant neurons. These connections are often assumed to be in the form of short-range excitation and longer-range inhibition. Although there is some evidence that such connections exist in reality, there is also evidence for longer-range excitatory connections which are patchy rather than spatially uniform.

Another important area of theoretical modeling of activity-dependent processes in the visual system is the development of ocular dominance and orientation columns. In the adult visual cortex of mammals such as cats and monkeys, a beautiful mosaic pattern of varying response properties is seen. Each neuron responds better to an input in one eye than to one in the other eye, and to an edge or bar of light at a specific orientation angle within its receptive field. The response properties of nearby neurons mostly vary smoothly as one moves across the surface of the cortex, so that a patch of neurons that prefers one orientation blends into a patch that prefers a similar but slightly different orientation, and there is a smooth variation in preference for one eye compared with the other eye (Figure 1). However, these patterns of stimulus preference are not present in very young animals, and they may emerge by a process of activity-dependent Hebbian learning during development. The evidence for this is particularly strong in the case of ocular dominance columns, since their overall structure can be altered by changing the correlations in the visual stimuli that are seen during the critical period for ocular dominance development. For instance, if one eye is sutured shut early in development, the size of the regions representing that eye in V1 shrink relative to the regions representing the other eye.

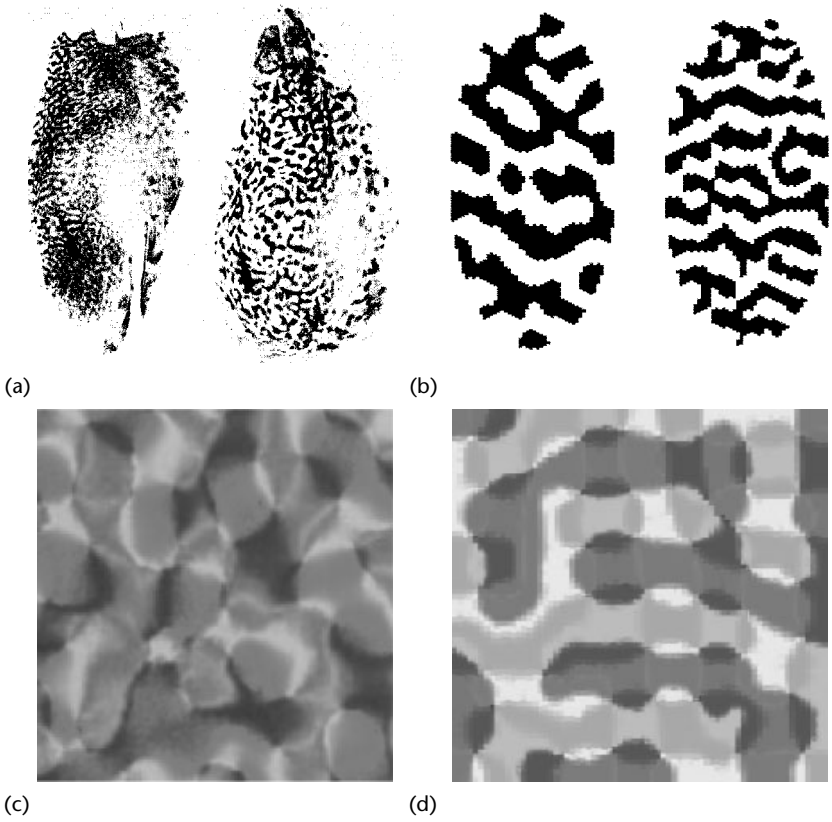

Figure 1. [*Figure is also reproduced in color section*.] (a) The pattern of ocular dominance columns in cat primary visual cortex. Dark patches are those regions of cortex dominated by one eye, and light patches are regions dominated by the other eye. Left: normal cat; right: strabismic cat. Note that columns are wider in the strabismic cat than in the normal cat. (From Löwel (1994) *Journal of Neuroscience* **14**: 7451–7468. Copyright Society for Neuroscience.) (b) Results of the author's analogous simulations using the elastic net algorithm. Left: 'normal' case; right: 'strabismic' case. (c) The orientation map in primary visual cortex of the tree shrew. The different colors represent patches that have different orientation preferences. (From Bosking *et al*. (1997) *Journal of Neuroscience* **17**: 2112–2127. Copyright Society for Neuroscience.) (d) Results of the author's analogous simulation using the elastic net algorithm.

The development of ocular dominance and orientation columns has been modeled by a variety of different versions of Hebbian learning. Three of the most important classes of models are high-dimensional, low-dimensional and filtering models. In high-dimensional models there is an explicit representation of each neuron (or each small group of neurons) in both the cortex and input layers (retina and/or lateral geniculate nucleus), and of all of the connections between layers. Patterns of stimulation are presented to the retina representing images either from the environment or generated by spontaneous activity. Activity is propagated to the cortex, and the lateral spread of activity through intracortical connections is taken into account. Weights are then updated by a Hebbian rule. Under appropriate conditions, orientation and ocular dominance columns can emerge in the cortical layer. Some high-dimensional models include hypotheses about the role of neurotrophins in mediating competition between cortical neurons. Low-dimensional models are more abstract, and instead of presenting explicit patterns of pixel intensity they consider that input images can be characterized by a small number of features, such as position in the visual field, orientation and ocular dominance. Each of these features is represented by an orthogonal dimension, and the weights of a cortical neuron now represent the selectivity of that neuron in the low-dimensional space of features. The learning rules can be seen as trading off 'matching' and 'stretching', so that all feature combinations in the input space are represented, while at the same time maximizing the degree to which neighboring cells in the cortex represent similar features. Although such models are more difficult to interpret biologically than high-dimensional models, they can often be more

robust, and they actually tend to produce a better match with the fine structure of real orientation and ocular dominance maps (Figure 1). More abstract still are the filtering models, which essentially repeatedly convolve the cortical layer with a filter, such as a difference of gaussians, as an abstract representation of the effect of intracortical processing on the cortical input.

SUMMARY

The way in which the immense complexity of the nervous system arises during development is still somewhat nuclear. Theoretical modeling has been applied to several different stages of neural development in the hope of shedding light on some of these mysteries. The best developed areas are axon growth, branching and gradient detection, and activity-dependent development in the visual system and at the neuromuscular junction. In each case, specific quantitative predictions can be derived. The comparison of these predictions with experimental data allows the assumptions underlying the models to be developed and refined.

Neural Development

Introductory article

Dale R Sengelaub, Indiana University, Bloomington, Indiana, USA

CONTENTS

The structure of the nervous system is determined developmentally through the interaction of genetic and nongenetic processes. These processes are progressive, wherein cells are added, connections are established, and functions mature, as well as regressive, involving substantial death of cells and loss of connections.

INTRODUCTION

The human brain contains over 100 billion neurons, with hundreds of differing forms and multiple functions. These neurons are organized into populations and circuits that communicate through 100 trillion synapses, intricately and precisely connected in a complex array. The amount of information that must be specified in assembling the nervous system is consequently vast. While some of this information is genetic, the surprising smallness of the human genome (perhaps at most containing 40 000 genes) clearly indicates that sources of information that are not genetic (epigenetic) are heavily involved in neural development.

Indeed, the development of the nervous system has traditionally been viewed as an interaction between a variety of factors including genes and changes in their expression, and the timing and spatial distribution of cues in the cellular environment which organize a host of developmental programs. These cues can be intrinsic, involving proteins inherited with each cell division, or extrinsic, utilizing such things as diffusible molecules, cell-membrane proteins, or even the early experience of the organism. Importantly, though it may seem counterintuitive, the developmental processes that sculpt the nervous system are regressive as well as progressive in nature, and the expected addition of newly generated cells, their growth and differentiation to mature form, and the establishment of their complex connections, is accompanied by massive remodeling of connections and even the death of substantial numbers of cells.

NEUROEMBRYOLOGY

All the cells of the nervous system – and of the entire body for that matter – arise from a single cell, the fertilized egg. Because this one cell will through repeated divisions produce all of the different cell types of the body, it is said to be totipotent, or capable of giving rise to cells of all kinds. This one totipotent cell contains all of the genetic information involved in developing all of these cell types (and as you will see, this is only a small part of the information required). As development proceeds, and this cell and the cells it generates divide and divide again, decisions about which subset of these genes will be expressed by the newly generated cells are programmed through cellular interactions, initially limiting the potential fates of those cells to a narrow range of outcomes (pluripotency). This 'progressive determination' continues as cells divide and differentiate, ultimately resulting in the restriction to one outcome.

The Germ Layers

As early as one week after fertilization, three distinct layers of cells can be recognized in the developing human embryo. These three layers are known as the 'germ layers', and each will give rise to a specific set of tissues in the embryo. The outermost layer, the ectoderm, is the origin of the cells that will become the nervous system and skin. The underlying mesoderm will give rise to many different things, including the skeletal muscles, most bones, and the cardiovascular and urogenital systems. The last layer, the endoderm, will give rise to other organs of the gut, the lungs, and the liver.

Neural Tube Formation

The formation of the nervous system begins in earnest two weeks after fertilization. The

ectodermal cells of the embryo will differentiate into skin unless directed not to by a signal that comes from the underlying mesoderm. This kind of interaction between tissues occurs throughout embryonic development and is known as 'induction', a phenomenon in which signals from one tissue modify the development of another tissue. In the case of the nervous system, chemical signals from the mesoderm block differentiation of ectoderm into skin and cause neural tissue to form instead. Several candidate molecules have been identified that act to direct the differentiation of the ectoderm into nervous system tissue.

As a consequence of these chemical cues, ectodermal cells differentiate into the neural plate, where changes in the shape of cells, addition of cells, and rearrangements of cells result in the formation of a groove along the midline of the embryo. Over the next few days this groove deepens and its edges fuse, forming a long, hollow tube along the back of the embryo (Figure 1). This neural tube is the embryonic origin of the central nervous system (the brain and spinal cord). By six weeks after conception, several swellings develop at the anterior end of this tube, corresponding to the major subdivisions of the brain. This tube will continue to distort its shape and size, eventually obscuring the fact that the structures of the brain and spinal cord are elaborations along a long tube, whose interior constitutes the fluid-filled ventricles of the brain and the central canal of the spinal cord.

The origin of the peripheral nervous system – the various ganglia and their connecting nerves that lie outside the brain and spinal cord – derives from a further differentiation of the neural plate called the 'neural crest'. Neural crest cells form at the edges of the neural plate, and come to rest on the top of the newly formed neural tube. These neural crest cells then migrate away from this position, and depending on the route they take, differentiate into a variety of tissue types including the facial bones, pigmented cells of the skin, and the cells of the peripheral nervous system. Again, the instruction of what type of tissue to differentiate into is an inductive event. The inductive cues appear to come from the interaction of these migrating neural crest cells with the cells that surround them. Molecules from these surrounding cells direct neural crest migration by permitting it (through providing adhesion) or inhibiting it (through repulsive factors). Once the crest cells have been guided to their final destinations, other adhesion molecules cause the cells to stop migrating and aggregate at the new location.

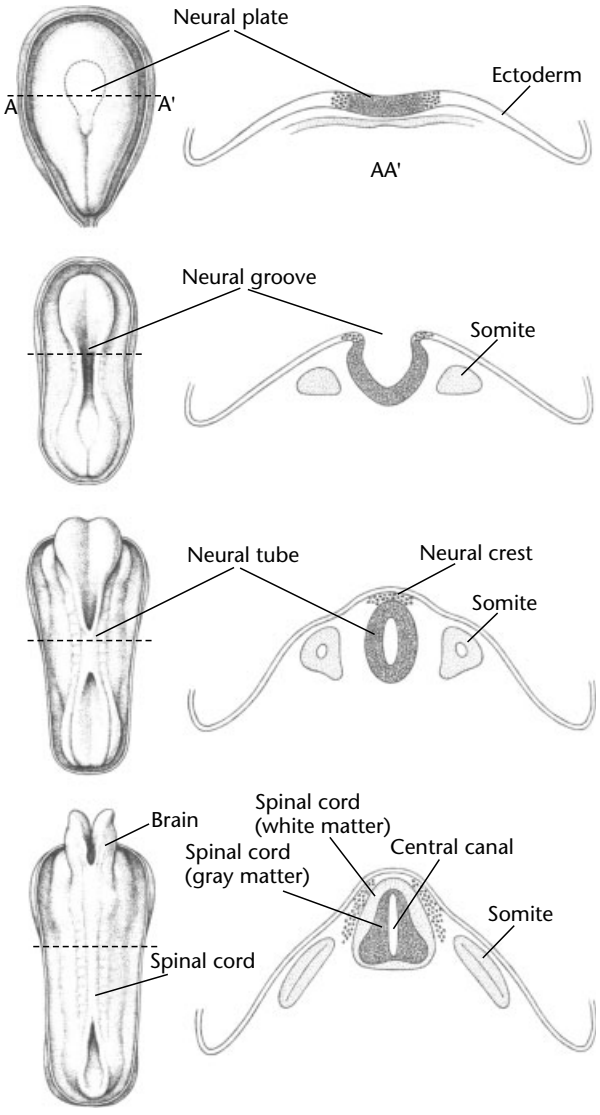

Figure 1. The nervous system has its origins during the first weeks after conception. External views of the embryo are shown on the left as well as cross-sections corresponding to the dashed lines on the right. At 18 days after conception, the neural plate develops from the ectoderm. Over the next few days the plate invaginates into a groove, and eventually closes itself into the neural tube, the embryonic origin of the brain and spinal cord. Structures of the peripheral nervous system arise from a population of cells called the neural crest, which migrate down the sides of the neural tube and aggregate into the peripheral ganglia. From Cowan WM (1979) The development of the brain. *Scientific American* **241**: 112–133.

DEVELOPMENTAL PROCESSES

Cell Proliferation

While it has recently been shown that the generation of neurons continues throughout life, the

majority of neurons are generated prenatally or early postnatally. Neural proliferation occurs primarily in ventricular zones that develop in the inner lining of the neural tube. Here, as cells divide, they undergo a series of well-defined stages known as the 'cell cycle'. During the cell cycle, germinal cells in the ventricular zone shuttle back and forth as they go through mitotic divisions. Early in this process, divisions are symmetrical, with each resulting in a doubling of the germinal cells; as development proceeds, these divisions become asymmetrical, and with each mitotic cycle, one germinal cell and either a neuron or glial cell will be produced. (Glial cells serve a variety of functions in the nervous system both during development as well as throughout life, and actually outnumber neurons.) The production of neurons (neurogenesis) during development is impressive, generating over 250 000 neurons per minute. Neurogenesis proceeds in a variety of spatial and temporal patterns, as well as a progressive generation of large neurons first followed by intermediate and then small neurons.

Migration

At some point, cells in the ventricular zones stop dividing and withdraw from the cell cycle. These cells migrate away from their site of generation and begin to differentiate into their final form, soon expressing proteins unique to their neural or glial type. The routes these migrating cells take are often tortuous, and can include secondary migrations as well. Neurons appear to use a variety of cues and mechanisms to guide their migration. Some cells actively move, while others are passive and are simply pulled and pushed to their destination by their active neighbors.

In the peripheral nervous system, sheets of neural crest cells are pulled through the surrounding cells by active pioneer cells. The mechanism that guides these migrations appears to be simply permissive, relying on adhesion or repulsion by surrounding cells. In the brainstem, displacement of cells from the ventricular zone is followed by mass migrations regulated by unknown mechanisms. The migrating cells then collect into masses called 'nuclei'. Again, expression of neural adhesion molecules is thought to be involved in establishing these cellular masses.

Perhaps the best-known mechanism for migration is provided by radial glia, specialized glial cells whose long processes appear to provide a guide along which migration occurs. These radial glia differentiate quite early and extend fibers from the ventricular zones out to the expanding edges of the growing nervous system (Figure 2). As neurons are generated and exit the ventricular zone, they attach themselves to the radial glia, and literally pull themselves along the glial fiber. The radial glia provide not only a means by which migrating neurons can travel, but also provide a direction for this primary migration.

The migration of neurons can contribute to the development of highly organized structures. Consider, for example, the formation of the neocortex. The neocortex is massive, covering most of the surface of the forebrain, and is organized into six layers, with large neurons projecting to subcortical areas residing in the deep layers, neurons receiving major inputs from the thalamus in middle layers,

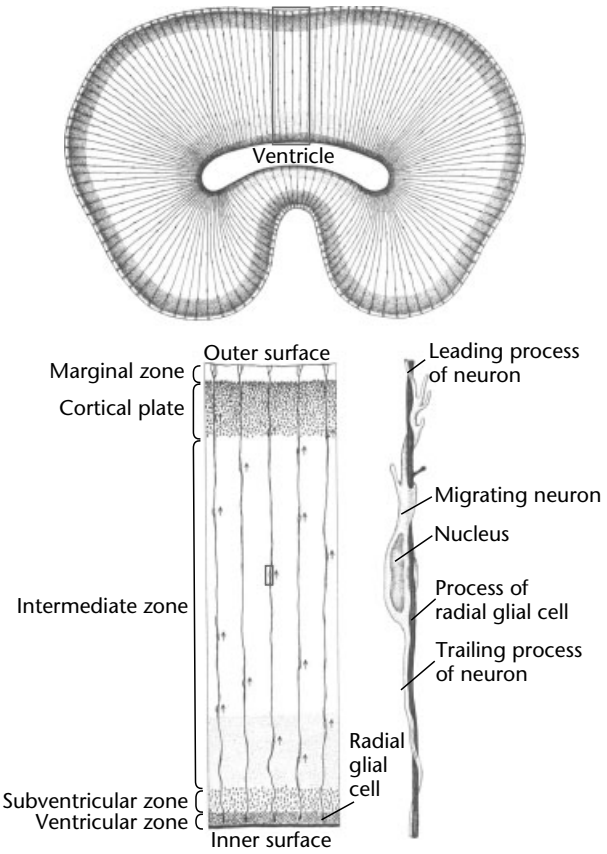

Figure 2. Processes from specialized cells called radial glia span the width of the developing brain and spinal cord, providing a path for migrating neurons. The illustration at the top shows the arrangement of radial glia in a transverse section through the developing cerebral hemisphere of a monkey. The successive enlargements below show migrating neurons attached to the radial glia, actively pulling themselves along the fibers. From Cowan WM (1979) The development of the brain. *Scientific American* **241**: 112–133.

and smaller neurons involved in sharing information with cortical areas on the opposite side of the brain occupying the superficial layers. The layers of the neocortex arise sequentially through successive waves of migration. The deepest layers of the neocortex form first, and as new cells are generated and migrate into the developing neocortex they migrate past the previously deposited neurons, establishing more superficial layers. Thus, the layers of the neocortex contain neurons that differ in age, with the oldest (earliest generated) neurons lying in the deep layers, and progressively younger (generated later) neurons in the outer, more superficial layers. Migration in the neocortex involves more than the simple radial migration along glia into successive layers, as tangential migrations across the cortex also occur.

Complex migrations of neurons using mixed strategies are seen elsewhere in the developing nervous system. For example, the cortex of the cerebellum also contains layers, with small granule cells lying below a layer of large Purkinje cells, which in turn lie below a surface layer of fibers. In the development of the cerebellum, two migrations occur. In the first, the developing Purkinje cells migrate from the ventricular zone to the cerebellar plate. Presumptive granule cells then stream in and spread over the Purkinje cell layer. These granule cells then extend axons horizontally across the cerebellar cortex, forming the superficial fiber layer. Lastly, the cell bodies of the granule cells then migrate down through the Purkinje cell layer, guided by specialized glial cells (the Bergmann glia).

Other patterns of migration exist as well. As in the developing brain, spinal cord neurons exit the ventricular zone surrounding the central canal and migrate radially along glial cell fibers. Curiously, these migrations can be bidirectional, with neurons migrating away from the ventricular zone out to the edges of the developing spinal cord, and then reversing course. Tangential migrations along bundles of axons within the spinal cord further complicate this process. Finally, not all of the neurons in the central nervous system are generated in ventricular zones. Certain neurons found in the hypothalamus are actually generated outside the neural tube in a structure known as the nasal placode. Cells from this placode give rise to structures of the nose, as well as producing cells that migrate into the developing hypothalamus.

Cell Differentiation

Migrating neurons have already begun to express proteins that identify them as neurons, but their differentiation into their adult form is far from complete. Migrating neurons might have leading and trailing processes, but their size and certainly the elaboration of their dendrites and axons that uniquely characterize them as particular types of neurons, as well as most of their functional properties including neurochemistry and receptor expression, have yet to be realized. The assignment of cellular identity, and the processes through which neurons develop their individual forms and functions, are controlled by factors that are both intrinsic as well as extrinsic to the neuron. The bulk of the evidence suggests that even intrinsic factors, such as differential gene expression, are in fact themselves regulated by extrinsic control.

As an example, neurons communicate primarily through chemical synapses, and different types of neurons use different types of neurotransmitters. For at least some neurons, the decision of which neurotransmitter to express appears to come from an interaction with the neuron's extracellular environment or target tissues, another example of an inductive event. In the peripheral nervous system, neurons aggregate into groups called 'ganglia', and these ganglia differ with respect to which neurotransmitter they will use in communicating with their target tissues. Neurons in ganglia that serve the sympathetic branches of the autonomic nervous system typically use the neurotransmitter noradrenaline (norepinephrine), while neurons in ganglia serving the parasympathetic branches use the neurotransmitter acetylcholine. The assignment of which neurotransmitter to express appears to depend at least in part on the influence of the local cellular environment. Different ganglia have different migratory routes, and cues in these routes influence the different neurotransmitter assignments for these neurons. In addition, the target tissues for these neurons also appear to have a role, and the neurotransmitter expressed can be switched by altering the nature of the target tissues they contact.

The type of neuron that differentiates also seems to be controlled by induction. For example, motor neurons are commonly organized into nuclei that are found in the ventral portion of the hindbrain and spinal cord. Neurons in these ventral areas develop into motor neurons early, and this differentiation is regulated through a protein cue that originates from cells in the neighboring notochord. The notochord is part of the mesoderm, and lies just below the growing spinal cord. Cells in the notochord express a protein called 'sonic hedgehog', which diffuses away from the notochord, causing the ventral spinal cord neurons to differentiate into motor neurons.

Dendritic and Axonal Growth

As neurons differentiate, they establish characteristic morphologies which correspond to their function and physiological properties. Neuronal morphologies vary widely, and these anatomical differences, including the branching patterns and distribution of processes, and overall shape of dendritic arbors, reflect important functional differences. To date, a variety of factors have been identified which may be involved in regulating the growth, distribution, and orientation of dendritic arbors. These factors include interactions with the axons that contact them (their afferents), their own targets, and a variety of trophic substances. Dendritic development begins after migration of the cell body is complete. The characteristic number and orientation of dendrites that are initially extended appears to depend on information contained in the neuron, perhaps specified early in differentiation, as neurons grown artificially in cell cultures nonetheless develop appropriate dendritic morphologies. However, further elaboration of the dendritic arbor, including the pattern of branching and the length of dendritic segments, is defined by agents and actions occurring outside of the cell. Electrical and chemical activity in a neuron's afferent inputs, factors from its targets, and other variables all interact to shape the developing dendritic array.

While the development of dendrites typically occurs after migration of the cell body, the growth of a neuron's axon often begins before migration is complete, and in some cases the axon has already grown into its target before the cell body reaches its final migratory destination. The growth of the axon occurs at the tip, in a structure called a growth cone, a small, spiky blob that sends out filaments in many directions which can adhere to particular surfaces, dragging the axon along behind it. The routes that growing axons take are often long and complicated, and as a consequence there appear to be multiple mechanisms involved in guiding the growing axon. For example, some growing axons rely on guidepost cells spaced along the route. These guidepost cells direct axon segments to the next set of cells containing guidance information for the subsequent leg of the journey. In many cases the guidance of the growing axons is quite precise, and chemical cues such as molecules from the surrounding cells, adhesion or cell recognition molecules on the surfaces of cells, growth factors, and signaling molecules organized in gradients, have all been identified as contributing to the establishment of correct axonal projections and complex mappings. Simple mechanisms also exist; for example, growing axons will travel along previously grown axons, or use the presence of blood vessels to guide them. Finally, in some systems axons will grow diffusely, sending branches into several potential target areas. Because many of these early diffuse branches are in fact in error, their later elimination (see below) is an essential process in the development of precise axonal projections.

With the arrival of the growing axon at its target, the formation of synaptic contacts (synaptogenesis) begins. Synaptogenesis is essential for the continued differentiation, growth, and even survival of developing neurons. As in so many earlier cases, this process involves interactions between cells. For example, axons of motor neurons grow into the muscles they will control and begin to form specialized synapses called neuromuscular junctions. The motor axons appear to signal the formation of the synapse by secreting chemicals that cause the muscle to make and cluster neurotransmitter receptors at the site of the developing synapse. The muscle in turn secretes chemicals that cause the motor axon to branch. The process of synaptogenesis can extend well into postnatal development. For example, in the human neocortex, synapse numbers increase dramatically through the first year of postnatal life.

Normally Occurring Neuron Death

The formation of synaptic contacts between neurons and their targets ushers in the next major process in neural development, the death of enormous numbers of neurons. The death of neurons during normal development is a surprising but well-documented phenomenon that occurs throughout the nervous system. Initially neurons are overproduced and their numbers are subsequently reduced during a period of normally occurring cell death. This death appears to be controlled by target availability, synaptic activity, and to some extent afferent input as well.

Normally occurring neuron death, or apoptosis, is sometimes called 'programmed' cell death because it is a predictable process that involves the switching on or off of a set of genes coding for enzymes that are used in the destruction of the cell. Which neurons survive and which die during development in the human nervous system is not genetically determined, but instead results from an apparently competitive process in which otherwise healthy, normal neurons are eliminated. This death of developing cells is not at all unique to neurons,

and in fact occurs in a variety of developing tissues, allowing the sculpting of specialized structures. For example, the development of the fingers and toes of the hands and feet includes the death of cells that lie between the forming digits. In the case of the developing nervous system, the death rate can range up to 80 percent of the initial neuron population in a given structure, with the deaths occuring over a brief period. Normally occurring neuron death contributes to the formation of a variety of structural specializations throughout the nervous system, creating local differences in neuron numbers that underlie functional specializations ranging from high-acuity vision to sex differences (Figure 3). In addition, neuron death appears to set the numbers of cells appropriately in interconnecting populations, as well as eliminating neurons that have established erroneous connections through diffuse growth of axons.

The onset of normally occurring neuron death coincides with the establishment of connections between neurons and their targets. Moreover, the activity in those connections plays an important part in regulating the amount and timing of neuron death. For example, altering the size of the target has a profound effect on the number of developing neurons that will survive the cell death period. Removal of target tissue, for example the target muscles of developing motor neurons, results in a proportionately larger death of motor neurons innervating those muscles. Conversely, adding additional target tissue, for example by grafting on an extra limb, results in a sparing of motor neurons that would otherwise have died. However, the simple presence of neuronal targets is not sufficient, as the process of neuronal death appears to also require communication between neurons and their targets. For example, blockade of the neuromuscular junction with drugs that prevent synaptic transmission (e.g. curare) reduces the amount of motor neuron death. The amount of input a neuron receives may also influence neuronal survival, as large removals of projecting neurons increases the amount of death seen in the target population.

The regulation of the amount of neuron death by targets and afferents suggests that developing neurons depend on factors that are in short supply: gaining access to sufficient amounts or types allows a neuron to survive, while failing to do so results in cell death. Several competition models have been proposed in which developing neurons must make adequate synaptic connections or obtain special chemicals that promote survival. Such chemicals are known as 'trophic factors', and numerous candidates have been identified. These trophic factors are thought to regulate neuron survival by either preventing the expression of genes that cause the death of the cell or triggering the expression of protective molecules that block products of lethal gene products. For example, neurons in the

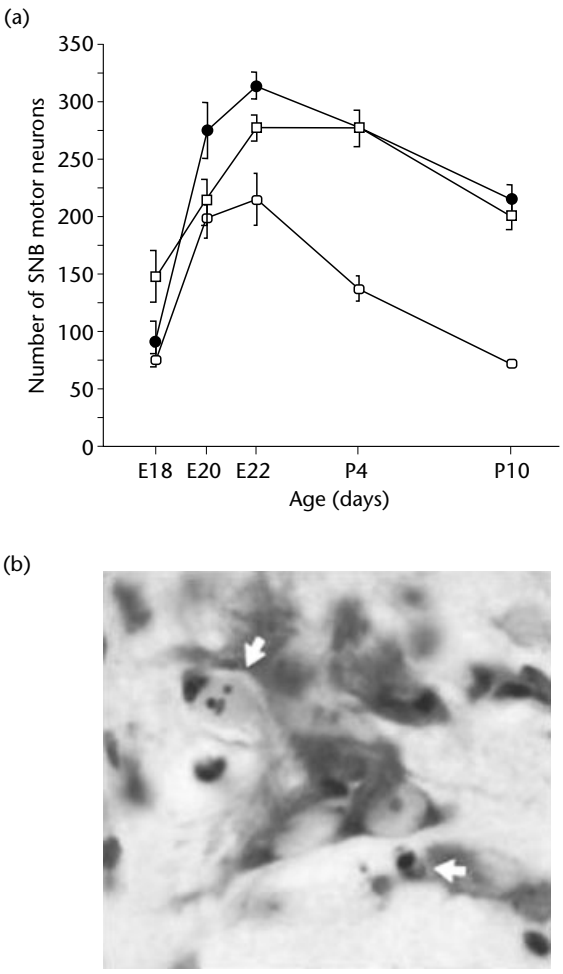

Figure 3. Normally occurring neuron death eliminates substantial portions of the developing nervous system. This death can be regulated by a variety of factors, including sex hormones, producing sex differences in neuron number. (a) Hormonally dependent death of motor neurons in the spinal nucleus of the bulbocavernosus (SNB) in the rat spinal cord over the late embryonic (E) and early postnatal (P) days. Female rats (white circles) lose many more SNB motor neurons than do male rats (black circles), and treatment of females with testosterone propionate (white squares) decreases that loss to male levels. (b) The photomicrograph shows degenerating cells (arrowed) in the SNB. Adapted from Nordeen EJ, Nordeen KW, Sengelaub DR and Arnold AP (1985) Androgens prevent normally occurring cell death in a sexually dimorphic spinal nucleus. *Science* **229**: 671–673.

sympathetic ganglia require nerve growth factor supplied by their target tissues, motor neurons require proteins that are produced in their target muscles, and even glia in the peripheral nervous system need trophic factors from axons to survive. Given that the survival of developing neurons also depends on activity, it is possible that activity might regulate access to trophic factors by influencing axonal branching or synapse formation.

Synapse Elimination

Just as neurons in the developing nervous system are overproduced and then reduced to mature amounts and distributions through the regressive process of neuron death, the synaptic connections made during development are also subject to an initial overproduction and then subsequent retraction. In some cases, it is the pattern of synaptic connections that is remodeled (and the actual number of synapses may actually increase), while in others, the overall amount of synapses declines dramatically. In the human nervous system, this process of synapse elimination typically occurs after the period of neuron death, and can take several years to reach completion (Figure 4).

A simple case of synaptic reorganization occurs in neuromuscular systems. At maturity, a typical muscle fiber is contacted by a single motor neuron, but developmentally, several motor neurons synapse onto a single muscle fiber. This polyneuronal innervation in neuromuscular systems is reduced through a retraction of axon branches from some neuromuscular junctions, eliminating the multiple neuron inputs to single fibers. Simultaneously, the remaining axons grow and branch, making numerous new contacts resulting in a net increase in synaptic numbers. This synaptic remodeling is driven by neuronal activity in the system, wherein synaptic activation maintains the active synapses and removes inactive ones. As in the case of activity-dependent neuron death, preventing activity at the neuromuscular junction arrests synapse elimination.

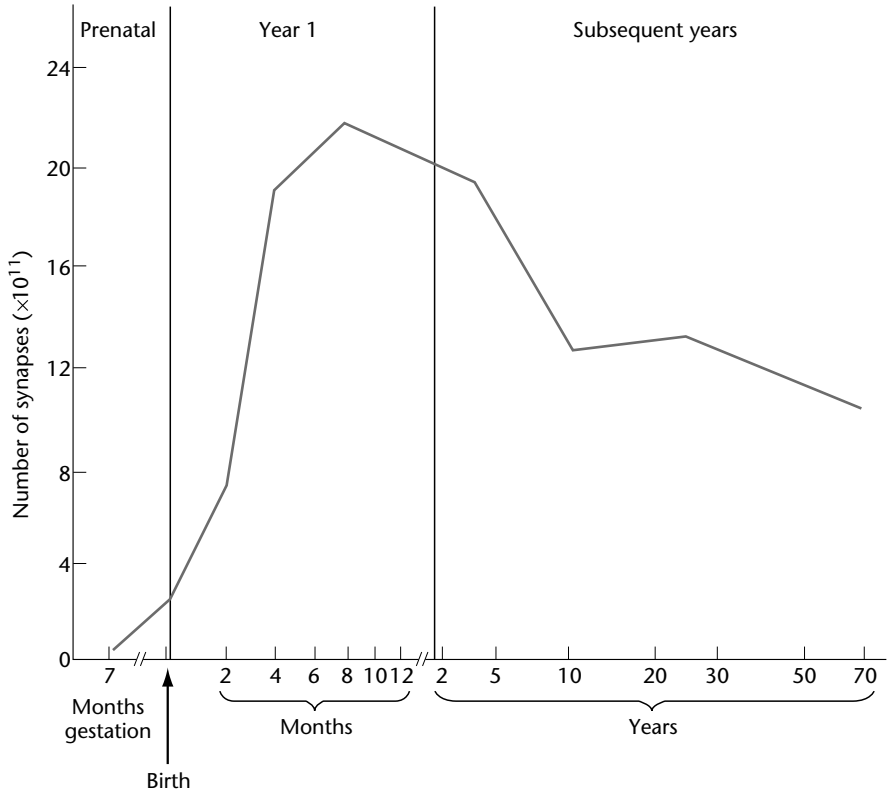

Figure 4. Synapse elimination in the human cortex occurs over a period of years. In the visual cortex, the number of synapses increases rapidly after birth, peaking at about one year of age. The number of synapses then declines dramatically over the subsequent 10 years. The number of synapses is stable through young adulthood, and then slowly declines thereafter. From Kolb B and Wishaw IQ (2001) *An Introduction to Brain and Behavior*. Worth Publishing.

Synapse elimination is involved in the establishment of more complex patterns of connectivity as well. In the mature visual system, projections from the retina to central visual targets such as the lateral geniculate nucleus of the thalamus and the superior colliculus of the midbrain show highly organized topographic maps such that a neuron's location on the retina (and hence the part of the visual world it responds to) is faithfully preserved in the representation across these structures. The initial retinal projections to these structures are far less organized and must be refined through activity-driven synapse elimination.

The classic example of synapse elimination in development comes from work examining the representation of visual input in the cortex. At maturity, neurons in the visual cortex receive information via the thalamus from both the right and left eyes. These neurons are organized into discrete, alternating columns which are more easily activated by information from one eye than from the other – hence they are called 'ocular dominance columns'. This organization is not as readily apparent at birth, and the distinction between columns is blurred because the thalamic axons carrying information from the two eyes are initially intermixed. The activity supplied by normal vision during postnatal development drives the process of synapse elimination in the visual cortex, and the overlapping axons segregate, retracting from inappropriate areas and elaborating in appropriate ones, refining the boundaries between ocular dominance columns.

This same phenomenon also occurs in the lateral geniculate nucleus, the thalamic nucleus that supplies the axons carrying the visual information to the cortex. In the lateral geniculate nucleus, information from both eyes is initially intermixed early in development. Through synapse elimination this mixing is removed, and at maturity, information from the left and right eyes are held separately in distinct layers.

Thus, in both the thalamus and the visual cortex, an activity-dependent sorting of synaptic connections refines the structure and function of visual neurons.

Early Experience

The development of normal vision depends on the presence of normal visual experience during the period in which synapse elimination, axonal segregation, and synaptic remodeling are occurring. If normal vision is disturbed during this period, permanent perceptual deficits will result.

This illustrates the concept of the critical period, a specific time in development when a neuron, system or organism is particularly sensitive to – and permanently altered by – environmental or other outside influences. Critical periods exist for all of the developmental processes, and the timing of these periods differs across neural systems, corresponding to their particular developmental programs. In the case of the developing visual system, depriving the eyes of normal vision during this postnatal critical period either through cataracts, vision problems such as uncorrected amblyopia or astigmatism, monocular eye patches, or rearing in complete darkness will result in permanent perceptual deficits. All of these conditions will alter the pattern of activity produced by stimulation of the two eyes, and as a consequence will affect the interaction between synapses that drives the normal segregation and elaboration or appropriate connections in the developing visual cortex. Importantly, if these same manipulations are applied after the critical period (that is, after synapse elimination has been completed), they have no effect.

The fact that the early experience of an organism can have profound effects on development has been amply demonstrated. Altering the early experience of a developing organism will alter both neural structure and function, and indeed the organism's behavior. Early experience is an essential element of development, providing a variety of stimuli and a wealth of information. Importantly, this early experience is not limited to laboratory experiment manipulations; for example, children who do not play or are rarely touched have significantly smaller brains than those of children who experience normal everyday childhood interactions.

The influence of the early environment on neural development has received a great deal of attention. Animal studies have repeatedly demonstrated that depriving developing organisms of normal social, cognitive, or environmental experiences has a profound detrimental effect on both the brain and behavior. Importantly, despite popular claims to the contrary, these animal studies do not support the hypothesis that enhancing the environment or experience above what is normally available has any positive effect whatsoever. Rather, these animal studies demonstrate that deficiencies in the early environment can be partly compensated for by adding stimulation, complexity, and novelty. In other words, the 'enriched' environments used in these studies are only poor approximations of the animal's natural normal environment.

CONCLUSION

The development of the human nervous system is a complex and protracted phenomenon, involving many processes spanning prenatal as well as postnatal development.

At birth, while the generation of neurons is by no means finished, the number and locations of neurons have essentially been established, and their differentiation to adult form is complete or well under way. However, the development of important structures still has a long way to go. Establishment of the basic structure of major brain areas such as the neocortex, hippocampus, and cerebellum will continue for many months postnatally. Major axon bundles are still forming at birth, including the corpus callosum which will bridge the cerebral hemispheres, and the corticospinal tract with its motor projections to the spinal cord. The development of the myelin sheaths that speed the conduction of action potentials along axons will proceed throughout adolescence, and the major changes in connectivity allowed by synaptic remodeling through synapse elimination will take years to complete.

This development involves both progressive and regressive processes that are influenced by multiple interacting factors. The dynamic assembly and destruction of the nervous system during normal development ultimately requires both genetic as well as epigenetic sources of information, including the behavioral experience of the organism.

Neural Inhibition

Introductory article

Kevan AC Martin, Institute of Neuroinformatics, Zurich, Switzerland

CONTENTS

Neural inhibition is an active process that reduces or suppresses the excitatory activity of synapses, neurons or circuits.

INTRODUCTION

Neural inhibition achieves its effect by reducing the excitability of neurons. Inhibition is not simply 'all or nothing' in its action, but provides a graded, analogue control of excitation. The most important actions of inhibition are effected through a large array of specialist inhibitory neurons integrated within brain circuits. Thus inhibition always acts in tandem with excitation. Although inhibition is usually regarded primarily as a synaptic event, any process that acts to reduce the excitability of synapses, neurons, circuits or systems is inhibitory. Paradoxically, without inhibition, no perception, decision or movement is possible. This is because inhibition not only acts to check excitation, but may also release excitation by inhibiting other inhibitory neurons that keep the excitatory neurons in check. The push–pull interplay between excitation and inhibition generates the rhythms in the brainstem and spinal cord that allow us to breathe, walk and perform most other basic functions. Inhibition thus expresses itself in different forms at all levels of organization of the nervous system.

MECHANISM OF INHIBITION

The basic inhibitory mechanisms apply to all neurons. Inhibition is based on channels in the membrane, which are selectively permeable to specific ions (e.g. sodium, potassium, chloride, calcium) (Figure 1). The channel permeability can be altered by neurotransmitters released at synapses or by changes in voltage, or indirectly by the concentration of ions such as calcium. The 'resting' membrane potential (about −70 mV between the inside and outside of the neuron) is determined by the ratio of the concentrations of the different ions inside and outside the neuron and the relative permeabilities of the ion-selective channels.

When synaptic current flows into the neuron, the membrane depolarizes and this activates voltage-sensitive channels, which open to allow sodium ions to move down their concentration gradient. This inward current depolarizes the cell further, opening even more sodium channels in a positive feedback loop. If the depolarization is sufficiently large (about 20 mV), the membrane potential crosses a threshold for generating an all-or-nothing action potential. Individual sodium channels only open briefly, and then inactivate when they initiate the nerve impulse. Simultaneously, the depolarization activates voltage-sensitive potassium channels, which open to allow an opposing outward current to flow across the membrane. Together with the inactivation of the sodium channels, the outward potassium current returns the membrane to the resting potential.

Other types of membrane ion channels are located at synapses (Figure 1). In their simplest form, these ion channels have receptors that bind the neurotransmitters which are released at synapses. These are termed directly gated channels, and the associated receptors are called ionotropic receptors. When a neurotransmitter binds, the ion channel opens and ions flow down their concentration gradients. The direction of the net current (i.e. whether it flows into or out of the neuron) determines whether that particular synapse is excitatory or inhibitory. The activation of an individual excitatory synapse evokes an inward current, which depolarizes the neuron slightly (0.1–1.0 mV) from its resting potential of about −70 mV. If many excitatory synapses are activated simultaneously, this can trigger an action potential. Inhibitory synapses also have ionotropic receptors. Unlike the excitatory synapses, the binding of the inhibitory neurotransmitter results in an outward current, which

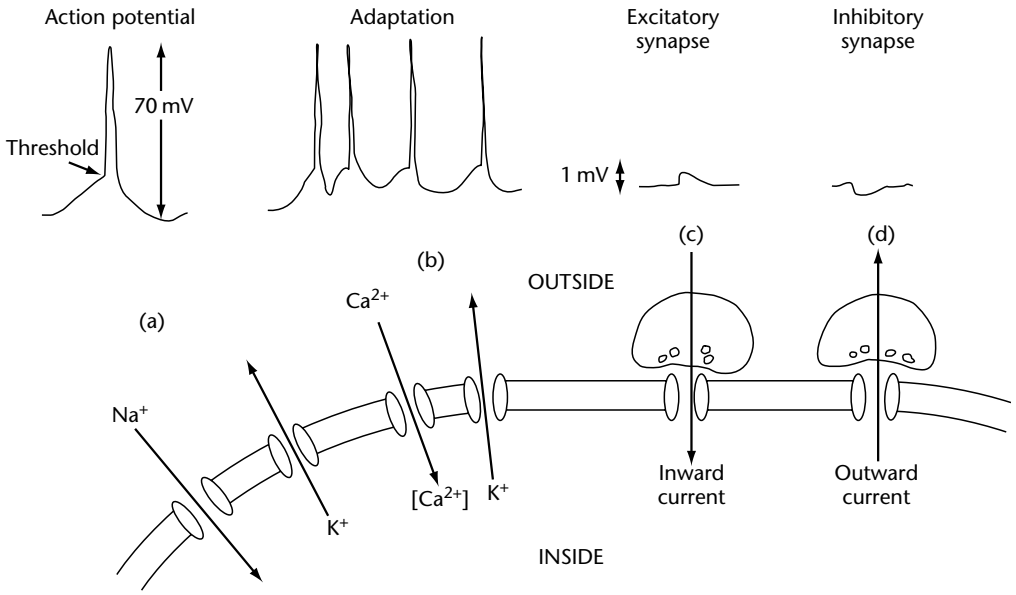

Figure 1. A segment of a neuronal membrane. Schematics indicate the direction of the currents associated with (a) the sodium and potassium channels responsible for the action potential (nerve impulse), (b) voltage-dependent calcium channels and the calcium-dependent potassium channels, which slow the rate at which the nerve impulses are produced (firing frequency adaptation), and the channels associated with (c) an excitatory synapse and (d) an inhibitory synapse. More than one ion species generally flows through the synaptic channels. The effects of activation of these channels on the membrane is shown above the schematic membrane. The magnitude of the action potential is about 70 times greater than the potentials generated by individual synapses.

tends to drive the membrane to more negative values, thus opposing the inward depolarizing current generated by excitatory synapses.

Although neurotransmitters are often described as 'excitatory' or 'inhibitory', it is not the neurotransmitter that makes the synapse inhibitory or excitatory, but rather the channel associated with the particular neurotransmitter receptor. Inhibitory synapses in the central nervous system are typically associated with potassium- or chloride-selective channels, both of which generate outward currents when activated at membrane voltages below -70 mV. In addition, the opening of the chloride channels significantly lowers the electrical resistance of the neuron, which allows the excitatory current to leak away. This is called 'shunting' inhibition.

FORMS OF INHIBITION

Synaptic Inhibition

There are two forms of inhibition that are mediated by synapses. In the more common form, inhibitory synapses on the target neuron directly reduce the neuron's excitability. This is called *postsynaptic inhibition*. In the less common form, namely *presynaptic inhibition*, the inhibitory synapse is on the terminal of the excitatory synapse itself. The presynaptic inhibitory mechanisms act by reducing the probability that excitatory neurotransmitter will be released from the presynaptic terminal. The role of both forms of inhibition is the same, namely to negate or reduce the effects of excitation. Most inhibitory synapses are formed by axons, but some neurons form their inhibitory synapses with their dendrites. Under the electron microscope the inhibitory synapses appear morphologically distinct from the excitatory synapses.

Intrinsic Inhibition

Not all inhibition is due to synaptic action. Many neurons have intrinsic mechanisms that reduce their excitability. These mechanisms usually involve potassium channels that are either directly activated by changes in the membrane voltage or indirectly activated via changes in the intracellular concentration of certain ions, especially calcium. In 'voltage-gated' potassium channels, the voltage of the membrane determines the activation or deactivation of the channels. When the membrane depolarizes, potassium channels open and the outward current opposes the depolarization.

Voltage-dependent channels also have a very important role in allowing neurons to fire repetitively at low frequencies, because they slow the rate at which the neuron can depolarize between impulses. Calcium-activated potassium channels (Figure 1) are sensitive to the free calcium concentration in the neuron, and respond to elevated calcium levels by repolarizing or hyperpolarizing the neuron. Other potassium channels are activated by internal 'second-messenger' systems, usually involving G-protein pathways, which are themselves often triggered by ions such as calcium either released from internal stores or entering via voltage-gated channels in the membrane. The effect is that more excitatory current is required to move the membrane to threshold, and the firing rate slows or even stops. This effect is known as firing frequency adaptation. These intrinsic inhibitory mechanisms are particularly significant with regard to producing pacemaker cells that have a spontaneous rhythm. Both voltage-dependent channels and channels gated by second messengers are influenced by neurotransmitters or neuromodulators.

NEUROTRANSMITTERS AND RECEPTOR TYPES

The principal neurotransmitters involved in inhibitory transmission in the central nervous system (CNS) are gamma-aminobutyrate (GABA), glycine and acetylcholine. Each of these binds to its own specific receptors, but there may be more than one receptor for the same neurotransmitter. Acetylcholine is an example of a neurotransmitter that can be either excitatory or inhibitory, depending on the synaptic receptor. When acetylcholine binds to nicotinic-type acetylcholine receptors, its action is excitatory, but when it binds to muscarinic receptors, its action is inhibitory. The muscarinic acetylcholine receptors are one of the family of 'metabotropic receptors', so called because the receptors are not directly linked to the ion channels, but are linked to them indirectly via a G-protein pathway. The binding of acetylcholine leads to a biochemical cascade that opens potassium channels, which then drive the resting membrane voltage to more negative values and so oppose the excitatory depolarization. Compared with ionotropic receptors, the onset of response is slower and the duration of response tends to be longer. Both GABA and glycine bind to ionotropic receptors on a chloride channel. Like potassium, the equilibrium potential of chloride is very negative relative to the action potential threshold. Therefore activation of the GABA and glycine receptors coupled to the chloride channels opposes the excitatory depolarization of the membrane. GABA also binds to a metabotropic receptor that is coupled indirectly to a potassium channel.

SHORT-RANGE AND LONG-RANGE EFFECTS

It is quite common to find that when a projection pathway is stimulated, its target neurons respond with monosynaptic excitation and disynaptic inhibition. This indicates that while most long-distance projections are excitatory, they connect to both excitatory and inhibitory neurons within their target area. Inhibitory neurons tend to connect only locally, and one of the most fundamental uses of inhibition in the CNS is to sharpen the spatial pattern of excitatory responses. The action of such *lateral inhibition* is to confine excitation to a core of the most active cells, and to prevent activity in the surrounding less excited cells. Lateral inhibition is a strong feature of retinal processing, where the retinal circuitry produces a spatial receptive field whose excitatory center is surrounded by a moat of inhibition. These lateral inhibitory influences are the cause of a number of visual illusions (e.g. Mach bands, the Craik–Cornsweet illusion, and the Hermann grid illusion). However, lateral inhibition is not confined to the sensory periphery – it is ubiquitous in the CNS. For example, in the spinal cord, the Renshaw cells (see below) mediate lateral inhibition of the motor neuron pool.

ROLE IN MICROCIRCUITS

A particularly well-studied microcircuit in the spinal cord coordinates muscle action around a joint (Figure 2). When a muscle is stretched, stretch receptors in the muscle excite the motor neurons which innervate that muscle and cause the muscle to contract. This is the *stretch reflex*, which acts to resist increases in muscle length. However, the same stretch receptors excite so-called '1a' inhibitory neurons that provide a *feedforward inhibition* to the motor neurons that excite the antagonistic muscles. If the 1a inhibitory neurons are themselves inhibited, co-contraction of opposing muscles can occur. Thus this circuit enables the stiffness of the joint to be set by controlling the relative amount of excitation and inhibition within the microcircuit.

The 1a inhibitory neuron itself makes only local connections in the spinal cord, but it is excited by long-distance connections from the muscle stretch

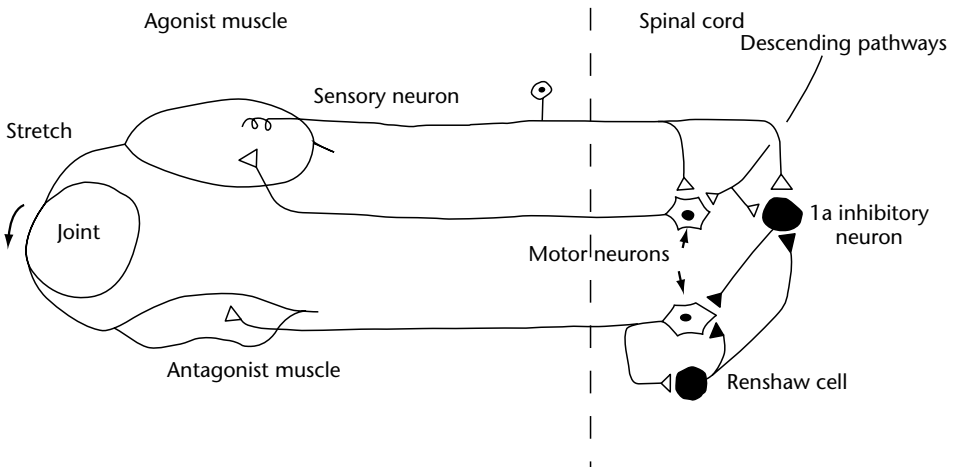

Figure 2. The circuit of the stretch reflex. When a muscle is stretched, spindles in the muscles sense the change in length and excite the motor neurons that cause the muscle to contract. The sensory neuron also excites the 1a inhibitory neuron, which inhibits the excitatory motor neurons of the antagonistic muscle. This is feedforward inhibition. The motor neurons also excite a class of inhibitory neurons called Renshaw cells, which provide feedback or recurrent inhibition to the same motor neurons. The Renshaw cells also inhibit the 1a inhibitory neurons, thus producing disinhibition. The excitatory neurons and synapses are indicated in outline, and the inhibitory neurons and synapses are indicated in black. The different inhibitory pathways are only illustrated for the antagonistic muscle. Identical circuits exist for the agonist muscle. Descending pathways from the cortex, cerebellum and spinal nuclei excite both motor neurons and inhibitory neurons.

receptors and descending pathways from the brain. This means that the same stretch reflex circuit can be used to coordinate voluntary movements and produce both the reciprocal activity that is required for walking and the co-contraction of opposing muscles that is required for precision movements.

The motor neurons themselves can be inhibited by another type of neuron, called the Renshaw cell, which also makes only local connections. A Renshaw cell lies in the vicinity of the motor neuron and is excited by it. In turn, it inhibits the motor neuron and its synergists. This is called *recurrent inhibition*, and the negative feedback that it provides regulates the excitability of the motor neurons and confines activity to the most active motor neurons through the mechanism of lateral inhibition. The Renshaw cells also inhibit the 1a inhibitory neurons of the antagonistic motor neurons, and so produce *disinhibition*. The motor neurons, the Renshaw cells and the 1a inhibitory neurons also receive long-range inhibition and excitation from descending spinal pathways. These descending pathways to inhibitory neurons can thus alter the excitability of all of the motor neurons around a joint. Motor neurons do not show strong spike frequency adaptation, so the major mechanism of inhibition in these spinal circuits is synaptic rather than intrinsic.

Local circuits involving feedforward and feedback inhibition and excitation are found throughout the central nervous system. Even simple circuits of excitatory and inhibitory neurons can generate great functional variety. Small variations in the spatial patterns and strength of connections, small differences in the intrinsic excitability of neurons and the timing of the interactions can produce large differences in the overall behavior of the system. For example, in four-legged animals the same basic spinal circuits can produce standing, walking, trotting and galloping.

NEUROMODULATORS AND INHIBITION

Neuromodulators act on inhibitory cells to vary their action. The thalamus is a nucleus that relays sensory information from the eyes, ears, touch receptors, etc. It also receives a variety of relatively diffuse inputs from the brainstem. When the parabrachial nucleus of the brainstem releases the transmitter acetylcholine from its terminals in the thalamus, it dramatically switches the firing mode of the thalamic neurons from burst to tonic firing. Nitric oxide, which is contained in the same parabrachial terminals, may also promote the transition from burst to tonic firing. The ability to change the mode of firing underlies the changing pattern that is seen in the electroencephalogram (EEG) when there is a transition from rapid eye movement (REM) to non-REM sleep. The former is

desynchronized and high frequency, whereas the latter is characterized by slow wave rhythms and is associated with a lack of activity in the acetylcholine-containing parabrachial terminals. In non-REM (slow-wave) sleep, inhibition is strongly active and a cycle of excitation and inhibition creates large rhythmic potentials in the thalamus and cortex. The effect of acetylcholine inhibits the inhibitory cells in the thalamus and excites the excitatory cells. This paradoxical action occurs because the two cells have different receptors for acetylcholine. As a result, the inhibitory cells are relatively inhibited and thus cannot contribute the inhibition that is necessary to maintain the rhythm.

In other neurons (e.g. in the olfactory bulb), noradrenaline (norepinephrine) reduces the release of inhibitory neurotransmitter. Noradrenaline and acetylcholine are also modulators of the intrinsic inhibition involved in firing frequency adaptation. Noradrenaline acts on channels that make the membrane slightly more negative, so potentiating the strength of adaptation. However, it also blocks firing frequency adaptation by blocking the activation of the membrane channels that normally open and act to slow the firing frequency. Acetylcholine has a similar effect. Both of these neurotransmitters are produced by neurons that form the diffusely projecting systems of the brain. Since these systems produce their relatively long-duration effects over a wide area of brain, they are probably involved in processes that alter the state of arousal or vigilance.

Neural Oscillations

Intermediate article

Xiao-Jing Wang, Brandeis University, Waltham, Massachusetts, USA

CONTENTS

Oscillations represent a general feature of neural firing patterns, produced by dynamical interplay between cellular and synaptic mechanisms. Large-scale synchronous neural population rhythms reflect different behavioral states, play a role in neural synchronization that contributes to the neuronal encoding of sensory stimuli, or may be correlated with cognitive processes such as attention and working memory.

INTRODUCTION

Integrative operations in the brain involve coordinated neural firing patterns in large-scale neural networks. Ever since Hans Berger discovered distinct electroencephalogram (EEG) wave patterns in sleep and waking states in 1929, synchronous brain rhythms have been recognized as one of the most conspicuous types of neural population dynamics. Describing a 'mathematical outlook' of the cortex, Charles C. Sherrington wrote a half-century ago:

> A scheme of lines and nodal points, gathered together at one end into a great ravelled knot, the brain, and at the other trailing off to a sort of stalk, the spinal cord. Imagine activity in this shown by little points of light. Of these some stationary flash rhythmically, faster or slower. Others are travelling points, streaming in serial trains at various speeds. The rhythmic stationary lights lie at the nodes. The nodes are both goals whither converge, and junctions whence diverge, the lines of travelling lights. (Sherrington, 1951, p. 176)

Today, there is a resurgence of interest in brain rhythms for two reasons. First, it is now known that neural rhythms occur in alert and behaving states (as well as in sleep), and that they may play important roles in cortical functions. Secondly, technical advances have led to significant progress in the elucidation of the cellular and synaptic mechanisms of these rhythms.

Broadly speaking, there are three categories of brain rhythms.

1. *Spontaneous rhythms* occur in brain states characterized by the absence of sensory inputs. These spontaneously occurring oscillations usually have low frequencies (< 15 Hz), and are remarkable for their large-scale synchronization across brain structures, detectable as large-amplitude brain waves by the EEG. Examples include the spindle rhythm (4–12 Hz) and delta rhythm (3–4 Hz) in the thalamocortical system, which are the hallmarks of non-dreaming sleep and disappear during dreaming sleep or wakefulness (Figure 1(a)). Spindle and delta rhythms are often temporally nested with another very slow rhythm (< 1 Hz).
2. *Induced rhythms* have been observed in waking states. They are typically evoked by external sensory stimulation and correlated with certain behaviors. In the olfactory bulb, fast synchronous oscillations (gamma at 30–60 Hz) can be induced by olfactory stimulation. For a given odor stimulus, the 'induced rhythm' (so named by E. D. Adrian, who discovered it) is synchronized transiently, in time (for a few hundreds of milliseconds), and only among a neural subpopulation which is selectively responsive to that particular odorant. Similarly, in the visual cortex of the cat and monkey, gamma oscillations were observed in evoked neural responses to optimal visual stimuli (Figure (1b)), and synchronization is realized within subgroups of neurons with similar stimulus specificity. Gamma oscillations are also present in the hippocampus and nearby limbic structures, where they are temporally nested with a slower, theta (4–10 Hz) rhythm. Theta rhythm occurs during exploratory movements and spatial navigation. Physiological studies of behaving rodents show that at any given time, only a subset of hippocampal neurons that encode the animal's current (or immediate future) spatial location is synchronized at a particular phase of the theta cycle (Figure 1(c)).

Therefore, in contrast to the 'spontaneous rhythms', neural rhythms of the waking brain are usually characterized by the presence of a prominent fast oscillatory component (gamma at 30–60 Hz). Synchronization is subtle, typically confined to a restricted (possibly small) subpopulation within a brain area, and occurs intermittently by short episodes in time. The synchronous events propagate from one neural

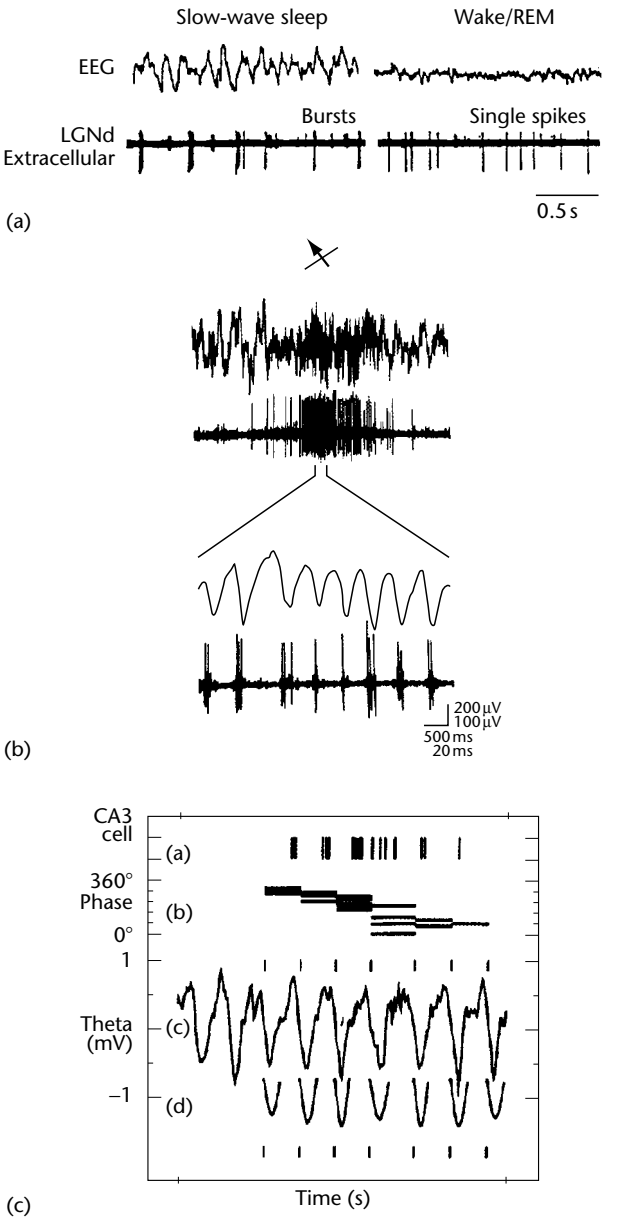

Figure 1. Neural rhythms correlated with behavior. (a) During slow-wave sleep, EEG shows slow synchronous oscillations and thalamic neurons in the dorsal lateral geniculate nucleus (LGNd) fire bursts of action potentials (left panels). In contrast, during waking or dreaming sleep (waking/REM), large-amplitude EEG oscillations are absent, and thalamic neurons fire single spikes tonically (right panels). assembly to another (e.g., in response to varying stimuli).

3. *Pathological rhythms* are associated with certain neurological conditions, such as spike-and-wave patterns (3–4 Hz) of epileptic seizures, or tremors (3–8 Hz) characteristic of Parkinson disease. They may be viewed as pathological cases of low-frequency and extremely synchronous oscillatory brain states.

Are there general principles for the rhythmogenesis in the brain? Typically, a coherent neural network rhythm is generated within a relatively localized brain circuit, which is nevertheless composed of many hundreds or thousands of neurons. Therefore studies of the neural mechanisms underlying brain rhythms provide an excellent means of investigating how circuit dynamics emerge from the interplay between synaptic and intrinsic cellular properties. There are two general questions with regard to the mechanisms of a coherent oscillation.

1. What determines its oscillation frequency? Are there pacemaker neurons or is the rhythmicity largely a network phenomenon?
2. What are the synaptic mechanisms for network synchronization?

These two issues will be examined in turn.

CELLULAR PACEMAKER MECHANISMS

Single neurons in the CNS are endowed with a large repertoire of voltage- and calcium-gated ion channels, distributed across the dendritic and somatic membrane, which can give rise to complex neuronal dynamics. In general, oscillation occurs in a single cell, when a strong fast positive feedback (generating the rising phase of membrane voltage) interacts with a slower negative feedback (producing the decay phase of the cycle). Positive feedback within a cell can be provided by activation of

voltage-gated inward Na^+ and/or Ca^{2+} currents, whereas negative feedback is mediated by either inactivation of inward currents or activation of outward K^+ currents. A group of neurons is described as pacemakers for a brain rhythm if (1) they are endowed with intrinsic membrane properties to display robust oscillations in a well-defined frequency range, and (2) that brain rhythm is critically dependent on the integrity of these cells.

Spindle sleep rhythm and rebound bursts in thalamic neurons

Spindle oscillations during quiet sleep originate in the thalamus, and have been reproduced *in vitro* in thalamic brain slices. It was discovered by Jahnsen and Llinás that thalamocortical projection cells and inhibitory neurons in the nucleus reticularis show two modes of firing patterns. On depolarization they discharge single spikes tonically, whereas on hyperpolarization they fire bursts of spikes, possibly in a rhythmic fashion (Figure 2(a), upper panel). During quiet sleep, thalamic cells are in the bursting mode and entrain the spindle oscillations in the entire thalamocortical system. Waking is associated with a switch of thalamic cells from the bursting to tonic firing mode, due to an increase in the neuromodulatory (cholinergic, noradrenergic and other) inputs.

The bursts of spikes are produced by a low-threshold voltage-gated Ca^{2+} ion channel I_T (of the T-type), which de-inactivates during hyperpolarization, and a hyperpolarization-activated cation channel I_h. Such a bursting mechanism is demonstrated by the single thalamic neuron model in Figure 2(a) (lower panel). Intuitively, rhythmic bursting can be generated as follows (Figure 2(a), upper panel). A hyperpolarizing input slowly activates I_h and de-inactivates I_T. The build-up of the I_T eventually leads to a depolarization wave that triggers a *rebound burst* of rapid (250–500 Hz) spikes. The burst is terminated by the inactivation of the same I_T at depolarized voltage, and the oscillatory cycle can start over again. The period of oscillation (*c.* 100 ms) is determined by the inactivation time constant of I_T and the activation time constant of I_h during hyperpolarization.

Gamma (c. 40 Hz) rhythm and chattering neurons in the neocortex

The mechanisms for the fast gamma (30–70 Hz) oscillations, commonly observed in waking and behaving states, have not yet been fully elucidated. In the neocortex, intrinsic gamma oscillations have been reported in a subclass of neurons termed 'chattering cells' (Figure 2(b), upper panel). These cells display repetitive burst firing in the gamma-frequency range, with intraburst spike rates of 300–500 Hz. A compartmental model suggests that the fast rhythmic bursting in chattering neurons is generated by a Ca^{2+}-independent ionic mechanism (Figure 2(b), lower panel). Instead, it relies on voltage-gated Na^+ currents in the dendrite. In this model, perisomatic action potentials propagate back to the dendritic sites, where an Na^+-dependent slow depolarization is produced, which in turn triggers more spikes in the soma. This somatodendritic 'ping-pong' interplay underlies a burst of spikes, which is terminated by the activation of a K^+ current. The de-activation of the K^+ current during hyperpolarization leads to recovery and eventually to the start of a new burst. Experimental evidence in support of such an Na^+-dependent, Ca^{2+}-independent mechanism has recently been reported from cortical slice studies. It has yet to be demonstrated that chattering neurons indeed play the role of pacemakers for gamma oscillations in the neocortex *in vivo*.

Hippocampal theta (7–10 Hz) rhythm and pacemaker neurons in the medial septum

The theta rhythm in the hippocampus and surrounding limbic structures is believed to be critically dependent on the input pathway from the medial septum, where pacemaker-like neural discharges have been observed. There are two major cell types in the septum, which are thought to play distinct roles in the generation of theta rhythm. Cholinergic cells slowly modulate the excitability of hippocampal neurons, whereas gamma-aminobutyrate (GABA)-ergic cells play the role of pacemakers. Recent physiological studies have revealed that non-cholinergic (putative GABA-ergic) neurons in the medial septum display robust intrinsic oscillations in the theta-frequency range, where clusters of spikes are inter-nested in time with episodes of *subthreshold membrane oscillations* (Figure 2(c), upper panel). Interestingly, similar membrane oscillations have been observed in single principal neurons of the rat olfactory bulb, which displays prominent gamma and theta rhythms. A conductance-based model (Figure 2(c), lower panel) suggests that such intrinsic rhythmicity can be generated by a low-threshold, slowly inactivating K^+ current I_{KS}. When the cell fires, the I_{KS} slowly de-inactivates during spike after-hyperpolarization, and a sufficiently large I_{KS} eventually terminates the spiking episode. When the cell does not fire spikes, I_{KS} slowly decreases due to inactivation, until the cell is sufficiently

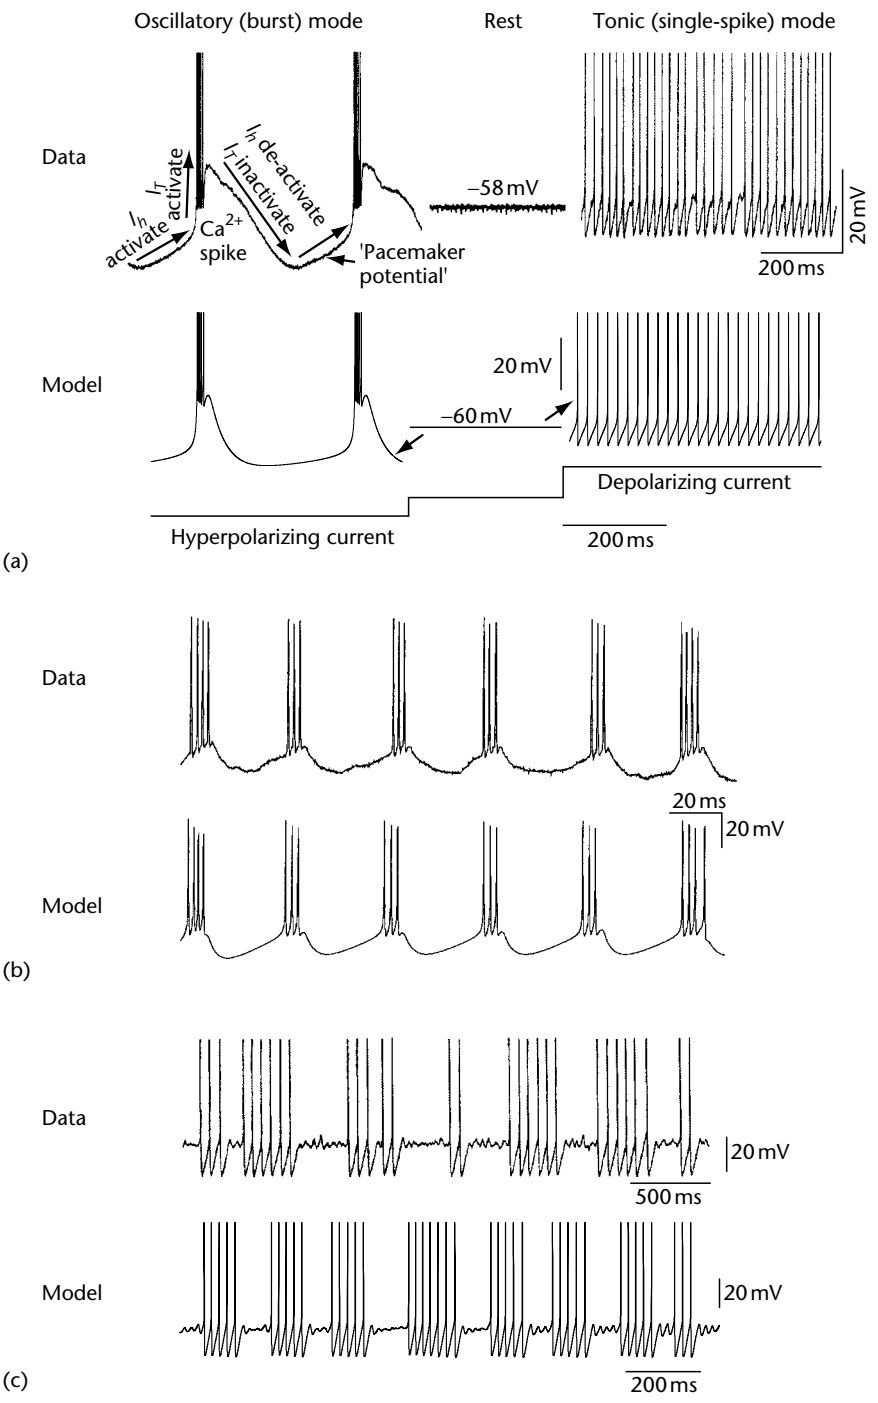

Figure 2. Intrinsic membrane oscillations of single neurons. Each panel shows experimental data and model simulations. (a) A thalamic relay cell displays two distinct spiking modes, namely tonic firing on depolarization, and burst discharges on hyperpolarization. Upper trace adapted from McCormick DA and Pape HC (1990) *Journal of Physiology* **431**: 319–342; lower trace adapted from Wang X-J (1994) *Neuroscience* **59**: 21–31. (b) A 'chattering' neuron from the cat visual cortex shows rhythmic bursting in the gamma-frequency range. Upper trace from Gray CM and McCormick DA (1996) *Science* **274**: 109–113; lower trace from Wang X-J (1999) *Neuroscience* **89**: 347–362. (c) A non-cholinergic (putative GABA-ergic) cell in the rat medial septum displays rhythmic alternations at theta frequency between 'clusters' of spikes and epochs of subthreshold membrane potential oscillations. Upper trace from Serafin M *et al*. (1996) *Neuroscience* **75**: 671–675; lower trace from Wang X-J (2002) *Journal of Neurophysiology* **87**: 889–900. The simulated oscillation is faster than the experimental data (see the different timescales), because the model simulation was performed at body temperature (37°C), whereas the *in-vitro* trace was recorded at 32°C.

recovered and can start to fire again. The subthreshold oscillations are produced by the interplay between an Na^+ current and the low-threshold activation of I_{KS}. In this model, the periodicity of the theta rhythm is largely controlled by a single current (the I_{KS}) in septal GABA-ergic cells. This hypothetical mechanism has not yet been tested experimentally.

Summary

To summarize, some general remarks can be made. First, a single neuron can display different dynamic (e.g., single-spiking and bursting) modes, which depend on the membrane potential level and are under neuromodulatory control. Secondly, there are at least two general classes of ionic mechanisms for rhythmogenesis, one of which depends on an interplay between Na^+ and K^+ currents, while the other depends on Ca^{2+} currents. Putative pacemaker neurons for the gamma and theta rhythms of the waking brain seem to rely on Na^+ and K^+ currents, whereas pacemaker neurons for the spindle and delta sleep rhythms are critically dependent on Ca^{2+} currents.

Thirdly, a given set of ion channels can generate qualitatively different membrane dynamics, depending on their relative strengths or their distributions across the dendro-somatic membrane. For example, I_T gives rise to subthreshold oscillations (at about 10 Hz) rather than bursts in inferior olive cells that send climbing fibers to the cerebellum.

Finally, subthreshold oscillations and repetitive bursting may have different implications for synchronization of coupled neurons. Subthreshold oscillations could subserve a signal carrier for phase-locking and resonance, by virtue of the cell's sensitivity to small but precisely timed inputs (at the peak of the membrane oscillation cycle). On the other hand, bursts may provide a reliable signal for the rhythmicity to be transmitted across probabilistic and unreliable synapses between neurons.

SYNAPTIC NETWORK MECHANISMS

A neural circuit, whether it is thalamic, neocortical or hippocampal, consists of two major cell types, namely excitatory principal neurons and inhibitory interneurons. It follows that three types of synchronization mechanisms by chemical synapses can be envisaged: recurrent excitation between principal neurons, mutual inhibition between interneurons, and feedback inhibition through the excitatory–inhibitory loop.

Recurrent Excitation Model

Recurrent excitatory connections have historically been the first synchronization mechanism to undergo detailed experimental and computational analysis. This was motivated by the observation that blockade of synaptic inhibition in a cortical network led to extremely synchronous neural firing patterns which resembled epileptic discharges. Intuitively, mutual excitation is expected to synchronize coupled neurons, if cells that fire earlier in time excite the others and advance their firing times, so that the network is brought to fire in phase. However, model simulations of biophysically realistic coupled neurons have shown that synaptic excitation often delays rather than advances the firing time in the postsynaptic cell (e.g., if its predominant effect is to increase a voltage-gated K^+ current). Therefore the ability of mutual excitation to synchronize depends on the intrinsic membrane properties of the constituent neurons (Hansel *et al.*, 1995; van Vreeswijk *et al.*, 1995). In general, synchronization of normal brain rhythms is not realized by excitation alone, but depends critically on synaptic inhibition.

Interneuronal Network Model

Computational studies have revealed that reciprocal synaptic inhibition is capable of synchronizing certain rhythmic activities in an interneuronal network (Wang and Rinzel, 1992; van Vreeswijk *et al.*, 1995). One general requirement for this mechanism is that the decay time of the inhibitory synaptic current should be long relative to the intrinsic membrane recovery time, and comparable with the oscillation period. For example, $GABA_B$-receptor-mediated inhibition with a time constant of 100–200 ms could in principle synchronize slow oscillations at a few hertz. $GABA_A$-receptor-mediated inhibition with a time constant of about 10 ms is too fast to syncronize an oscillation at a few hertz, but is sufficiently slow for a 40-Hz oscillation (with a period of about 25 ms) (Figure 3(a)). Indeed, a physiological study using *in-vitro* slices provided evidence that $GABA_A$-receptor-mediated inhibition in a hippocampal interneuronal network, without the involvement of pyramidal neurons, could give rise to coherent 40-Hz oscillations (Whittington *et al.*, 1995).

Thus the interneuronal network model suggests a candidate scenario for the gamma rhythmogenesis in the hippocampus. Because this mechanism requires an optimal match between the synaptic time constant and the oscillation period, coherent

network oscillations are possible only within a frequency range. In other words, synchronous oscillations with a well-defined frequency can be realized even without pacemaker neurons.

Feedback Inhibition Model

A competing network mechanism for coherent gamma oscillations is based on feedback between excitatory and inhibitory neural populations. W. J. Freeman first proposed this scenario to explain 40-Hz oscillations observed in the olfactory bulb. Similar models have been applied to the olfactory cortex and to the hippocampus.

A recent study (Fisahn *et al*., 1998) demonstrated such a scenario in hippocampal slices, where spontaneously occurring 40-Hz oscillations have been shown to depend on both excitatory and inhibitory synaptic transmissions. This experiment can be reproduced robustly in a network of pyramidal cells and interneurons, even in a randomly connected network model (Figure 3(b)). Thus the interneural network mechanism and the feedback inhibition mechanism do not have to be mutually exclusive. Rather, the two mechanisms are likely to operate cooperatively in a cortical network.

Note in Figure 3(b) that while the neural population as a whole oscillates in the 40-Hz frequency range, individual neurons fire more randomly and intermittently in time (at about 10 Hz for interneurons and only 2 Hz for principal cells), as is the case in the experiment of Fisahn *et al*. (1998). These intermittently firing dynamics are similar to neural firing activities during gamma rhythms of the intact brain. Such network dynamics cannot be adequately described in terms of coupled oscillators, with individual neurons firing regularly like a clock. A new conceptual framework is needed (Brunel, 2000) to describe coherent oscillations that emerge from complex and irregular firing patterns involving many thousands of neurons in a random network, in a very similar manner to the vivid picture envisioned by Sherrington 50 years ago.

Summary

A major conceptual advance resulting from experimental and computational work was the recognition that inhibitory neurons play a critical role in the synchronization of cortical networks. With the exception of pathological brain rhythms, synchronization of cortical oscillations appears to rely primarily on synaptic inhibition within interneuronal networks and/or through feedback between excitatory and inhibitory cells. Recent studies have revealed that electrical coupling as well as chemical synapses between interneurons could contribute to network synchronicity, and that diverse subclasses of interneurons could be involved in different types of cortical rhythms.

POSSIBLE FUNCTIONS

Neural oscillations are obviously the modus operandi of central pattern generators – neural circuits that produce rhythmic motor movements such as respiration and walking. At the other end of the sensorimotor continuum, in the early stages of sensory information processing, the functional role of network rhythms is less obvious. Several proposals have been advanced, all centered on the idea that neural representation of sensory inputs is dynamic (as opposed to static), distributed in both space and time. This *dynamic stimulus-encoding hypothesis* is supported by data from the olfactory system, where an odor stimulus induces fast oscillations in a number of odor-specific neural assemblies, each of which is briefly synchronized at a different time epoch of the population response. Such activity patterns of oscillating neural assemblies in temporal sequence may be important for encoding, perhaps for temporally dissecting, and ultimately for identifying an odor stimulus. In the hippocampus, the spike times of a pyramidal cell progressively shift to earlier phases of the population theta cycle when the animal passes through the cell's spatial field (Figure 1(c)). Therefore spike firing time relative to a network oscillation cycle, in addition to the firing rate, may contribute to the hippocampal coding of spatial trajectory for animal navigation.

It has been proposed that neural synchronization provides a substrate for feature integration. For example, groups of neurons that detect different local features of a visual object can encode ('bind') the integrated whole image by synchronization of their spike discharges. Note that synchronization between neurons (which is a much more general phenomenon) does not necessarily imply oscillations. Indeed, unit-recording data from the visual cortex indicate that synchronization between nearby neurons can occur without oscillations, but long-range (> 2 mm) synchronization often occurs concomitantly with fast neural oscillations. Similarly, synchronization of a neural assembly in the motor cortex could reflect an integrated representation and association of movement features in a skilled action. This *temporal correlation hypothesis* for the 'binding problem' is still the subject of active debate. The contentious issues include the

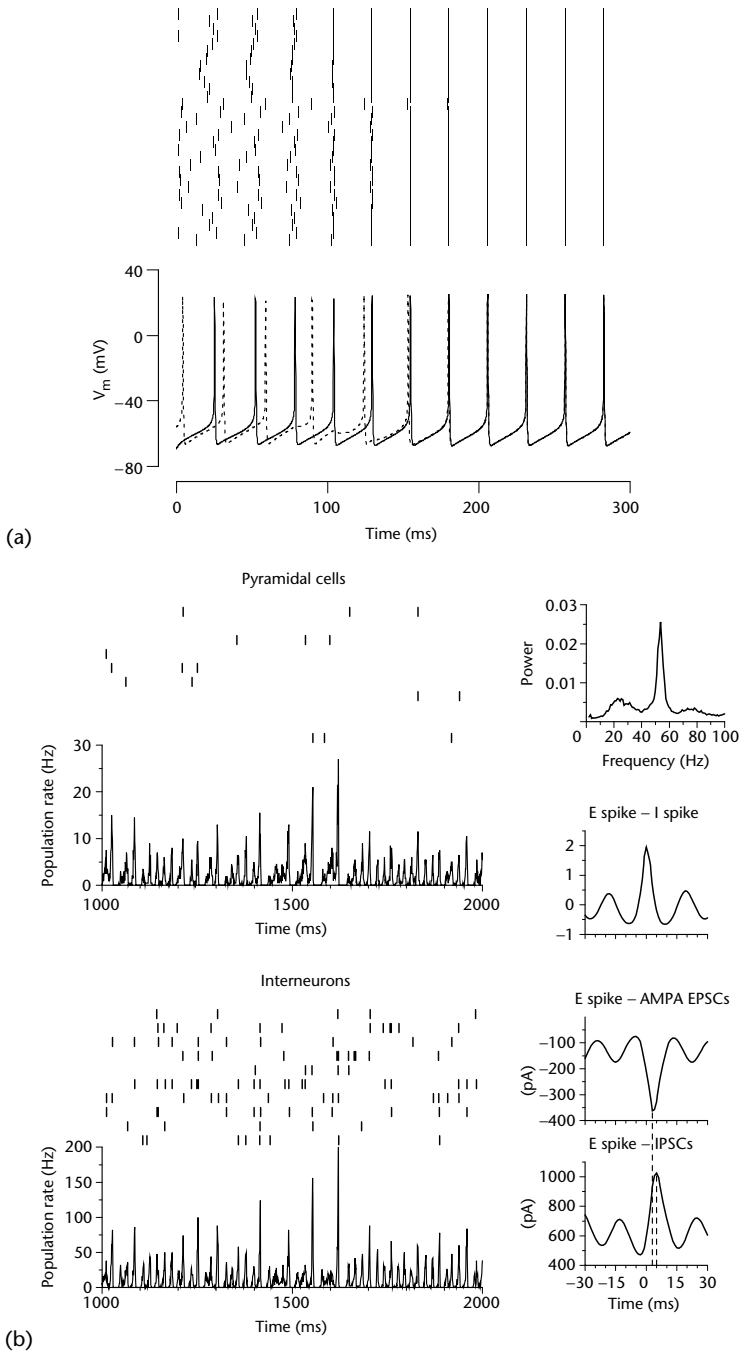

Figure 3. Synaptic mechanisms for network synchronization. (a) The interneuronal network model. A population of interneurons is synchronized at gamma frequencies, by mutually inhibitory connections mediated by $GABA_A$ receptors. Upper panel: the rastergram where each row of vertical bars represents spikes discharged by one of the neurons in the network. Neurons are intially out of phase, but quickly become perfectly synchronous after a few oscillation cycles. Lower panel: the membrane potentials of two neurons. From Wang X-J and Buzsáki G (1996) *Journal of Neuroscience* **16**: 6402–6413. (b) The feedback inhibition model. Computer simulation of a model with two neural populations (pyramidal cells and interneurons) in a sparsely connected random network. The network shows a collective oscillation at 55 Hz (see population rates, and the power spectrum), whereas single neurons fire spikes intermittently in time at low rates (2 Hz for pyramidal cells and 10 Hz for interneurons; see rastergrams). The spike discharges are synchronized to zero-phase between the two populations (second trace on the left), whereas the inhibitory synaptic current shows a phase lag of about 2 ms compared with the excitatory synaptic current (third and bottom traces on the left). From Brunel N and Wang X-J, unpublished data.

prevalence of the oscillatory activities in evoked neural responses, and the extent to which neural oscillations are correlated with sensory perception or motor behavior. Several physiological studies show that fast gamma-frequency-band oscillations in the primate motor cortex usually occur during the preparatory phase of a motor task, before the movement onset, rather than during the motor action itself. Therefore synchronous neural discharges may be associated with anticipation or planning.

Anticipation, planning, and other cognitive processes depend on association cortical areas. Neural circuits in these areas are believed to be highly recurrent, since reverberatory excitations are thought to generate the mnemonic persistent neural activities that are observed in association cortices. Since strongly recurrent network dynamics readily give rise to oscillations, it is possible that in the alert brain of behaving animals synchronous fast oscillations occur as a result of the activation of a highly recurrent cortical circuit (Wang, 1999). If this is so, one would expect an increased occurrence of cortical gamma oscillations with working memory or attention which requires top-down signals from the parietal and frontal cortices. Indeed, working memory (Pesaran *et al*., 2002) and selective attention (Fries *et al*., 2001) have been shown to enhance gamma oscillations in monkeys' cortices. These recent studies, if confirmed, suggest that fast (gamma) rhythm may be a characteristic sign of the engagement of strongly reverberatory cortical circuits in cognition and memory.

Neural Prostheses

Introductory article

John K Chapin, SUNY Health Science Center at Brooklyn, New York, USA

CONTENTS

A neural prosthesis is an electronic device that uses electrode stimulation to artificially activate muscle, nerve or brain tissue that has lost its normal functional capacity.

INTRODUCTION

A broad range of neural prostheses (or 'neuroprostheses') are now being developed to palliate neurological dysfunctions throughout the body. Nearly all of these devices transform electrical signals into neural signals by stimulating tissues through electrodes placed on the skin or implanted in peripheral or central nervous system (CNS) structures. The full potential of neural prostheses for restoring human nervous system function has not yet been achieved, though a few such devices are already widely used.

AUDITORY PROSTHESES

The cochlear implant is widely recognized as the most effective means for restoring auditory sensation in patients with sensorineural hearing loss. This disorder involves partial degeneration of the peripheral processes of spiral ganglion cells that normally carry auditory signals from the auditory receptor (hair) cells in the cochlea. The central processes of these ganglion cells, which normally transmit these auditory signals through the auditory nerve to the brain, are less affected. Cochlear implants bypass the degenerated peripheral processes by using microphones to record incoming sounds and then processing them into electrical signals that directly stimulate the neural fibers in the cochlea through implanted electrodes. Since the cochlea contains a 'tonotopic' map, multiple electrodes are needed to transfer differentially high and low tones to the auditory system. Recent research suggests, however, that this stimulation does not by itself produce a sufficiently high fidelity of sound transmission to allow patients to understand normal human speech. Instead, auditory perception in some patients with cochlear implants appears to be sufficiently enhanced by a general increase in auditory nerve cell activity produced by the electrical stimulation (the activity of these nerve cells is severely degraded in sensorineural hearing loss). One hypothesis is that merely increasing the noise input to the auditory nerve cells allows them to more easily transmit natural auditory signals from the receptor cells.

In cases where the hearing loss is caused by damage to the auditory nerve itself, auditory brainstem implants can be placed over the surface of the cochlear nucleus, which is the primary CNS target of the auditory nerve. Current research is focusing on increasing the accuracy and efficiency of such stimulation by implanting stimulating electrodes directly into the cochlear nucleus. Advanced thin-film technologies allow such electrodes to be designed and fabricated to include relatively large numbers of stimulus contacts on arrays of thin 'daggers' that penetrate through the auditory representation in the nucleus. By increasing the packing density of these contacts it will be possible to activate selectively large numbers of functionally specific neural targets using minimal stimulus currents. Some issues remain to be resolved, particularly that of decreasing the nonspecific and artifactual effects of electrical brain stimulation to ensure that the sensory perceptions evoked in the patient are as natural as possible. Although these technologies are currently far from adequate, the use of high-density penetrating electrode arrays might one day allow the extension of the neural prosthetic approach to the restoration of function in the brain itself.

VISUAL PROSTHESES

Despite the possibility of implanting neural prostheses in higher brain areas, most attention still focuses on peripheral sites. Thus, while early

investigations found some success in using electrode arrays to stimulate the surface of the visual cortex, current efforts to develop visual prostheses are focusing more on the development of microfabricated multi-electrode arrays for implantation on the retina. Although this technology is still in its infancy, it could theoretically allow one to input relatively detailed stimulation patterns into the visual system. It remains to be determined, however, whether such large numbers of individual stimuli can be perceived as an integrated visual percept.

SOMATOSENSORY PROSTHESES

As with the other sensory systems, most investigations of neural prostheses in the somatosensory system are focused on the periphery. Nerve cuff electrodes are being developed not only to stimulate nerve fibers that have been disconnected by injury or amputation, but also to record impulse activity of intact peripheral sensory nerves. The latter may ultimately be important for the restoration of somatosensory function after spinal cord injury. In this scenario, neural activity recorded in peripheral sensory nerves would be used to actuate stimulating neural prostheses implanted in somatosensory pathways on the proximal side of the spinal cord lesion.

FUNCTIONAL ELECTRICAL STIMULATION

Many neural prosthesis applications involve the use of implanted or surface electrodes for functional electrical stimulation (FES) of muscles or muscle nerves (functional neuromuscular stimulation, FNS). The cardiac pacemaker might be considered as the prototypical FES neural prosthesis in that it uses electrical stimulation to restore function normally mediated by endogenous neuromuscular control mechanisms.

Implanted FES devices are also used to remedy autonomic or motor dysfunctions caused by spinal cord injury (SCI). For example, SCI-related bowel and bladder dysfunction can be remedied by using implanted neural prostheses to stimulate the nerves that normally control these organs. Similarly, neural prosthetic stimulators implanted on the phrenic nerves or the diaphragm muscles are used to pace breathing movements in patients with SCI-induced respiratory muscle paralysis. Finally, FES stimulators have been widely studied for their potential to activate the limb musculature of paralysis patients. This approach is useful not only because of its ability to produce movements, but also because it can allow paralyzed patients to exercise their muscles in order to maintain their trophic integrity. Traditionally, stimulating electrodes mounted on the skin surface have been used to activate specific groups of skeletal muscles in patients with various paralysis syndromes. An early example was the alleviation of 'foot-drop' by stimulating the nerve that lifts the foot up during stepping. More recently, FES stimulation electrodes have been implanted in or near target muscle groups. Although these implanted systems present somewhat greater risks of infection, they can produce more specific movements with lower stimulus currents and hence less tissue pathology than is caused by surface electrodes. Much effort is currently being devoted to the development of FES stimulating electrodes that do not require implanting wires through the skin, but instead are implanted with data receivers and inductive power systems that allow them to be controlled and sustained through wireless connections.

There are, however, unresolved problems with the use of FES to activate muscles directly. For example, such stimulation activates both sensory and motor fibers within these nerves. Thus the same nerve stimulation that produces bladder contraction also stimulates a reflex loop that closes the bladder's sphincter, preventing urine from flowing out. For this reason, such patients often require surgical sectioning of the sensory nerves that mediate this reflex (posterior rhizotomy) to ensure that the sphincter is relaxed during bladder voiding. Another problem is that muscle nerve stimulation tends to recruit muscle fibers in an incorrect order, producing movements that are jerky and difficult to control. This is just one of many problems that prevent the clean and selective stimulation of all the muscles that are normally used to produce smoothly coordinated movements.

One possible solution to these problems may be to activate movements by stimulating through electrodes implanted in interneuron pools in the spinal cord. In theory, spinal cord neural prostheses could be more effective and less cumbersome than traditional FES devices. Moreover, spinal circuits are thought to help integrate and finely coordinate the timing and recruitment of different muscles, and also to regulate sensory feedback from the periphery. Current investigations are determining whether spinal cord implants can selectively activate these circuits and thereby elicit smoothly coordinated patterns of muscle contraction. For example, through stimulation of the appropriate subzone of the sacral spinal cord one might

produce simultaneous bladder contraction and urethral sphincter relaxation, thus obviating the need to perform posterior rhizotomy. Recent research suggests that spinal cord stimulation may also improve neuroprosthetic control of limb movements. Localized microstimulation of spinal interneuron pools can produce integrated multi-muscle directional movements and also a relatively normal order of muscle fiber recruitment.

PROSTHETIC CONTROL

Along with technological improvements in FES systems and other neural prostheses to activate motor systems, one must also improve the methods for controlling them. Current motor prostheses tend to employ either mechanical or electromyographic (EMG) recordings from unparalyzed body parts (e.g. the shoulder) to allow the patient to control the prosthesis. Electroencephalographic (EEG) recordings from scalp electrodes have even been used to allow paraplegics to move computer cursors slowly across a screen to spell words. To obtain natural and efficient control of a body limb, however, the command signals would best be recorded directly from the areas of the nervous system that are normally used to process that motor function. It has long been known that voluntary movements are planned and executed through neural processing in the primary and premotor cortices, and that various mechanical parameters of such movements are encoded in the spiking activity of neurons in these brain areas. Although single neuron recordings cannot provide enough information to drive a motor prosthesis, technology is now available for simultaneously recording more than 100 neurons from the brains of rats and monkeys performing trained limb movements. Moreover, it has recently been shown that it is possible to use online computers to 'decode', in real time, the motor control information from such simultaneously recorded neuronal populations and to use this motor information to move a robot arm. These results have demonstrated the essential feasibility of using cortical recording arrays to allow paralyzed patients to control an external robot arm, or even an FES device.

One potential problem is that it may be difficult to extract appropriate motor signals from the motor cortices of long-term paralysis patients. Indeed, it is generally believed that functionally deprived cortical areas tend to be 'remapped' to assume the functions of adjacent areas. This potential problem may, however, be solved by the patient's own ability to adapt and learn. In fact, recent studies have shown that animals using their cortical neurons to control a robot arm can rapidly adapt these neurons to optimize this control. Thus human quadriplegics might, with practice, learn to use their motor cortical 'arm' areas to control a robot arm, an orthotic device, or even their real arm via neural prosthetic stimulators implanted in the muscles or the spinal cord.

Neural Regeneration

Introductory article

Christine E Bandtlow, University of Innsbruck, Innsbruck, Austria
Thomas Oertle, University of Zurich, Zurich, Switzerland

CONTENTS

In the mammalian nervous system nerve fibers of the peripheral nervous system can regrow upon injury; in contrast, fibers of the central nervous system lack this regenerative capacity. Research into the molecular and cellular processes of nerve repair is improving the prospects of successful treatment of spinal cord injury.

INTRODUCTION

Restoration of axonal function after nerve damage is not only a topic of great research interest, it is also an area of vital concern to people with spinal cord injuries. A prerequisite for functional recovery is the successful regeneration of the injured axons; this depends on many factors, such as survival of the corresponding cell body, the elongation and growth of newly sprouted fibers, and establishment of contacts with the appropriate targets. Cold-blooded vertebrates such as fish and amphibia have been used extensively to study the biochemistry of successful regeneration of both the central nervous system (CNS) and the peripheral nervous system (PNS). In adult mammals, however, an intriguing difference is observed when comparing the capacity to regenerate axons in the CNS versus PNS. The mammalian PNS is able to support axonal regeneration, often resulting in functional restoration of nerve circuits; in the CNS, however, although nerve fibers initially start to sprout, they fail to regenerate over long distances to contact their target cells, resulting in the permanent loss of function.

REACTION OF NEURONS TO INJURY

Injury or trauma of the nervous system can vary from minor contusions or crushes to open injuries associated with partial or even complete disruption of the nerves. Any type of axonal injury induces an array of dramatic molecular and cellular responses at the level of the cell bodies and at the site of the injury. Following an injury, a sequence of reactions takes place that has a direct impact on the potential for successful regeneration. One of the most immediate changes is the destruction of tissue at the site of the injury, or lesion, which can vary greatly depending on how the injury occurs. Damage to the axons of nerve cells may lead in its most severe form to the complete transection of the nerve fiber and thus to the subsequent death of the neuronal cell body. The most important requirement for regeneration of injured axons is the successful survival of the nerve cell bodies and their capacity to meet the new commands to initiate axonal regrowth and reconnection with the original targets. The closer the axonal insult occurs to the cell body, the less likely it is that the neuron can be maintained in a healthy state. Injuries that sever axons some distance from the cell body produce a severe reduction in neuronal size (atrophy) several weeks after axotomy, but the neurons will normally survive. Surviving neurons switch their metabolism in such a way that restoration of the axon will be facilitated. They undergo morphological and molecular changes involving major rearrangements of the endoplasmic reticulum and Golgi apparatus, a process referred to as chromatolysis. Chromatolysis is often accompanied by an increase in expression of a set of genes associated with axon growth and protein synthesis. These metabolic changes probably meet the affected cell's requirements to initiate regeneration. Even if the cell ultimately survives the injury, the nerve terminals and the entire segment distal to the lesion site (i.e. the one that has lost contact with the cell body) will degenerate. This process, called 'Wallerian degeneration', is associated with myelin breakdown and the removal of axon and myelin debris. Early experimentation in the field of regeneration in

mammals indicated that regrowth of axons could occur in the peripheral nervous system, such as the nerves of the arms and legs. However, similar experiments performed in the CNS suggested that damaged neurons of the CNS could not regrow. For this reason, it was long believed that there is a primary difference between the regenerative capacity of central and of peripheral neurons which may explain the lack of successful regeneration of fibers after spinal cord injuries.

NEURONAL REGENERATION IN THE PERIPHERAL NERVOUS SYSTEM

Damage to the PNS is frequently reversible. Under certain circumstances neurons are able to survive and regenerate their axonal projections to reestablish contact with their former target cells. Provided that such connections are regained, a considerable degree of function can be restored. The reason peripheral neurons are more likely to survive axonal damage may be due to many factors, both intrinsic and extrinsic to the neurons. Studies of the development of peripheral nerves demonstrated that neurons require an array of neurotrophic factors for survival and maintenance. These factors are not only important in the development of the PNS but also in regeneration. Neurotrophic factors are polypeptides required for survival of discrete neuronal populations (sensory, sympathetic, motor neurons). They are divided into three major families: the neurotrophins, the cytokines, and the transforming growth factor family. Such trophic factors are produced by many different sources, such as the innervated target cells and the axon-surrounding glial cells, the Schwann cells. Production of neurotrophic factors by Schwann cells may explain why the closer the axonal injury is to the cell body, the less likely the neuron is to survive.

Upon damage to the PNS a remarkable sequence of cellular and molecular changes, associated with Wallerian degeneration, occur in the distal nerve segment. Morphological changes appear in the distal nerve segments during the first 3 days after injury, the segments becoming fragmented and starting to shrink, and within a few weeks the entire distal segment is destroyed. One of the first cellular responses is the proliferation and infiltration of macrophages. Macrophages are predominantly recruited from the circulating pool of hematogenous monocytes. This response begins within 2 days of axonal injury and reaches its peak by 4–7 days. Macrophages have an enormous phagocytic ability and can remove myelin and axonal debris within a few days. This is in sharp contrast to the CNS, where myelin clearance may take months. After the initial extrusion of myelin debris by macrophages, Schwann cells that are normally in close contact with the axon detach, dedifferentiate and proliferate. Dividing Schwann cells line up along the preserved basal lamina tube that surrounded the original fiber to form endoneurial Schwann cell tubes (bands of Büngner) which function as channels for regenerating sprouts from the proximal segment. Most importantly, however, Schwann cells prepare the local environment that supports and guides regenerating nerve fibers to their denervated targets. They not only produce a variety of cell surface molecules and basement membrane components that support neurite growth, they also express neurotrophic factors and their corresponding receptors to ensure the survival of regenerating axons and their corresponding cell bodies.

Full recovery from nerve injury requires reestablishment of connections between neurons and their appropriate targets. Reinnervation is more accurate after crush lesions than after transections. In a crush injury axons are severed, but the integrity of the nerve sheaths and the basement membrane of myelinated axons is maintained. Regenerating axons seem to prefer to grow inside the internal structures of endoneural Schwann cell tubes, suggesting that the basement membrane is essential as a guidance structure for growing axons to find their appropriate targets. In contrast, a completely transected nerve with separation of the proximal and distal nerve stumps will not successfully regenerate without surgical intervention, despite the proliferation of Schwann cells and fibroblasts at the site of the lesion. The ability of axons to sprout from the proximal stump towards the distal stump is limited to a few millimeters. To facilitate axonal crossing of the gap, microsurgical repair is often required to bring the ends of the nerve together as closely as possible. Large gaps, however, need to be bridged in some way. A common method is to use an autografted nerve segment which already contains Schwann cells, essential for axonal regeneration. However, if several pieces of nerve are required (e.g. to repair complex, highly branched nerves like the brachial plexus) the material available for grafting is often limited. In view of this problem, alternative methods are being developed which encourage axonal regeneration between the cut ends of the nerve stumps. Using tubes of silicone or other materials to bridge the gaps, axons can regenerate up to 1 cm between the stumps of the cut nerves. To encourage axons to grow over even

longer distances, a variety of materials including Schwann cells or trophic factors and extracellular matrix (ECM) molecules which are known to stimulate axonal growth have been inserted into the tubes.

The rate of regeneration depends not only on the type of injury but also on the age and type of fibers that are affected. In experimental animals such as rodents, the rate of axonal elongation is 3–4 mm per day in a crushed nerve, but only 2.5 mm per day after a complete transection. In humans the distances over which nerves must regenerate are correspondingly longer and the daily growth rate may be only 1–1.5 mm. Since delay in reinnervation may result in atrophy of the endoneurial tubes and (more importantly) degeneration of the denervated muscles, there has been considerable interest in speeding up regeneration. Various methods have been used including electromagnetic stimulation and treatment with hormones or trophic factors that have been shown to stimulate neural growth in a culture dish. Reinnervation of denervated target organs such as muscle and skin is a prerequisite for functional recovery. Most often it occurs with a relatively high specificity, even from mixed sensory and motor nerves. However, experimental observations also indicate that regenerating fibers explore several pathways by sending out sprouts (collateral branches) into inappropriate endoneurial tubes, which results in disorganization and imprecision of their innervation patterns.

NEURONAL REGENERATION IN THE CENTRAL NERVOUS SYSTEM

In contrast to peripheral nerves, damaged axons in the adult mammalian brain and the spinal cord do not spontaneously regenerate and consequently there is little functional recovery. When a spinal cord injury occurs, many axons are damaged or destroyed, which disrupts communication of signals between the brain and neurons below the level of the injury. As a result, normal bodily functions are impaired or lost. The extent of paralysis depends on the severity and location of the damage. If the site of injury occurs at the waist, only movement and sensation to the legs are lost. The closer the level of injury is to the brain, the more extensive the loss.

The CNS Reaction to Injury

An injured CNS axon does have an encouraging initial response to axotomy. As in the PNS, the surviving proximal segment of the axon is seen to exhibit a regenerative response within 6 h of injury as 'sprouts' develop at the severed nerve end which are directed towards the injury site. Disappointingly, these sprouts are able to extend for only up to 1 mm before growth is aborted and the new sprouts are gradually resorbed and retracted. The reason why the regenerative process cannot be furthered is likely to be multifactorial, given the complexity of the CNS.

Intrinsic Neuronal Properties

One major hurdle is that injured CNS neurons often fail to reinitiate and maintain a general growth program required for axonal elongation. In the PNS, particular growth-associated proteins (GAPs) and cytoskeletal proteins typically present in growing axons during development are reexpressed upon injury, and remain increased throughout the regenerative period. In contrast, the initial upregulation of such proteins is often only transitory or completely absent in the majority of injured CNS neurons. The sustained reactivation of the genes expressing these proteins appears to be crucial in determining the success or failure of axon regeneration.

Extrinsic Factors

The CNS as a nonconducive growth environment

Besides the differential regulation of intrinsic properties that determine a neuron's commitment to regrow, the local environment of the CNS tissue is nonconducive to neuronal growth. Even peripheral neurons which are able to regrow in PNS tissue show only limited growth when transplanted into the brain or spinal cord of adult vertebrates. In contrast, injured CNS neurons were seen to grow through peripheral nerve grafts which were transplanted as bridges into the brain or spinal cord of adult rats. Fibers that entered the grafts ceased growth, however, when they reentered CNS tissue. These experiments demonstrated that (a) adult CNS neurons process mechanisms for axonal growth over long distances if they are provided with an appropriate environment; and (b) adult CNS tissue is unfavorable for neuronal growth. What are the molecular signals that make the CNS tissue such a poor environment for nerve repair? Several different cell types are involved in the CNS injury response, and these are recruited at different times. Thus, the environment of a cut axon that is

trying to regenerate will vary over time, particularly in the first 2 weeks after injury.

Secondary cell death

An important event induced within the first few hours after CNS injury is the development of secondary injury changes; these take place at the damaged area for a prolonged period after the injury and can include tissue swelling, chemical imbalances within the tissue, and delayed death of cells within the lesion. The secondary injury was long thought to be due to the continuation of cellular destruction through necrotic (or passive) cell death. However, evidence from brain injury and ischemia suggested that cellular apoptosis, an active form of cell death, could have a role in CNS injury in adulthood. Apoptosis occurs mainly in populations of neurons and oligodendrocytes. The death of oligodendrocytes in white-matter tracts continues for many weeks after injury and may contribute to postinjury demyelination. The mediators of injury-induced apoptosis are not well understood, but there is a close relationship between recruitment of CNS microglia, peripheral monocytes and cell death, suggesting that proinflammatory responses may play an important part. Microglial cells are activated by CNS injury, then divide and migrate to injury sites. After 24 h CNS injuries therefore contain large numbers of activated microglial cells, and they may also contain large numbers of blood-derived macrophages if the vasculature has been damaged. These cells are certainly capable of producing toxic molecules. Activated microglia have most of the properties of macrophages, and when stimulated can undergo a respiratory burst and release free radicals, nitric oxide, arachidonic acid derivatives and other toxic molecules. However, there is also evidence that microglia and macrophages (as in the PNS) can be neuroprotective and help to stimulate the repair response. Whether these cells are beneficial or harmful for nerve repair in the CNS is therefore somewhat controversial.

The glial scar at lesion sites

Traumatic injury to the adult CNS results furthermore in a rapid response from resident astrocytes around the injury site, a process often referred to as reactive astrogliosis or glial scarring. Although the functional role of glial scarring is not completely understood, it has been suggested to be an attempt made by the CNS to restore homeostasis through isolation of the damaged region. There are many different glial cells and cellular signals involved in the formation of the glial scar. Besides astrocytes, leptomeningeal cells, which are normally found on the surface of the CNS, as well as fibroblasts migrate towards the injured site. Within 3–5 days after injury, these cells create a dense plexus by interdigitating their processes and thereby walling off the lesioned region. In order for axons to regenerate, they must grow across the damaged tissue left by the injury, as well as this scar tissue. Observations of the course of fibers at lesion sites show that in adult mammals these scars are not penetrated by regrowing fibers. The high density of the astrocytic process network may provide a physical barrier to the axons. More recent experimental studies question whether this limited growth through scar tissues is simply the result of a physical barrier created by the density or the three-dimensional geometry of the scar. It seems likely that changes in the molecular properties of cells forming the scar create a nonpermissive or inhibitory environment that prevents fiber penetration. Associated with the glial scar is an increased deposition of a number of ECM molecules including tenascin-R, collagens III and IV and chondroitin sulfate proteoglycans. Many of these molecules have been shown to repulse or inhibit neurite outgrowth of a variety of neurons *in vitro* and are therefore strong candidates that prevent regenerative responses of CNS neurons *in vivo*. The molecular signals that induce the upregulation of these proteins are not well established, however.

Myelin-associated neurite growth inhibitors

Central nervous system injuries – in particular spinal cord injuries – are associated with direct damage to myelin sheets leading to the immediate release of myelin debris at the lesion site. It has long been recognized that CNS myelin and the cells that produce it (the oligodendrocytes) inhibit neurite growth *in vitro*. Consistent with this view is the observation that CNS injuries in very young mammals, i.e. before the onset of fiber myelination, are not detrimental for axonal regeneration and often lead to full functional restoration. Furthermore, a delay of myelination in experimental models prolonged the period during which regeneration of injured fibers was possible. Following the realization that myelin in the CNS impedes axonal regrowth, a number of myelin-specific inhibitors have been identified, such as the protein NI250 or Nogo-A, myelin-associated glycoprotein (MAG), tenascin-R and chondroitin sulfate proteoglycans. These molecules are capable of preventing the growth of nerve fibers *in vitro*. The main evidence for the inhibitory effect of myelin on CNS regeneration *in vivo* comes from experiments using

antibodies that neutralize one of the myelin inhibitory molecules, NI250/Nogo-A. In the damaged spinal cord, blockade of this molecule with antibodies can improve regrowth of axons and motor function in experimental animals. It seems that intact myelin may not be inhibitory *per se* but is most inhibitory to axon regeneration where there has been substantial trauma to the CNS. Inhibitory components or inhibitory domains of proteins will become exposed immediately after injury where the damage has actually disrupted myelinated axons. Myelin debris containing inhibitory components will be present not only at the lesion site, but also distal to the lesion site in degenerating myelinated tracts when axons and their surrounding myelin fragment over a period of days following axotomy. In contrast to the PNS, the debris is removed only slowly owing to the low phagocytic activity of the CNS microglial/macrophage cells, and may remain for several months.

REGENERATION IN FISH AND AMPHIBIA

In contrast to mammals, lower vertebrates show spontaneous recovery after injury. This observation is reflected in the difference of epimorphic regeneration in general. When a planarian worm is transected, the head fragment is able to regenerate the tail, and the tail fragment regenerates a new head structure. An adult urodele is capable of regenerating its limbs, tail, jaws, retinas and eye lenses, neural crest, spinal cord and heart ventricle. A teleost fish can regenerate not only its fins but also its spinal cord. Crucial for the absence of these epimorphic regenerative processes is the lack of apparent cellular dedifferentiation in higher vertebrates, i.e. they lack the capacity to successfully reenter the cell cycle from the differentiated state.

Behavioral observations in fish and amphibians also provide evidence for a successful axonal regeneration process in the CNS giving rise to functional recovery. Fish are paralyzed immediately after a spinal transection. They tend to lie on their sides, unable to move their tail and caudal fins. After several weeks, however, their swimming ability is regained. Although there is evidence that not all classes of axons regenerate equally well when severed, the question remains why anamniotes show an excellent capacity for axonal regeneration. One likely explanation is the observation that the CNS tissue in anamniotes responds to an insult in ways that promote regeneration rather than impeding it as seen in amniotes. Spinal cord axotomy in an adult fish appears not to induce cell death among neurons projecting from the brain to the spinal cord. At present the reasons that enable fish CNS neurons to survive after axotomy remains unknown. The identification of genes involved in the axotomy-induced death pathways in mammals may help to elucidate whether similar mechanisms are present in fish and how they are regulated after a lesion.

At the morphological level two observations stand out that distinguish the reaction of the fish CNS from the mammalian. There is no conspicuous glial scar formation, and there is a robust infiltration of macrophages. After a spinal cord lesion in the goldfish, astrocytes seem to dedifferentiate and together with fibroblasts and Schwann cells fill in the gap resulting from the injury. Repopulation of the lesion gap by immature astrocytes has been proposed to support axonal regeneration in the fish as they may produce factors that enhance axonal regrowth. Furthermore, following injury, the number of macrophages and microglia increases dramatically at the lesion site. As in the mammalian PNS, these cells help to remove axonal and myelin debris and may conceivably speed up the removal of putative inhibitory proteins from the local environment. In addition, macrophages may also secrete factors that support axonal regeneration. Another striking difference between the fish and the mammalian CNS is the long-lasting upregulation of growth-associated molecules in neurons of the fish brain that show relatively high rates of regenerative success. Whether the presence of inhibitory molecules associated with oligodendrocytes and myelin, such as MAG and Nogo-A, is a fundamental property distinguishing mammals from fish is not entirely clear, and is a question that will only be solved when the corresponding fish orthologs are cloned. The possibility that such inhibitors are present, although in lower amounts than in the mammalian CNS, cannot be excluded. While in adult mammals regeneration of somatic axons is often inaccurate, resulting in severe motor dysfunction, regeneration of sensory and motor axons in amphibia is quite accurate. In urodeles, regenerating axons find their correct destinations although they may not use their original trajection. It appears that the selective innervation of muscles is based on positional information and the involvement of target recognition molecules. In newts and frogs, motor nerves can be induced to innervate incorrect muscles, but the synapses formed are less stable and release of neurotransmitter per nerve impulse is reduced. In mammals, in contrast, the synapses formed when a nerve innervates an incorrect muscle are as effective as those in correct muscles.

TREATMENT OF SPINAL INJURY

For many years it was believed that the brain and the spinal cord were a hard-wired system where any type of fiber regrowth was truly impossible. However, research into the molecular and cellular signals that impair nerve repair in the CNS has raised hopes that regeneration can be induced under certain conditions.

Current Treatment

A therapy that is already in use in humans with spinal cord injuries is treatment with methylprednisolone, a steroid drug which must be administered to a patient within a short period after the injury. It is believed that this drug acts by preventing the secondary changes after injury, allowing more spinal cord tissue to remain healthy and functional. Patients who have received methylprednisolone treatment show a greater recovery of motor and sensory function than do patients with similar injuries who have not received treatment. The success of methylprednisolone in treating spinal cord injuries has stimulated research to characterize all the damaging events that take place in the spinal cord in the days and weeks following an injury and to develop drugs that can block these events. Efforts to control the glial scar, to block inhibitory proteoglycans expressed in these regions, and to prevent the secondary cell damage resulting in cavitation are required to improve regeneration.

Transplantation

One important area of continuing research is the transplantation of different types of tissue and materials into the site of the spinal cord injury to connect the ends of the damaged spinal cord. These materials can produce an environment that is highly conducive to the growth of axons. Success has already been achieved in animals using transplants of nerves from the PNS and tissue from the spinal cords of embryonic animals. Tissue from the PNS is believed to be helpful because regeneration of nerves does occur in this part of the nervous system. Embryonic tissue may promote growth because it is still developing and may provide a supportive environment for growing nerve fibers. Transplantation technology has been advancing at a rapid rate, and many different techniques are currently being optimized for use in spinal cord injuries. To overcome the cavitation resulting from tissue necrosis, Schwann cell tissue, olfactory ensheathing (glial) cells or tanycytes have been successfully grafted. These transplanted bridging tissues not only provide a permissive pathway to nerve regeneration, but could also represent sources of trophic support. Schwann cells use cell adhesion molecules and tight junctions to provide morphological stabilization of the contact with the elongating axon, as well as small-scale gap junctions to facilitate traffic of substances between them.

Neural Transplantation

Introductory article

Stephen B Dunnett, Cardiff University, Cardiff, Wales, UK

CONTENTS

Neural transplantation is the transplantation of nerve cells and tissues into the brain and spinal cord. First developed as an experimental strategy to study development and plasticity in the brain, it has led to new strategies to treat injury or disease throughout the nervous system.

INTRODUCTION

For fifty years after the publication of *Degeneration and Regeneration of the Nervous System* by Ramóny Cajal, neurology was dominated by the widespread belief that all regeneration was 'abortive' in the mature central nervous system (CNS), with the consequence that early attempts to transplant nerve cells in the brain were widely ignored – even when successful. The turning point came in 1969 and 1970 with two seminal studies: the demonstration by Geoff Raisman in London that adult axons can sprout to reinnervate vacated synapses, and a second by Lars Olson and colleagues in Stockholm that neuroendocrine cells from the adrenal gland and developing neurons of the embryonic brain can survive transplantation into the adult eye. These studies confirmed that growth and plasticity are indeed possible in the mature CNS, and quickly led to the discovery of new methods for transplantation of neurons in the adult mammalian brain, leading to novel strategies for cellular repair of damage in the brain and spinal cord associated with a variety of forms of trauma, injury, and neurodegenerative diseases. (*See* **Neural Development**; **Neural Degeneration**; **Neural Regeneration**; **Brain Damage, Treatment and Recovery from**)

NEURAL TRANSPLANTATION

Methodology for Fetal Cells

For transplantation of CNS neurons it is necessary to employ donor tissues harvested from embryos at the time of initial formation of those cells in early development. A variety of methods are available (Figure 1), including implantation as solid pieces of tissue into natural cavities of the brain (such as the ventricles), or injection of the tissue in fragments or as suspensions of dissociated cells directly into the host brain tissue. Provided the critical developmental time window is selected and that the grafts are positioned in a site where they can acquire the necessary nutrients by access to the host blood circulation, transplantation of embryonic neuron into the brain and spinal cord can be achieved reliably and reproducibly, whether the recipient is immature, adult, or aging.

Peripheral Tissues

In contrast to CNS neurons, glial cells and peripheral neurons (which continue to divide throughout life) can survive transplantation from neonatal and adult donors as well as from embryos.

Immunology

The brain has been found to be an immunologically privileged site. Neural tissues exhibit relatively low immunogenicity. Moreover, in contrast to other organs and tissues of the body, allografts (i.e. from the same species) implanted into the brain are protected behind the blood–brain barrier and are not recognized as foreign by the host immune system. However, once species boundaries are crossed, xenografts (i.e. from different species) are much more susceptible to rejection but can still be protected using immunosuppressant drugs.

FUNCTIONAL NEURAL TRANSPLANTATION

Neuroendocrine Grafts

The first systematic study of functional recovery following transplantation into the brain was

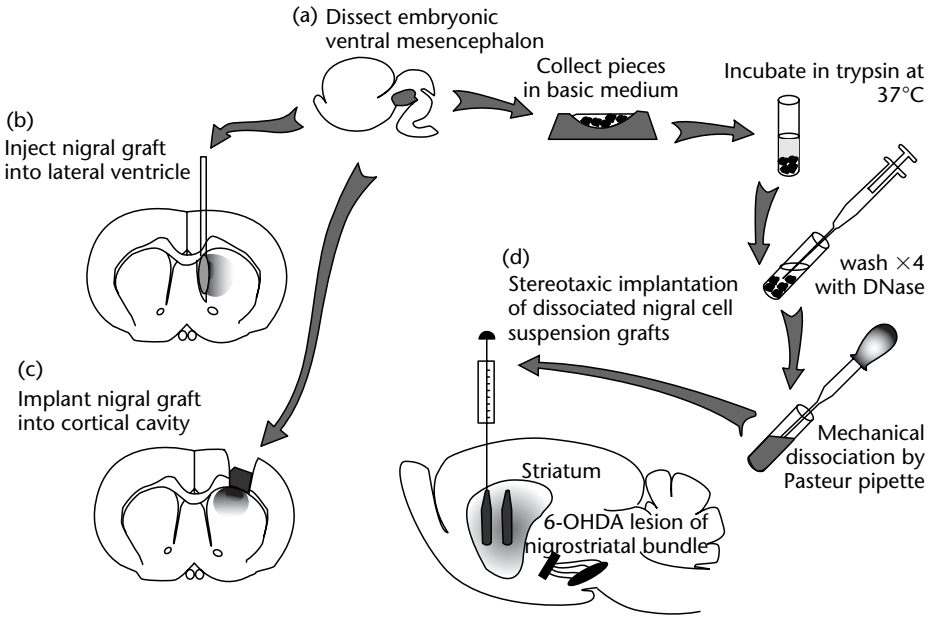

Figure 1. Methods of cell transplantation. (a) Dissection of the ventral mesencephalon, containing dopamine cells, from the embryonic brain. (b) Implantation of solid graft tissue into the lateral ventricle. (c) Implantation of solid graft tissue into an artificial cortical cavity. (d) Preparation and injection of dissociated tissue suspension into brain parenchyma. Abbreviations: 6-OHDA, the dopamine-specific neurotoxin, 6-hydroxydopamine; DNase, deoxyribonuclease, to inhibit reaggregation.

achieved in the 1960s, using neuroendocrine tissues to alleviate pancreatic dysfunction in rats. Subsequently, similar studies used hypothalamic tissues to alleviate a variety of neuroendocrine deficits associated with genetic and lesion-induced dysfunction in hypothalamic hormonal control, including loss of gonadotrophins controlling sexual maturation and behavior, diabetic symptoms associated with loss of antidiuretic hormone neurons, and disrupted circadian rhythms associated with mutation or degeneration of the suprachiasmatic nucleus. Although these grafts could in principle alleviate deficits by diffuse secretion of the missing neurohormones, in fact it has generally been found that the transplanted neurons provide a more complete repair by integrating into the host brain and extending axons to make specialized contacts with the appropriate host capillary circulation to restore normal neuroendocrine control.

Dopaminergic Grafts

A second main area of investigation has been the recovery of motor deficits following transplantation into the basal ganglia in animal models of Parkinson disease. This disease is characterized by degeneration of dopamine neurons of the substantia nigra and an associated loss of dopaminergic innervation in the neostriatum and other nuclei of the basal ganglia, resulting in impairments of voluntary motor control. A comparable syndrome, involving akinesia and impairments in the initiation of voluntary movements, can be reproduced in experimental animals by selective toxins. (*See* **Parkinson Disease**)

Many of these symptoms are alleviated by transplantation of embryonic dopamine neurons into the striatum, the primary area of terminal loss. In contrast, implants in the substantia nigra itself survive but have no functional benefit, indicating that recovery is dependent upon restitution of an appropriate dopaminergic innervation and reactivation in the striatum itself. Recovery of parkinsonian symptoms with embryonic nigral grafts, first demonstrated in rats, has been replicated in other species including mice, rats, and monkeys, laying the foundation for clinical trials in human patients.

CLINICAL APPLICATIONS IN PARKINSON DISEASE

Adrenal Grafts

The first neural transplants in humans were undertaken in the early 1980s, by grafting adrenal medullary tissues in patients with Parkinson disease (PD).

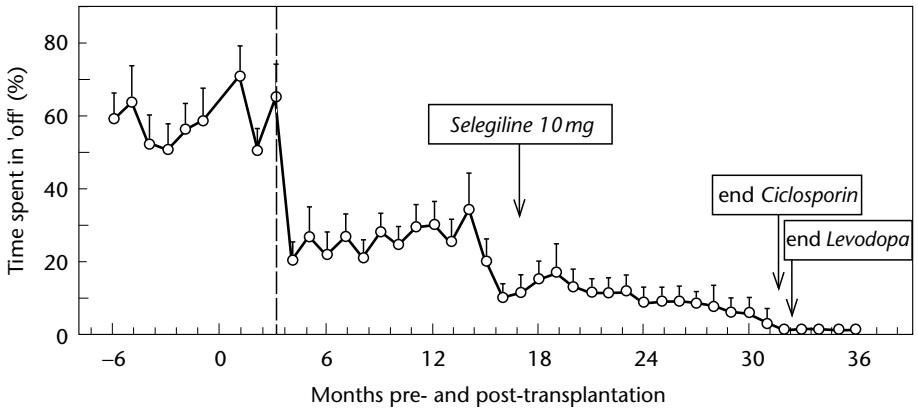

Figure 2. Progress of neurological symptoms in a patient with Parkinson disease, from the University of Lund series in Sweden. The 'off' period is the percentage of time during each day when the patient is suffering full parkinsonian symptoms without alleviation by the administered levodopa. Data kindly provided by Professor Olle Lindvall.

This tissue was selected as a peripheral source of catecholamine neurons which could be harvested from the patients themselves, circumventing both the poorly understood issues surrounding immunological compatibility and the ethical issues associated with using fetal tissues. However, the grafts did not survive well and resulted in significant adverse morbidity and mortality for limited clinical benefit. Therefore, after a flurry of interest and several hundred operations worldwide, a consensus was reached by the early 1990s that use of this source of tissue for transplantation in PD was not warranted.

Fetal Tissues

Since biological factors favored the efficacy of primary fetal tissues for transplantation, the ethical use of aborted human fetal tissues for research and therapy has been and is still much debated. This debate has resulted in acceptance in many (but not all) Western countries that it is ethical to use fetal tissues for developing new therapies, subject to a variety of regulations and guidelines to ensure that the decision and conduct of the abortion is not influenced by the subsequent use of the tissue.

Nigral Grafts in PD

Since the first operations in 1988, several hundred further patients with PD have now received transplants of fetal dopamine cells. The procedure is both safe and effective provided that the tissue collection and surgical implantation are firmly based on strict biological principles. Thus, systematic longitudinal follow-up is now available from several centers, and shows that patients can exhibit a significant alleviation of neurological signs, improved manual dexterity and control, reduced dependence on drugs, and an improved efficacy and reduced side-effects from the drugs that are taken (Figure 2). These effects take 1–3 years to develop and stabilize, which corresponds to the time required for normalization of the images in positron emission tomography scans of a functional dopamine system. The benefits can last for at least 11 years, the longest period studied. In contrast, other centers that have diverged from experimentally validated methods – whether for ease of tissue preparation, availability, or surgical convenience – have generally achieved poorer results, and in a few cases unacceptable side-effects. Neural transplantation is therefore now demonstrated to be effective in some patients, but efficacy is highly dependent on the procedures adopted.

Improving Graft Viability

The biggest technical problem facing clinical neurotransplantation is the limited availability of suitable fetal tissues. This problem is exacerbated by the fact that, at best, only 5–10% of the dopamine cells survive transplantation, requiring three to seven donor fetuses to be used for each hemisphere of the brain, for maximum efficacy. Consequently, there is currently a major research effort into discovering ways of improving graft survival, including treating the cells with growth factors, antioxidants, anti cell-death proteins and other neuroprotective agents. A combination of treatments can now more than double cell survival, but methods are still far from optimal.

ALTERNATIVE SOURCES OF CELLS

Even if 100% cell survival can be achieved, there will always be ethical, practical, and safety concerns limiting the availability of primary fetal cells for transplantation. Consequently a major topic for research is to identify alternative sources of cells that can be available 'off the shelf' for transplantation, in unlimited supply, properly standardized and fully characterized for safety. A number of alternatives have been suggested.

Stem and Other Precursor Cells

Stem cells are early precursor cells that have the capacity to divide exponentially to generate multiple duplicate copies of themselves as well as to differentiate down diverse lineages to produce a multiplicity of different cell types. Stem cells have been isolated from adult as well as developing brains, massively expanded, and differentiated to form large samples of both neurons and glia. The difficulty with applying this technology for cell therapy is that it is not yet possible to control precisely the fate of the progeny, and the majority of expanded cells when transplanted differentiate into immature neuroglia and astrocytes. The problem of understanding the signals that control differentiation of individual types of cells of therapeutic interest, such as developing and mature dopamine neurons, is potentially soluble but is not yet resolved.

Xenotransplantation

Grafting from other species would allow breeding of animals to provide well-defined cells and tissues for human transplantation. Pigs are widely considered the species of choice; they are of similar physical size and rate of development, there is considerable experience of pig husbandry, they can be bred under sterile conditions, and they produce regular large litters which can provide large quantities of fetal donor tissues. The two main problems relating to nigral xenotransplantation are that the methods for effective long-term immunoprotection across the species divide are still not well understood, even within an immunologically privileged site such as the brain, and there is a widespread safety concern about the theoretical risk of introducing new pig pathogens and viruses into the human population.

Cellular Gene Therapy

If we can understand the developmental signals that determine cell phenotype, then it should theoretically be possible to harvest cells from the patients themselves (thereby obviating any immunological problems) and engineer them to express the particular phenotypes required therapeutically. Although a variety of cells, such as fibroblasts, and cell lines have now been engineered to expressed particular components of a relevant phenotype (e.g. to synthesize dopamine), the requirements of developing cells to exhibit all the features of a developing neuron – to grow, extend neurites, seek appropriate targets, establish synaptic connections, transduce inputs, transmit electrochemical signals, and regulate synaptic release of transmitter-mediated outputs – remain poorly understood, and clinical applications are certainly not imminent.

Neuroprotection

Most transplantation therapies are based on the principle of cellular repair, as distinct from strategies based on delivery of neuroprotective molecules that might slow the course and progression of neurodegenerative disease. However, many of the neuroprotective molecules discovered in the 1990s – including a variety of growth factors, transcription factors, antioxidants, and antiapoptotic molecules – do not cross the blood–brain barrier, so targeted delivery to specific sites in the depth of the brain is proving to be an obstacle. Neural transplantation of cells engineered to express particular neuroprotective molecules, in particular when combined with molecular triggers for controlled release, provides one of the most likely prospects for providing targeted delivery for therapeutic application, although again a variety of technical and safety issues remain to be solved.

PROSPECTIVE APPLICATIONS IN OTHER NEURODEGENERATIVE DISEASES

Huntington Disease

Huntington disease is characterized by a selective degeneration of intrinsic striatal neurons. Following a similar strategy to that used in PD, striatal neurons can be transplanted into the patient's brain, and there is now preliminary evidence

from the first clinical trials that this is not only safe but can also alleviate cognitive as well as motor symptoms of the disease. (*See* **Huntington Disease**)

Stroke

Loss of blood supply in a circumscribed area of the brain leads to infarct and extensive cell loss at the focus. There have been claims that neuronal precursor cells can migrate to, and repopulate, the site of injury with functional benefit in rats, and this has already led to an initial clinical trial. The data remain controversial. (*See* **Stroke**)

Multiple Sclerosis

In multiple sclerosis the oligodendrocytes that myelinate long-distance axons of the brain and spinal cord are lost in 'plaques', the foci of sporadic acute inflammatory reactions. Experimental models of the focal plaque are available, and these can be effectively remyelinated by implants either of immature oligodendrocytes or their precursors. The problems yet to be solved for this to become a clinical therapy are how to stimulate migration of implanted oligodendrocyte precursors to widely scattered plaque sites; and second, how to inhibit the formation of new plaques which can rapidly lead to further deterioration in this disease. (*See* **Multiple Sclerosis**)

Spinal Cord Injury

It is now possible to reduce the formation and spread of spinal cord cysts using embryonic implants and to use a variety of cellular and matrix materials to bridge a site of transection injury. However, the main problem in achieving functional repair in spinal cord injury is how to stimulate extensive regrowth of cut long-distance sensory and motor axons through the host spinal cord and back to remote targets distal to the site of injury. Although a major area of investigation, the technical problems still to be overcome remain massive.

Neurogenesis

Introductory article

Brandi K Ormerod, University of British Columbia, Vancouver, Canada
Erin M Falconer, University of British Columbia, Vancouver, Canada
Liisa A M Galea, University of British Columbia, Vancouver, Canada

CONTENTS

Adult neurogenesis has been found to occur in the olfactory bulb and the hippocampus of all vertebrate species studied but has been most extensively characterized in birds and mammals. Although its function is unknown, neurogenesis is influenced by physical activity, learning, environmental complexity, season and photoperiod, exposure to stress, and experimental brain pathology.

INTRODUCTION

For many years, researchers thought that plasticity within the adult vertebrate brain consisted only of changes in synapse efficacy or number. However, research has now conclusively demonstrated that regions of the adult vertebrate brain retain the capacity to produce and/or incorporate new neurons. In avian species, new neurons are incorporated into the entire telencephalon, preferentially into the song-learning circuit and hippocampal complex. In mammals, new neurons are incorporated more discretely into the dentate gyrus of the hippocampus, olfactory bulbs, and perhaps the association areas of the nonhuman primate neocortex, albeit to a lesser extent.

Neurogenesis occurs when precursor cells divide, producing daughter cells that migrate to target locations where they differentiate into neurons. To evaluate neurogenesis in adult vertebrates, investigators capitalize on the fact that cells in the synthesis phase of mitosis will incorporate the traceable markers [^{3}H]thymidine or bromodeoxyuridine (BrdU; a thymidine analogue) into their deoxyribonucleic acid (DNA). Figure 1 shows examples of cells labeled in this way. The synthesizing precursor cells and their progeny (precursor cells, neurons, and glia) can be counted and the phenotype verified immunohistochemically by applying antibodies raised against the proteins specific for neurons versus glia. Using a combination of techniques, investigators have identified factors that influence adult neurogenesis by altering cell proliferation, migration, differentiation, and/or survival.

ADULT NEUROGENESIS IN BIRDS

Early work investigating song acquisition in canaries described the phenomenon that, although adult females typically do not sing, adult female canaries produce male-like song following androgen treatment. Along with the male-like song acquisition, the hyperstriatum ventrale, pars caudalis (or higher vocal center, HVc), the primary telencephalic song-control nucleus, doubles in size in adult females treated with androgens. Fernando Nottebohm and Steven Goldman proposed the hypothesis that the expansion in HVc volume following androgen treatment in adult female canaries reflected the addition of new neurons. After treating adult female canaries with exogenous testosterone and injecting the birds with [^{3}H]thymidine, they found that many HVc cells had recently undergone mitosis. Later studies indicated that these new cells responded to auditory stimuli, received synaptic input, and had neuronal morphology, suggesting that the new cells were incorporated into functional neural circuitry. As a cautionary note, the initial studies did not use immunohistochemical markers for neuron identification (because they were not yet available), but characterized the new cells as neurons using [^{3}H] thymidine, Nissl staining, and observations of ultrastructural characteristics such as dendrites and axonal hillock.

The discovery of neurogenesis in the HVc of songbirds, along with evidence that these neurons were responsive to auditory stimuli, prompted Barnea and Nottebohm to suggest that these new cells contributed to avian song learning. This suggestion

Figure 1. (a) Photomicrograph of a cell labeled with bromodeoxyuridine in the subgranule zone of the dentate gyrus, having the morphology of an immature neuron of an adult rat. (b) Photomicrograph of a [^{3}H]thymidine-labeled cell in the subgranule zone of the dentate gyrus in an adult female meadow vole. GCL, granule cell layer.

was supported by studies identifying that juvenile male zebra finches, during a sensitive period for song acquisition, add more neurons to the HVc than do juvenile females, which do not learn to sing. Further, in adult canaries there is a seasonal change in the expression of new song patterns that corresponds with a seasonal change in the number of neurons in the HVc.

Neurogenesis in the adult bird is not limited to the HVc. Indeed, neurogenesis exists in the ventricular zone in adult birds that do not learn song in adulthood (such as the chicken, quail, parakeet, and dove), suggesting that this phenomenon may be widespread in the brain across different bird species. Barnea and Nottebohm found that new cells are produced in the hippocampus of wild blackcapped chickadees in a seasonally dependent manner, with more cells produced in the autumn than in spring. Interestingly, during the autumn these birds store food in unique cache sites, never reuse a cache site, and can take up to 4 weeks to retrieve food from a particular cache site, suggesting that they need a large capacity for spatial memory in the autumn and winter.

The study of adult avian neurogenesis, coupled with earlier reports of new cells in the hippocampus of adult rats, prompted further study of hippocampal and olfactory bulb neurogenesis in mammals.

ADULT NEUROGENESIS IN THE MAMMALIAN HIPPOCAMPUS

Joseph Altman described neurogenesis within the dentate gyrus of adult rats and cats in the 1960s, but few studies investigated adult neurogenesis following Altman's discovery. Early researchers were skeptical that the newborn hippocampal cells described by Altman could be neurons; perhaps the most obvious reason for this was that immunohistochemical markers that could positively identify new cells as neurons had not yet been developed.

Renewed interest in adult neurogenesis followed Fernando Nottebohm and colleagues' report in the early 1980s of season-dependent fluctuations of neuron production within the adult canary song circuit, described above. However, hope that the adult primate brain could produce and incorporate new neurons was diminished when Pasko Rakic reported that although new cells are produced within the adult nonhuman primate hippocampus, they could not be definitively identified as neurons.

In the early 1990s, Heather Cameron and colleagues used immunohistochemical markers to establish that many new neurons are produced within the dentate gyrus of the adult rat. At about the same time, Mark West and colleagues developed an unbiased stereological technique to estimate the total number of new neurons in the granule cell layer of the dentate gyrus. In fact, work combining immunohistochemical and stereological methods suggests that as many as 4000 new neurons could be produced in the dentate gyrus of untreated adult laboratory rats following 2 h of proliferation.

A team headed by Elizabeth Gould, Bruce McEwen and Eberhard Fuchs in 1997 provided the first hint that neurogenesis might occur within the primate hippocampus. They discovered new neurons in the dentate gyrus of the adult tree shrew, an insectivore phylogenetically related to primates. Then Gould and colleagues reported neurogenesis in the hippocampus of adult

marmoset monkeys and, concurrently with David Kornack and Pasko Rakic, the dentate gyrus of adult macaque monkeys.

Finally, a study headed by Peter Eriksson and Fred Gage confirmed the presence of neurogenesis within the adult human dentate gyrus. They found evidence of new neurons in the brain tissue of human patients who had received the DNA marker BrdU up to 2 years prior to succumbing to cancer. This study confirmed that investigating the factors that influence the proliferation, migration, differentiation, and survival of new neurons could have profound relevance for adult human brain trauma or disease.

Neurogenesis in the Adult Mammalian Brain

Although neurogenesis in adult mammals is characterized most extensively in the hippocampus, studies have shown that the olfactory bulbs of mammals and perhaps the neocortical association areas of nonhuman primates incorporate new neurons throughout adulthood. However, new neurons are probably produced in only two areas of the mammalian brain: the subventricular zone that lines the anterior lateral ventricles, and the subgranular zone that borders the granule cell layer and hilus of the dentate gyrus. Because precursor cells derived from many areas of the adult vertebrate brain will divide *in vitro*, the subventricular zone and subgranular zone are probably the only areas of the adult brain to retain an environment that permits cell proliferation postnatally.

The daughter neuroblasts (immature neurons) of precursor cells located in the mammalian subventricular zone migrate tangentially into the olfactory bulbs and possibly into association areas of the neocortex. Upon reaching their target location in the olfactory bulb, the neuroblasts differentiate into glutamatergic, GABAergic or tyrosine hydroxylase-secreting neurons. The daughter neuroblasts of precursor cells located in the subgranular zone migrate, probably along radial glia, into the granular cell layer where they differentiate into glutamatergic granule neurons. Some evidence suggests that as granule neurons age they migrate deeper into the granule cell layer where they may eventually die and be replaced by new neurons. Many new cells are born daily but studies have shown that the total number of labeled cells diminishes between 1 week and 3 weeks, because many new cells die before becoming incorporated into the granule cell layer.

Cell Development in the Dentate Gyrus

The majority of labeled cells in the dentate gyrus of adult mammals become neurons. For example, labeled neuroblasts migrate into the granule cell layer where they acquire a granule neuron morphology. Like other neurons, they receive presynaptic input and extend an axon into the mossy fiber pathway to target CA3 pyramidal neurons. Antibodies raised against proteins expressed specifically by neurons during various stages of maturation can be used to further verify the phenotype of newborn cells. For example, in adult mammals the protein TUC-4 is expressed by precursor cells undergoing division and by immature neurons in the process of axon extension. Because axon extension is probably completed by 4–10 days after birth, anti-TUC-4 can be used to verify the phenotype of new immature neurons. In contrast, neuron-specific enolase is expressed by adult-generated neurons 2–3 weeks after division, presumably when the new neuron establishes a synapse with a CA3 pyramidal cell during development. New granule neurons produced within the dentate gyrus are likely to be functional, as they demonstrate paired-pulse facilitation similar to mature granule neurons but – interestingly – are more plastic electrophysiologically than mature granule neurons.

PUTATIVE MECHANISMS AND FUNCTIONS

Many factors regulate the different facets of neurogenesis (cell proliferation, migration, differentiation, and survival) within the adult vertebrate brain, suggesting that their mechanisms are complex (Table 1). To understand the mechanisms and function of adult neurogenesis, researchers must delineate the factors that affect adult neurogenesis at each stage of maturation (i.e., cell proliferation versus cell survival). For example, a treatment administered prior to or during the uptake of a DNA marker will affect cell proliferation (brains are examined within 24 h), but a treatment administered during migration, differentiation, or maturation will affect cell survival (brains are examined between 24 h and 3 weeks). Cell survival can be influenced independently of cell proliferation: for example, learning a hippocampus-dependent task enhances the number of new neurons surviving without influencing cell proliferation. Factors that increase the number of new neurons in existing circuitry would probably more readily influence behavior relative to factors that increase cell

Table 1. Factors affecting cell proliferation and granule cell survival

	Cell proliferation	*Cell survival*
Adrenal steroids	↓	No change
Adrenalectomy	↑	↑
NMDA	↓	
NMDA-R antagonist	↑	↑

proliferation, owing to their immediate potential to influence circuitry.

Regulation of Neurogenesis in Birds

Although neurogenesis occurs in other areas of the avian brain, the HVc has been the site most studied in songbirds. In male canaries, most neurons outside the telencephalon are born before hatching, whereas new neurons continue to be added to the telencephalon during adulthood. New neurons found in the adult bird HVc are derived from precursor cells in the walls of the lateral ventricles.

The newly proliferated cells remain in the subventricular/ventricular zone for at least 4 days before migrating into the forebrain parenchyma. Studies *in vitro* have identified factors that might regulate the time taken before the new cell initiates migration (one should recognize that mechanisms *in vivo* might differ). The cell adhesion molecule N-cadherin has been implicated as a factor that might restrict migration, and factors such as insulin growth factor (IGF) increase the number of neurons that migrate. The new cells migrate over distances of up to several millimeters, aided initially by radial glia. About two-thirds of these new neurons die on their migratory route, close to the radial glia. Evidence suggests that estrogen aids the survival of these cells by enabling neural cell adhesion molecules (NCAM) to couple with calcium signaling pathways, and that this process may be necessary for cell survival during migration. After 30 days, these neurons are differentiated, form synaptic contacts, and respond to auditory stimuli with action potentials. Many of the new neurons project outside the HVc and connect to distant targets.

Factors other than estrogen have also been shown to influence the survival of new neurons in the avian brain. In the adult canary, testosterone induces an increase in HVc neuron number and HVc volume, and it is thought that testosterone exerts its effects through brain-derived neurotrophic factor, a neurotrophin that affects the survival of neurons in the developing and adult brain. Other neurotrophins may also play a part in neuron survival.

Potential Function of Adult Neurogenesis in Birds

The existence of neurogenesis in the song nuclei of adult songbirds suggests that the new cells may regulate song learning. As mentioned above, neurogenesis in the songbird HVc varies seasonally along with testosterone level. During the autumn there is an increase in cell numbers, commensurate with the time when songbirds modify their song patterns. It has been suggested that changes in neurogenesis may have a role in modifying song control circuitry to allow plasticity in song behavior. In adult male white-crowned sparrows, an increase in HVc neurogenesis is accompanied by an increase in the development of song stereotypy. However, in songbirds that retain the same song for life (e.g., the song sparrow), there is still a seasonal fluctuation in neuron density and number in the HVc. Although the seasonal difference in neuron number and density in the song sparrow is not as large as that found in the canary, this evidence suggests that neurogenesis in the HVc may serve a function other than song learning and this function has yet to be determined.

An area of the avian brain not involved in song production, the hippocampus, also incorporates new neurons in adulthood. In birds, differences in hippocampal density and cell number are seen between species that store food and those that do not, with food-storers showing increased hippocampal size and neuron number. David Sherry

and colleagues have found that food-storers (but not non-storers) have a seasonal change in the rate of new cell birth. Hippocampal cell survival peaks at the time when the blackcapped chickadee engages in the most food-storing behavior. When given experience in foodstoring, juvenile laboratory marsh tits increase the number of neurons and size of the hippocampus compared with birds deprived of food-storing experience. Such experience-dependent neurogenesis suggests that neurogenesis in the hippocampus may have a role in spatial behavior, as behaviors such as food-storing are dependent on the integrity of the hippocampus.

Regulation of Neurogenesis in the Adult Mammalian Hippocampus

Corticosterone and glutamate

Many factors have been shown to suppress cell proliferation within the dentate gyrus of adult rodents. The first inhibitory factors discovered were adrenal steroids, via corticosterone, and glutamate, via *N*-methyl-D-aspartate receptor (NMDA-R) activation. While high levels of either corticosterone or NMDA-R activation suppress cell proliferation, low levels increase cell proliferation. In fact, corticosterone and glutamate coregulate cell proliferation within the dentate gyrus of adult rodents. Specifically, NMDA-R activation prevents adrenalectomy-induced increases in cell proliferation, and NMDA-R inactivation blocks corticosterone-induced suppression of cell proliferation. However, corticosterone and glutamate indirectly coregulate cell proliferation as precursor cells do not express the NMDA-R NR1 subunit and express type I and type II glucocorticoid receptors 24 h and 2 weeks after cell division, respectively.

Corticosterone may also inhibit cell migration within the dentate gyrus of adult rats. Polysialylated neural cell adhesion molecule (PSA-NCAM) is only expressed in the dentate gyrus and olfactory regions of adult mammals by immature neurons in the process of migration and differentiation. Administering corticosterone can reverse adrenalectomy-induced increases in PSA-NCAM expression in the young adult rat.

Estradiol

Exposure to high levels of estradiol for 4 h enhances cell proliferation, but 48 h after this exposure there is a suppression in cell proliferation within the dentate gyrus of adult female meadow voles. The effect of estradiol on cell proliferation is likely to be time-dependent within the dentate gyrus of adult female rats. Female rats exposed to high endogenous levels of estradiol (proestrus) 7 h prior to labeling have higher rates of cell proliferation than rats exposed to a high level of estradiol 30 h prior to labeling (estrous or diestrous). The effect of estradiol on cell proliferation may be indirect, as traditional estrogen receptors are not expressed in the precursor cells within the dentate gyrus.

Dopamine, serotonin, and growth factors

While dopamine has been shown to suppress cell proliferation, serotonin and growth factors have been shown to enhance cell proliferation within the dentate gyrus of adult rodents. When D2 dopamine receptors are inactivated the rate of cell proliferation increases, but when dopamine synapses are activated the rate of cell proliferation decreases in the dentate gyrus of adult gerbils, relative to animals that receive an injection of saline.

When the dorsal raphe nucleus, the main serotonin-mediated input into the dentate gyrus, is removed, the rate of cell proliferation in the dentate gyrus of adult rats decreases. Similarly, when serotonin (5-hydroxytryptamine, 5-HT) is inactivated by an antagonist, cell proliferation is diminished. Alternatively, cell proliferation is increased when 5-HT release is enhanced by 5-HT agonists. The effect of 5-HT may be mediated by the 5-HT_{1A} receptor, because 8-hydroxy-2(di-n-propylamino) tetralin (8-OH-DPAT, a 5-HT_{1A} receptor agonist) increases cell proliferation in the dentate gyrus of adult rats. Serotonin may also affect the migration of new cells into the granule cell layer. When the dorsal raphe nucleus is removed, PSA-NCAM expression decreases in the dentate gyrus of adult rats.

Growth factor peptides are expressed largely during development. When adult rats are given multiple injections of insulin-like growth factor I, cell proliferation is increased and, furthermore, a greater percentage of new cells differentiate into neurons than in rats treated with vehicle only. Other growth factors, therefore, may affect both cell proliferation and cell differentiation in the dentate gyrus of adult rats.

Signals from dying cells

Some researchers have postulated that dying cells trigger cell birth within the adult mammalian hippocampus. For example, high levels of corticosterone reduce both cell birth and cell death within the granule cell layer. Furthermore, the degree of unilateral lesion-induced damage to the granule cell layer is related to the degree of proliferating cells on the same side. The number of new cells

produced in the dentate gyrus can be increased by experimentally induced ischemia (which prevents oxygen flow to the brain) in rats. Longer bouts of ischemia, which increase the level of cell death, produce higher rates of cell proliferation.

Possible Function of Neurogenesis in the Adult Mammalian Hippocampus

Stress

Separate studies have shown that cell proliferation in the dentate gyrus of adult rats, tree shrews, and marmoset monkeys is suppressed by exposure to an ecologically relevant stressor. Rats exposed to predator odor, subordinate tree shrews, and 'intruder' marmoset monkeys, all show a rapid suppression of cell proliferation within the dentate gyrus. It is not clear what long-term effect, if any, an acute exposure to stress has on the animal. Exposure to a stressful event elevates a number of factors that have been shown to suppress cell proliferation within the dentate gyrus of adult rats (such as adrenal steroids and glutamate). Preliminary evidence has shown that scopolamine (an acetylcholine muscarinic receptor antagonist) blocks the suppression of cell proliferation induced by predator odor in the dentate gyrus of adult rats.

Aging

Both the rate of cell proliferation and the percentage of new cells that differentiate into neurons are reduced within the dentate gyrus of senescent (21 months old) adult rats relative to young (6 months old) adult rats. Levels of PSA-NCAM are also reduced in the dentate gyrus of senescent rats, suggesting that the reduced percentage of new neurons observed might reflect a diminished ability of new immature neurons to migrate into the granule cell layer.

Kindling

Repeated low-intensity electrical stimulation of various brain areas can produce progressively intense seizure activity in a process called 'kindling'. Kindling to a moderate seizure intensity (class 5) is accompanied by a drastic increase in cell proliferation within the dentate gyrus of adult rats. The mechanism mediating amygdala kindling-induced increases in cell proliferation may become desensitized. For example, if BrdU is administered before each kindling session, increases in cell proliferation can be observed following four class 5 seizures, but if BrdU is administered after kindling sessions have ended, increases in cell proliferation can only be observed following nine (and not four) class 5 seizures. Alternatively, the process of kindling could enhance the survival of new neurons.

Season

Within the dentate gyrus of adult female meadow voles, cell proliferation varies seasonally. During the non-breeding season cell proliferation is elevated, concurrent with an increase in territory size and an enhancement in spatial performance in the laboratory. However, the same relationship between increased territory size and increased cell proliferation is not seen in male meadow voles, indicating that female brains may be more plastic than male brains. Seasonal changes in cell proliferation have also been reported in the adult male golden hamster, with an enhancement in cell proliferation during the short photoperiod relative to the long photoperiod. However, no seasonal change in cell proliferation in wild adult gray squirrels of various ages has been demonstrated, despite the fact that these animals are known to cache food during the autumn. This suggests that the mechanisms and factors controlling cell proliferation may not be conserved across all species.

Hippocampus-dependent learning

Successful performance in the Morris water-maze task relies upon the integrity of the hippocampus. In this task, rats use information in the environment to locate a platform hidden beneath water made opaque by nontoxic paint or milk; removal of the hippocampus impairs the rats' ability to find the platform. When training on this task commences a week after BrdU has been administered (at a time when these new neurons are in the process of extending dendrites and an axon), more labeled neurons are found within the dentate gyrus compared with rats trained on tasks not involving the hippocampus. However, training does not enhance the survival of 1-day neurons or neurons that are more than 12 days old. In fact, new neurons may only be susceptible to the survival-enhancing effects of hippocampus-dependent learning when they are immature (about 7 days old) and in the process of dendrite and axon extension.

Experience

Mice living in an enriched environment are exposed to social (cage partners) and inanimate (running wheel, tunnels and toys) stimulation. Such mice have more new neurons (but no change in cell proliferation) in the dentate gyrus than mice living in standard laboratory conditions. This

finding is interesting because the hippocampus appears to have a role in rats' abilities to learn about different contexts or environments. In addition, mice given access to a running wheel have enhanced cell proliferation, better performance in the Morris water maze, and increased long-term potentiation (a putative cellular model of learning) relative to mice without access to a running wheel.

CONCLUSION

New cells are produced within the subventricular/ventricular zone of birds and mammals and the subgranular zone of mammals. Many of the new cells are incorporated into the song-learning circuit and hippocampus of birds, and into the hippocampus and olfactory bulbs of mammals. Many factors have been shown to influence cell proliferation and/or cell survival in both birds and mammals. Although the function of new neurons is unknown, adult neurogenesis in the dentate gyrus is modified by hippocampus-dependent behavior. However, manipulations that enhance cell proliferation in the hippocampus of adult rodents (e.g., adrenalectomy, NMDA-R antagonist administration, hippocampal lesions, and kindling) also impair hippocampus-dependent learning. In contrast, factors that enhance cell survival, such as housing in a complex environment, generally enhance hippocampus-dependent learning. Thus, the challenge for future research is to determine not only which factors affect adult neurogenesis but also how they do so, as well as the consequences of alterations in adult neurogenesis on behavior.

Neurogenetic Approaches

Introductory article

Hans-Peter Lipp, University of Zürich, Zürich, Switzerland
David P Wolfer, University of Zürich, Zürich, Switzerland

CONTENTS

The relation between genes and cognition is analyzed using two approaches: identification of genetic traits and statistical mapping to chromosomes, and by studying the effects of targeted deletion of genes on brain and behavior.

INTRODUCTION

Does heredity control cognition and intelligence, and if so, to what extent? This question has been a conceptual battleground for two hundred years. The debate is not only a scientific one but carries implications for social sciences, education, and even politics. It can be traced to two concepts of individuality.

In the older and mechanistic view of the late sixteenth and the seventeenth centuries, humans and animals were considered as invariant prototypes created by god or nature. Thus, differences between individuals were considered as random deviations from a predefined norm. This interpretation of individual variation is still prevalent in engineering, where individuality is considered as error.

A biological view of mental processes was introduced in the early nineteenth century as phrenology (initially the science of mind) by Gall, and advanced further by Darwin. Both of them focused on individuality as starting point. Gall assumed that behavioral individuality of animals and humans was rooted in different volumes and connections of brain modules, and Darwin offered a functional role for such biological variation, namely as a substrate for natural selection. With the discovery of genes as units of hereditary transmission and the acceptance of evolutionary theory, the study of heredity of mental traits became the focus of a subspecialty of genetic research known as behavior genetics. This individualistic approach is merging today with the expansion of mechanistic molecular techniques into the fields of cognition and learning. (*See* **Concepts, Philosophical Issues about**; **Epistemology**; **Scientific Thinking**; **Evolutionary Psychology: Applications and Criticisms**)

Correspondingly, there are two conceptual approaches to study the role of genes in cognition. One, the top-to-bottom approach, searches for individual differences in talents and temperaments, and tries to identify whether they have a genetic base, and, eventually, to identify the genes involved. The other approach starts with defined mutations of genes that either occur naturally, or were induced experimentally, and studies changes in higher brain functions that can be attributed to the inactivated gene.

FROM GENE TO COGNITION: THE ROLE OF BRAIN DEVELOPMENT

In order to understand the relations between genes and cognition, one must consider how genes interact with the developing brain, and how they might specifically affect cognition. This is most easily achieved if one assumes that the brain forms a hierarchy of systems (Figure 1): the lowest level is formed by the spinal cord and brain systems which represent several input channels for sensory information, and the only output channel, the motor system. These channels are controlled and modulated by a superimposed hierarchy of neural systems that can be compared with a bureaucracy. The topmost levels with respect to cognition are the frontal, parietal, and temporal parts of the cerebral cortex, the ensemble known as associational cortex. This cerebral system hierarchy has one goal, keeping sensory and motor systems finely tuned under all possible conditions, even in the presence of disturbing factors such as mutated genes or brain diseases. Such adaptability is known as 'brain plasticity' and is the main mechanism in masking gene effects.

The second point to keep in mind is brain development. It starts early in embryogenesis, but takes

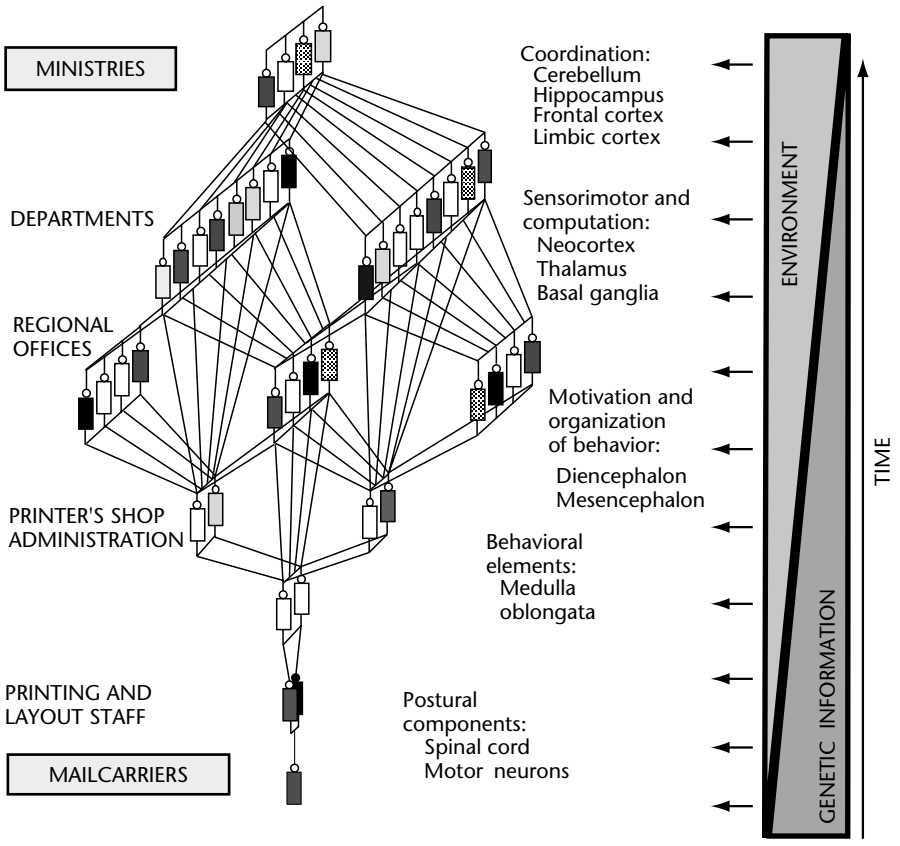

Figure 1. The brain as a cerebral bureaucracy which can be targeted by single gene effects. The relations between system levels and anatomical systems are arbitrary. The penetrance (visibility and predictability) of a mutation is low when it affects the middle levels of the bureaucracy because of homeostasis and other buffer mechanisms. It is high if the final common pathway is affected, but will appear as a mixture of neurological and behavioral deficits that can barely be disentangled. Mutations affecting the top layers are likely to be specific for cognitive processes, but will tend to have discrete effects that will become visible only in a test challenging the affected system. System specificity of gene effects can be obtained by proper timing (see time arrow at right). Early-acting genes encode primarily the layout of body and brain, and depend little on environmental factors. Genes with late activation have no other targets than the late differentiating coordination systems of the brain, and their effects are coincident with the action of environmental factors. Thus, developmental syndromes affecting behavior may have both a genetic and an environmental origin, but the two are not necessarily intertwined.

considerable time. There is always a postnatal phase of brain development and maturation which extends until puberty or even beyond, depending on the species. Mammalian brain development is characterized by dynamic plasticity. Developmental inaccuracies or even insults are often compensated for by rearrangement of connections and compensatory growth. This represents a second factor masking genetic influences. (*See* **Neural Development**; **Neural Development, Models of**; **Reorganization of the Brain**)

How could a particular mutation have a predictable impact on cognition, despite such powerful masking factors? The easiest way would be by timing. The neural system hierarchy is built up progressively: simpler systems form first, complex ones later. The transition from a crying baby to a talking child reflects such developmental stages accurately. Yet, development is under genetic control. Genes are not activated all at once. Some are switched on early and remain so, others are switched on late, and others are switched on and off. It is obvious that lately activated developmental genes can influence specifically the differentiation of the top level of the system hierarchy, without being masked by developmental brain plasticity. Such late-acting genes are mostly of no particular importance for the proper functioning of the rest of the brain. Because spontaneously occurring mutations among them are not rapidly eliminated by natural selection, one can expect to find many such mutated genes in the gene pool of a population.

This implies that a considerable proportion of individual differences in cognition is caused by such subtle mutations. On the other hand, it is also obvious that environmental factors are modifying the impact of these mutations: the later-acting the gene, the stronger the influence of the environment (Figure 1). (*See* **Language Development, Critical Periods in**; **Memory, Development of**; **Piaget, Jean**; **Neuropsychological Development**; **Individual Differences**; **Early Experience and Cognitive Organization**)

LINKAGE STUDIES

What is a Trait?

How can the effects of such subtle mutations be identified, and how is it possible to associate them with a particular gene in both humans and animals?

The classic 'top down' approach tries first to identify genetic variation of mental traits. A trait means a difference between individuals. It is defined as qualitative when it describes a noncontinuous difference, such as blond or black hair. A quantitative trait is a measurable difference between groups; however, individual members of the groups show considerable overlap, such as body height differences between men and women. Because mental traits depend heavily on the external environment and brain plasticity, they are invariably quantitative.

Behavior genetics assumes that a mental trait can be caused by actions of single genes (monogenic), or by joint action or interaction of many genes (polygenic). In either case, effects from the environment are expected. In the broadest sense, they include anything not coded directly by genes and may encompass the internal environment of the body, including internal factors such as brain plasticity, and external factors such as education. Note, however, that the frequently used term 'gene' denotes a defined string of two deoxyribonucleic acid (DNA) sequences located in a defined part of the genome (locus). Thus, a gene itself cannot cause observable differences between individuals unless there are corresponding differences in their nucleotide sequences. Alternative variants at the same locus are known as 'alleles', and their occurrence as 'genetic polymorphism'. For the sake of simplicity, we will keep the expression 'gene' as a shorthand for alleles.

Testing Twins and Inbred Mice

The classic way to recognize whether a mental trait has a genetic component is to compare individuals with an identical set of genetic information. This is done most easily by subjecting inbred mouse strains to various behavioral tests. The resulting scores will often reveal a difference between the mean values, which roughly reflects the effect of one or several genes, while the variation around the mean reflects the dissimilarity caused by environmental factors.

In humans, the approach is modified because genetically identical individuals are found only as twins or triplets, which is insufficient for an analysis of replicates. Here, two strategies prevail. One is to compare many pairs of concordant (genetically identical) with discordant (dissimilar) twins, both combinations growing up in the same environment which is assumed to be constant. If mental traits are more similar between concordant twins than between discordant ones, it is possible to calculate the impact of genetic factors in the form of an index dubbed 'heritability'. If, on the other hand, concordant and discordant twins show on average equal differences, then the mental trait must have a purely environmental origin. The other approach is to compare the cognitive abilities of concordant twins raised apart in different environments. Here, small quantitative differences indicate strong heritability, large differences weak heritability.

The sophisticated quantitative partitioning of genetic and environmental components is the hallmark of classical quantitative genetics and has been useful in evidencing genetic variation of mental traits. The technique has been broadly accepted for animals but has met strong opposition when applied to humans – partly for ideological reasons, but also because the complex statistical procedures and underlying assumptions can be criticized on technical grounds.

From Population Genetics to Linkage Analysis

For a long period, the population genetic approach focused on demonstrating heritability and was less interested in identifying the genes and brain processes causing mental traits. This scenario has changed with the rapid progress of molecular genetics which has permitted both the deciphering of the DNA sequences of the human and mouse genome, and the mapping of the location of genes on the chromosomes. Moreover, these techniques have also identified many short nucleotide sequences, some of which are part of functional (coding) genes, while others belong to noncoding DNA sequences. This has enabled new forms of genetic linkage analysis combining sophisticated statistical techniques with molecular biology.

What is a marker?

Genetic transmission involves the random breaking up and recombination of chunks from maternal and paternal chromosomes in the germ-line cells, a process called 'segregation'. These chunks still contain hundreds and thousands of genes which cosegregate together; such genes are said to be 'linked'. In principle, linkage analysis requires easily identifiable markers with genetic polymorphism and known chromosomal location. For example, in the mouse the *PrnP* gene encoding for the prion protein is located not too distant from the *albino* locus. In creating knockout mice (see below), the chromosomal segment from the donor strain carrying the inactivated *PrnP* gene encoded a brown coat color. Using coat color as a marker made it possible to discriminate without molecular testing between mutant and wild-type mice.

Molecular markers

Today, many thousands of polymorphic DNA markers of different types are mapped to chromosomal locations, and computerized databases exist for both mice and humans. This progress permitted new forms of quantitative genetics such as quantitative trait loci (QTL) analysis. In mice, QTL techniques are used to analyze the cosegregation of molecular markers and both behavioral and cerebral traits. This is done by cross-breeding inbred strains known to carry unique DNA markers and to show differences in cognitive abilities. This strategy can identify statistical associations between markers and mental traits in the offspring. By using available databases and software, putative chromosomal locations can be computed which may harbor known or unknown candidate genes contributing to the genetic variation of the trait. It is then a matter of molecular biology to isolate DNA strings and to test whether the parental strains show discordant DNA sequences.

In humans, the QTL mapping method is employed in twin research, and for screening people with outstanding cognitive performance. Since it is not known *a priori* whether these groups carry a specific marker, it is necessary to test associations with a large battery of DNA markers with the hope of finding a significant association between certain markers and mental traits. Moreover, such findings need replication in other samples. Nonetheless, this approach has resulted in the identification of several candidate loci responsible for individual differences in cognitive abilities and disabilities of humans. (*See* **Behavior, Genetic Influences on**)

Another line of linkage research focuses on mental disabilities which are linked to an identifiable chromosome. For example, forms of nonspecific learning difficulties are known to be associated with suspected mutations on the X chromosome. In contrast to traits, these more severe manifestations of mutations are termed 'phenotypes'. By mapping the X chromosome for markers found in afflicted families, candidate regions on the chromosome were identified and subsequently analyzed by DNA cloning. This led to the identification of mutations in a gene (*GDI1*) encoding a protein essential for vesicular transport within neurons. (*See* **Fragile X Syndrome**)

GENE KNOCKOUT TECHNIQUES

The Rationale of a 'Bottom Up' Approach

The second conceptual approach to the analysis of relations between genes and mental abilities is a 'bottom up' strategy derived from the classical studies of known single gene mutations (such as albinism) and cognitive correlates. The advances in molecular biology have now added a new perspective: targeted inactivation of genes suspected of having a fundamental role in memory and learning, followed by an analysis of brain structures, neurophysiology, and behavior in order to recognize the chain of action between genes and mental processes. The target may be chosen for theoretical reasons, using gene deletion as a refined lesion technique to inactivate brain processes inaccessible by other methods. Alternatively, the target is selected because mutations of a human gene have been found in association with mental retardation. In fact, mouse mutants with a deletion of the above-mentioned *GDI1* gene have been produced; these show impaired memory for aversive tastes and inappropriate social behavior. Up to now, these techniques have been confined to mice for technical reasons. This restriction poses some problems in assessing mutation-induced cognitive changes in a species with fairly limited mental abilities. On the other hand, this handicap is compensated for by the vast knowledge amassed through behavioral genetic studies of mice, a factor that facilitates comparative behavioral analysis.

Conventional Knockout Mice

Conventional gene targeting is done in mice in dividing embryonic stem (ES) cells maintained in cell cultures, mostly by inserting an artificially constructed DNA strand which binds to the complementary targeted gene during replication

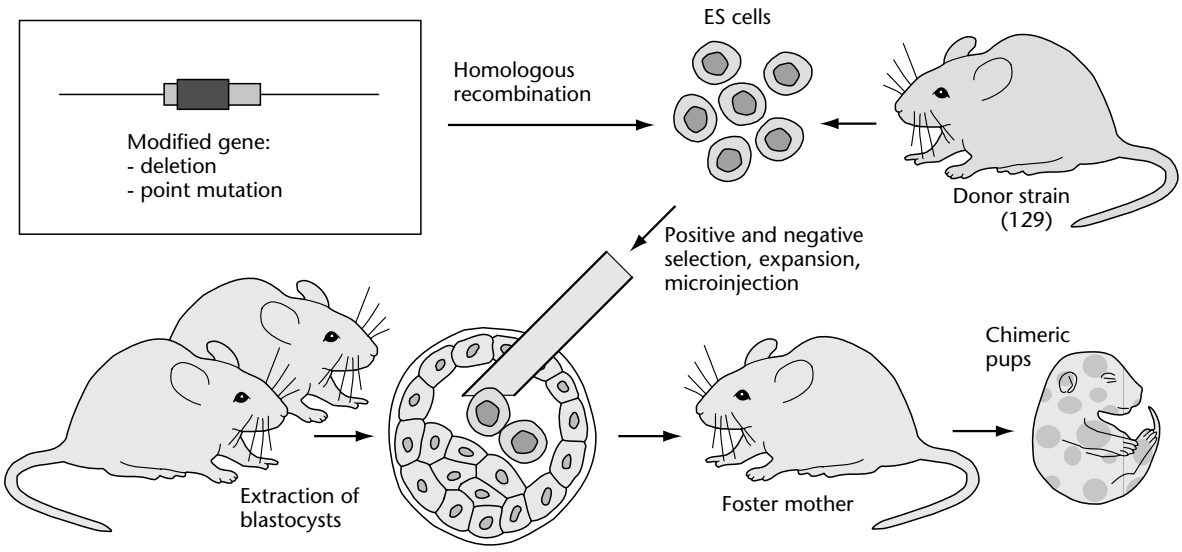

Figure 2. Production of transgenic mice with general knockout of target genes (conventional knockout). The genetic material is injected into embryonic stem (ES) cells, and binds specifically to the target gene which it may replace during recombination of chromosomes (homologous recombination). The inserted nonfunctional gene is often linked with molecular markers for easy detection. Inserting a normal or slightly modified gene is called a 'knockin'.

(Figure 2). Stable topological incorporation of the foreign strand into the chromosome can prevent the reading of the entire gene (null mutation). Alternatively, the allele may still function but yield much less protein, in which case it is termed 'hypomorphic'. The ES cells with stable targeted mutations are then identified in cell cultures, merged with blastocytes from another mouse strain and implanted into foster mothers. This procedure results in 'chimeric' mice, among whom a few individuals might be found in which the targeted mutation has been incorporated in germ-line cells differentiating into sperm and eggs. The entire process thus takes considerable time and is costly.

Like a spontaneous mutation in germ-line cells, gene knockout in ES cells results in inactivation of a gene in all tissues of the body. Also, inactivation starts with conception and lasts throughout life. For reasons explained above, alterations of brain and behavior in such mutants are often difficult to interpret and it may sometimes be impossible to establish a direct causal link to the gene product. This is because compensatory mechanisms may not only mask phenotypic changes, resulting in variable expression (penetrance of the mutation) but also because they interact unpredictably, entailing different patterns of expression (pleiotropy). Thus, it can never be excluded that the phenotype reflects compensation mechanisms rather than the functional inactivation of the gene. On the other hand, mutations may have such devastating consequences that affected individuals die during development and cannot even be examined. All these difficulties have motivated molecular biologists to make remarkable efforts to develop new techniques that permit 'conditional' gene targeting; that is, to introduce genetic changes in a tissue- and time-dependent manner.

Tissue-specific Knockouts

The frequently used tissue-specific technique exploits the activity of the enzyme Cre recombinase which removes pieces of DNA in a chromosome that are flanked by the enzyme's recognition sequences, the so-called loxP sites. In nature, the enzyme is used by viruses to recombine their own DNA with that of the infected bacterial cell. Thus, neither Cre recombinase nor loxP sites occur in normal mammalian cells. This makes it possible to exploit the system to generate tissue specific knockouts in a process that involves three main steps:

- conventional insertion of an intact gene flanked with loxP sites in a mouse line
- production of transgenic mice carrying the gene for Cre recombinase in specific parts of the body
- crossing the two lines.

During recombination, the 'floxed' gene will be excised in those brain cells which contain the recombinase. For details see Figures 2 and 3.

This technique has proved particularly useful in the examination of genes whose loss is fatal if it

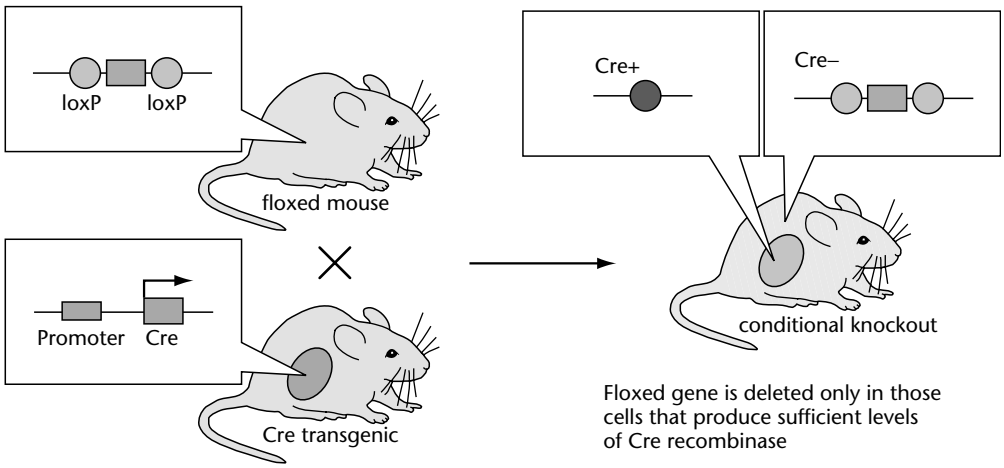

Figure 3. Production of mice with tissue-specific knockout of genes, the so-called 'conditional knockout' by Cre/loxP-mediated recombination. First, conventional gene targeting in embryonic stem (ES) cells is used to replace the gene of interest with a copy that is flanked by loxP sites but otherwise remains fully functional. The resulting 'floxed' mouse is completely normal and cannot be distinguished from wild-type mice without specialized assays that detect the presence of loxP sites in mammalian tissues. In a second step, using conventional pronuclear injection, a transgenic mouse line is created that expresses Cre recombinase in the tissue where one wants to inactivate the gene of interest. Depending on the questions that one is asking, the transgene will be constructed in such a way that Cre recombinase will become active early in development or only later when the animal approaches adulthood. The last step consists in crossing the 'floxed' mouse with the transgenic line expressing the Cre recombinase. In double mutant offspring, the 'floxed' gene of interest will be destroyed in every cell that expresses sufficient amounts of Cre recombinase.

occurs early in development and in the whole body. One example is the cell membrane protein trkB which serves as receptor for brain-derived growth factor (BDNF). It has been suggested that trkB plays an important role in the modifications of neural circuitry that underlie learning and memory in mammals, including humans. However, conventional gene targeting could not be used to test this hypothesis, because inactivation of the trkB gene is lethal if it occurs in the whole body and early in development. Using the technique described above, a tissue-specific knockout has been generated in which the trkB gene is removed only in the forebrain, and not before completion of development. These mutant animals survive and are healthy, making it possible for the first time to study brain function and behavior in adult animals in the absence of trkB receptors. Several experiments with these mice confirmed the hypothesis that trkB receptors are essential for both synaptic function and learning. Conceptually, the Cre–lox technique is an example of late-acting mutation effects.

Inducible and Reversible Transgenes

An even more flexible time-dependent control is achieved through the introduction of genetic changes that put the activity of a transgene under the external control of a drug. Feeding the drug or withholding it from a mutant mouse switches the mutation on or off. Several such systems have been developed or are under development.

The technique which thus far has made the most substantial contribution to the investigation of cognition is the control of the expression of a transgene by the antibiotic drug group known as tetracyclines. This approach exploits the fact that gene expression in living cells is controlled by the binding of endogenous regulatory proteins to specialized chromosome regions called 'promoters'. By combining bacterial and viral DNA sequences, molecular biologists have engineered an artificial system consisting of the tetracycline-controlled transactivator (tTA) and a corresponding promoter (tetO). The tTA turns on any transgene that is connected to tetO, but this activation is blocked by tetracycline. Normal mammalian tissues contain neither tetO promoters nor a gene that codes for tTA. Therefore, as with the Cre/loxP system described above, generation of an inducible mouse model requires three main steps:

- production of mice with a transgene for tTA in selected tissues
- production of mouse lines linked to the tetO promoter
- crossing the two lines and feeding or withholding the antibiotic to double mutant offspring (Figure 4).

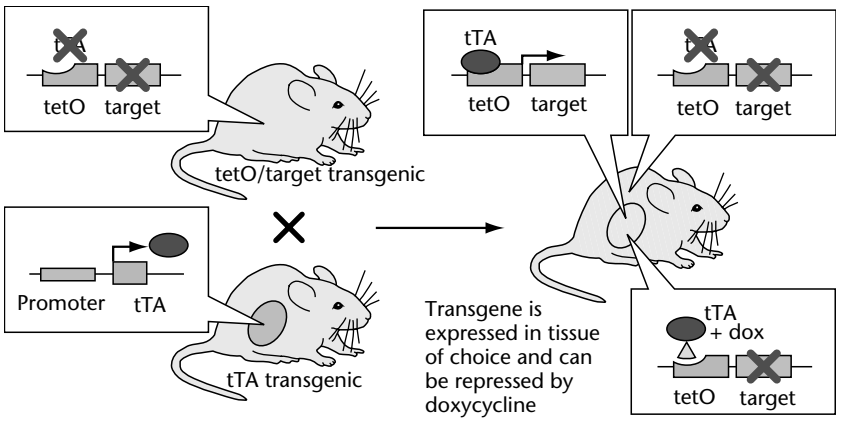

Figure 4. Producing switchable knockout mice using a tetracycline-controlled transactivator (tTA) system which permits reversible transgene repression by doxycycline. First, pronuclear injection (see Figure 5) is used to create a transgenic mouse line that bears an artificial gene expressing tTA in selected tissues, such as the forebrain. Next, a second mouse line is engineered that carries the transgene of interest linked to the artificial promoter (tetO). Finally, the two engineered lines are crossed. In double mutant offspring, expression of the transgene occurs only in selected tissues and can be reversibly suppressed at any time by feeding the animals a tetracycline antibiotic such as doxycycline. More recently, the system has been made even more flexible by engineering a reversed transactivator (rtTA). If rtTA is used instead of tTA, tetracycline activates rather than suppresses the expression of the transgene. The rtTA/tTA and Cre/loxP systems can be combined by putting the expression of Cre recombinase under the control of tTA or rtTA. The generation of such triple mutant mice is complicated, but allows flexible control of the time point at which a 'floxed' gene is effectively knocked out. In other studies, the tTA/rtTA system has been used to control transgenes that interfere directly with cellular function.

It can be shown that such a manipulation does indeed affect memory and learning. The approach has been used to create mice that overexpress the phosphatase calcineurin whenever they are fed tetracycline. It has been known for a while that transient protein phosphorylation in neurons has an important role in learning and that this phosphorylation is controlled by a fine balance between kinases and phosphatases, enzymes that add phosphate residues to proteins or remove them, respectively. However, conventional genetic models have not addressed the question whether protein phosphorylation in neurons is needed only to form new memories, or also to recall previously established memories. (*See* **Memory, Neural Basis of: Cellular and Molecular Mechanisms**; **Synaptic Plasticity, Mechanisms of**; **Memory Consolidation**)

Because overexpression of the phosphatase calcineurin potently disturbs protein phosphorylation in neurons, the rtTA/calcineurin mice were most useful in addressing this question. When calcineurin overexpression was switched on while the mice had to learn to find a hidden platform in a water pool, they failed to learn and were later unable to find the platform. This confirmed the hypothesis that protein phosphorylation was needed to form new memories. In a second experiment, the mice were first taught to find the hidden platform and were fed tetracycline only after learning. This treatment clearly blocked their ability to recall what they had previously learned without problems.

Together, these two elegant experiments provide strong evidence that fine control of protein phosphorylation in neurons is needed not only to form new memories, but also to recall those that are already formed. They also come closest to the premise of gene knockout techniques as an ultrafine brain lesioning tool for the study of memory and learning.

GENE REPLACEMENT TECHNIQUES

Molecular biologists have also succeeded in replacing nonfunctional or artificially deleted genes.

Transgenic Animals

The first and most simple way of inserting genes is a kind of shotgun approach. Isolated and cloned genetic material can be injected into an oocyte (pronuclear injection; Figure 5). The inserted genes integrate randomly into the chromosomes of the recipient egg cell. The oocyte is then implanted into a foster mother, yielding an animal that carries one or many copies of the inserted gene. Further

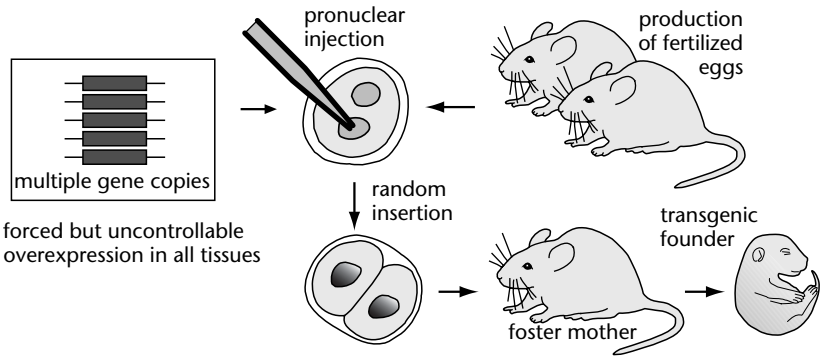

Figure 5. Production of transgenic mice by injection of genetic material into fertilized eggs (pronuclear injection). Historically this was the first rather primitive genetic manipulation.

breeding of such animals leads to a transgenic line. The technique has been applied to many animal and plant species.

The analysis of cognition in such transgenic mice has become somewhat obsolete, because the number of gene copies and their location cannot be determined. Moreover, uncontrolled integration can entail additional gene deletions obscuring the behavioral phenotype. At present, two applications of transgenic animals remain. One is the creation of mouse models of degenerative diseases. For example, there are transgenic mouse lines carrying multiple copies of a human mutant gene for the β-amyloid precursor protein (β-APP) which show increased amyloid deposits in their brain. Since they show also deficits in learning tasks, they are used to test drugs designed for the treatment of Alzheimer disease. The other application is to rescue learning performance in knockout mice by reinserting copies of the deleted gene. This technique serves mainly to validate knockout effects, although it does not really allow discrimination of direct gene effects from compensatory processes. Finally, transgenic mice are used for the production of advanced gene targeting techniques.

Gene 'Knockins'

The gene 'knockin' technique is a much more sophisticated variant of the knockout methods described above. Instead of targeted insertion of a disabling DNA sequence, an allele can be inserted which encodes a modified protein. This has been used, for example, to study memory formation in mice with a knocked-in gene carrying a point mutation that blocks the autophosphorylation of α-calcium–calmodulin kinase II. These mice showed a spatial memory deficit combined with blockade of long-term potentiation (a change in the signal transduction property of neurons thought to underly memory formation).

Viral Gene Transfer

The techniques above have a severe limitation: mutations must be incorporated into the germ line, they must become heritable in order to study their effects, and most of them are confined to mice. Somatic mutations, on the other hand, die with the cells of their carrier, and would seem desirable for medical reasons as well as for studies of gene–brain interactions. The problem is how to insert such manipulated genes into the brain and into the right neurons. A potential solution is to use viruses with low infectivity that can enter brain cells without damaging them. Transferring specific DNA into cells maintained in culture by the intermediary of a virus is relatively easy. However, applying the technique to living organisms faces numerous obstacles, and is still in an early experimental stage. Nonetheless, the procedure bears great promise.

POTENTIAL OF GENETIC RESEARCH IN THE STUDY OF COGNITION

Scientific Development

It would seem realistic to expect rapid developments in the molecular genetics of cognition. The lead is likely to be taken by the 'bottom up' approach of molecular biology. The number of scientists working in this field is large, and the development of new methods is more dynamic than in psychology and classic behavioral genetics. Moreover, the techniques that are evolving for analyzing other parts of the body can be transferred readily to the brain.

One can expect many new conventional knockout models, owing to the rapid spread of this more simple procedure. Unless natural genes can be targeted which are known to act selectively on given brain systems, they may be less useful for studying relations between genes and cognition. On the other hand, they may serve well to analyze hereditary mental disabilities because they share the same developmental pathways as the natural mutations.

The new generation of knockout and knockin models is likely to generate insights into the general cellular mechanisms underpinning memory and learning. Success in microanalyzing brain systems will depend, however, on better knowledge of brain systems and their mode of interaction.

The experimental stage in the uses of somatic mutation induced by viruses or other carriers will probably continue for some time, certainly in the field of genetics and cognition. However, the enormous potential for medical application is a strong driving force that will eventually result in substantial progress, whose ramifications cannot be estimated yet.

The 'top down' approach will profit from a merger with molecular biology. Its main asset is the ability to identify unknown genes by behavioral screening, and the traditional knowledge about relations between complex behavior and brain systems. Thus, its chief role will be to provide empirically relevant target genes for molecular biology, and to analyze the pathways from gene to behavior.

Impediments

The technical impediment of the main molecular approach is the limitation to germ-line mutations in mice, which is likely to persist for several reasons. Another related obstacle is the simplistic approach to analysis of using a few not always appropriate tests of cognition in mice and extrapolating the results to humans.

A nontechnical impediment is the confrontation between mechanistic and evolutionary biological thinking, as the two have different priorities in setting research goals. However, the dividing line cannot be drawn clearly between molecular biologists and psychologists, because the latter include both categories. In order to merge the two fields fruitfully, psychologists have to abandon, or to soften at least, some deeply rooted prototypical thinking, while molecular biologists have to understand the meaning of biological variability and plasticity of the brain.

The last and perhaps most serious impediment is the public perception of this research. Members of the public tend to think in mechanistic terms, assuming that genes are the first link in a machinery in which every step predicts the next one – hence genes control the fate of the individual. It means also that experiments with genes are perceived as attempts to control cognition and thinking; moreover, they seem to challenge divine or natural wisdom, thus bearing the risk of punishment. Similarly, such mechanistic oversimplification carries political implications, provoking unnecessary opposition by concerned people. Thus, meaningful progress will depend on the public and politicians as well as scientists understanding the probabilistic nature of behavior. The only way in which a mutated gene can manifest itself, be it of natural or technical origin, is to bias the probability of innate or acquired motor actions such as movements and speech. Likewise, natural genetic variation of mental traits is a property of populations useful for evolution but of minor significance for the carrier, because individual genetic biases are automatically counterbalanced by brain plasticity, learning, and appropriate environment – the latter two of which are in the hands of people and politicians.

Neuroimaging

Intermediate article

James B Rowe, Wellcome Department of Imaging Neuroscience, London, UK

CONTENTS

Neuroimaging techniques include magnetic resonance imaging (MRI), positron emission tomography (PET), and single photon emission computed tomography (SPECT). These techniques provide information about the structure and function of the brain in health and disease, and have increased our understanding both of regional specialization and functional integration of different brain regions.

INTRODUCTION

Since 1980 there has been an explosion in brain imaging technologies. Neuroimaging has a central role in cognitive neuroscience, including the organization of language, memory, sensory perception, control of action, and the mechanisms of emotional experiences and learning. It is advancing our understanding of the neuropsychological consequences of brain injury, and the mechanisms of recovery.

This article attempts to provide the reader with a rational structure for understanding these emerging techniques, and introduce key concepts in the acquisition, analysis and interpretation of data. A broad distinction is made between functional and structural neuroimaging. However, this distinction is not absolute. Increasingly, functional studies incorporate prior anatomical knowledge. Conversely, the analysis of brain structure is guided by our understanding of local functions. In both functional and structural neuroimaging lie two complementary approaches to the organization of the brain. Firstly, that there is some regional specialization by which different regions serve different functions. Secondly, that connections within and between specialized regions support functional integration, such that tasks utilize a network of regions distributed across the brain.

PRINCIPLES OF FUNCTIONAL NEUROIMAGING TECHNIQUES

Table 1 provides an overview of the common neuroimaging techniques. Magnetic resonance imaging (MRI) is perhaps the most versatile method, used to characterize structural (MRI), functional (BOLD-fMRI, blood oxygenation level dependent-functional MRI) and chemical (MRS, magnetic resonance spectroscopy) changes in the brain. Positron emission tomography (PET) and single photon emission computed tomography (SPECT) can be used to study neuropharmacology as well as neuronal metabolic function. These methods differ in their spatial and temporal resolution (illustrated in Figure 1), as well as cost and safety considerations.

Blood Flow and Aerobic Metabolism

Functional neuroimaging techniques exploit the close relationship between neuronal activity and metabolism, and the secondary effects on local vasculature (see Figure 2). Although some details of neurovascular coupling remain controversial, particularly for fMRI, there is a linear relationship between neuronal activity and the measured signal (Logothetis *et al.*, 2001). Increased local neuronal firing causes greater post-synaptic activity in a population of neurons.

The increased neuronal activity leads to greater aerobic metabolism of glucose. This may be measured directly by PET using [^{18}F]-2-fluoro-2-deoxyglucose (FDG). Alternatively, $H_2{}^{15}O$ can be used to measure the distribution of blood flow to active brain tissue. The isotopes decay to produce a positron, which in turn produces two photons, detected by an array of sensors around the subject's

Table 1. A summary of common neuroimaging techniques by principal subject and mechanisms together with abbreviations

Neuroimaging subject	*Principal mechanism*	*Object of measurement*	*Method*	*Abbr.*
Neuronal activity	Endogenous metabolites	E.g. actate, choline, n-acetylaspartate	Magnetic resonance spectroscopy	MRS
	Exogenous metabolites	Radiolabeled metabolites	Positron emission tomography	PET
		E.g. fluoro-deoxy-glucose	Single photon emission computed tomography	SPECT
	Neurovascular responses	Perfusion	Positron emission tomography	PET
			Single photon emission computed tomography	SPECT
			Arterial spin labeling	ASL
		Blood oxygen level dependent (BOLD) MRI signal	Functional magnetic resonance imaging	fMRI
Neuropharmacology	Radioligand binding	Radiolabeled agonists/ antagonists	Positron emission tomography	PET
		E.g. fluoro-dopa	Single photon emission computed tomography	SPECT
Structural	Nuclear magnetic resonance	Tissue type and distribution	Magnetic resonance imaging	MRI (VBM, TBM, DBM)
	X-ray absorption		X-ray computed tomography	CT
Neuronal electrical activity	Focal coherent neuronal electrical activity	Induced electric field	Event related potentials	EEG/ ERP
		Induced magnetic field perturbations	Magneto-encephalography	MEG

head. With adjustments for the attenuation of photons by brain and skull tissues, the computed tomograph of the photons' sources may be read as a 'map' of regional cerebral metabolism or blood flow. Multiple scans are made, with subjects performing different cognitive or motor tasks. The maps may be contrasted in order to determine regions in which a particular task was associated with greater neuronal activity.

fMRI exploits the properties of oxygenated blood flowing in a magnetic field. Increasing aerobic metabolism requires increased local oxygen extraction from blood. There is increased blood flow locally. The increase in blood flow is greater than that required to supply the increase in oxygen consumption, by a factor of about two. The result is a paradoxical fall in deoxyhemoglobin concentration near increased neuronal activity. Unlike oxygenated hemoglobin, deoxyhemoglobin is paramagnetic. This is the basis of the BOLD signal used for fMRI. A 'map' of the changes in brain activity may be inferred from the changes in BOLD signal. For normal subjects in typical scanning environments, there is a very gradual drift in the baseline BOLD signal over minutes or hours. In contrast, the BOLD signal change due to neuronal activation occurs over 5–15 seconds.

Complex Metabolic Indices

The BOLD signal used in fMRI depends on the nuclear magnetic resonance of water protons. However, protons in complex molecules (e.g. creatine, choline, glutamate, n-acetyl-cysteine or lactate), and nuclei of other elements (e.g. ^{31}P) also exhibit nuclear magnetic resonance, at slightly different frequencies. This forms the basis of MRS. It is very informative about metabolic states, and therefore subtle differences between pathological processes. It has been used to try to distinguish different brain tumor types, or demyelinating diseases. However, MRS has poor spatial and temporal resolution, because the signal is weaker than that of BOLD-fMRI.

Neuroimaging can also be used to identify the distribution and function of specific neurotransmitter receptors, using radiolabeled agonists or antagonists such as 6-[^{18}F]-dihydroxy-phenylalanine

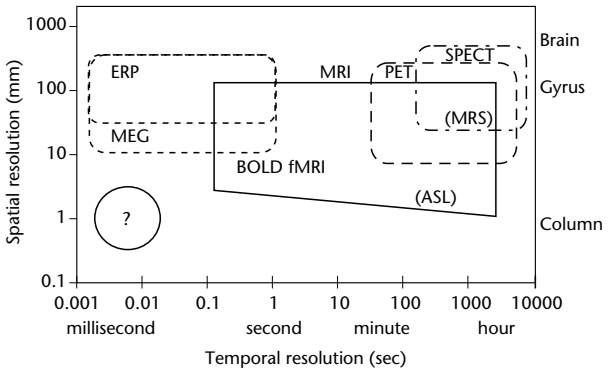

Figure 1. Diagrammatic representation of spatial and temporal resolution of minimally invasive human functional imaging techniques (adapted from Belliveau *et al*. (1992) *Investigative Radiology* **27**: S59–65). More invasive methods such as implanted electrodes' recording may offer higher combined spatial and temporal resolution in limited brain regions, but are rarely possible in humans. The ideal method (suggested by '?') would provide high spatial and temporal resolution across the whole brain at low cost and with high safety. The highly versatile platform of MRI may eventually be extended, alone or in combination with electrophysiological techniques, to provide this optimal imaging technique.

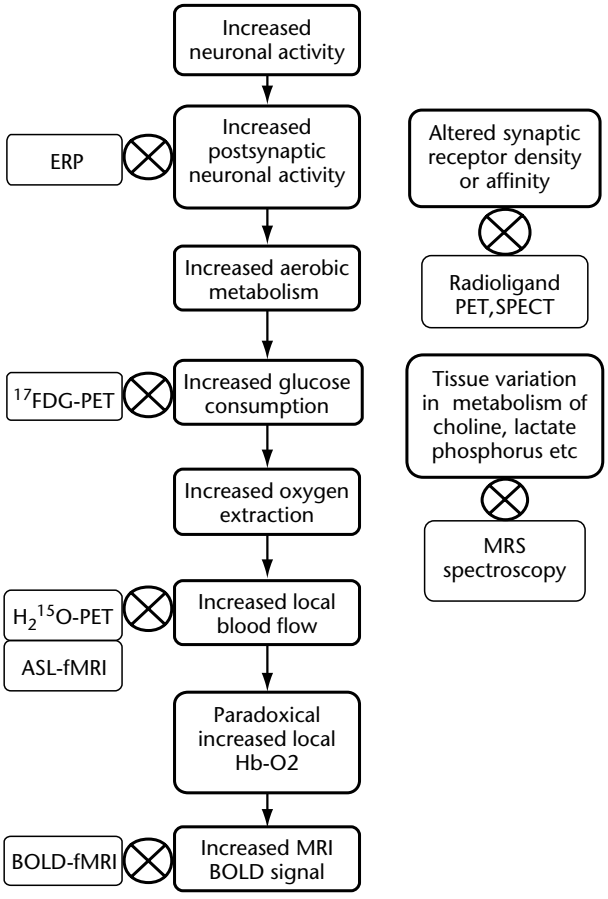

Figure 2. Increased neuronal activity has a series of electrical and metabolic consequences (dark outlines), which are detectable by different neuroimaging techniques (light outlines).

(fluoro-DOPA) and [^{11}C]-raclopride. Fluoro-DOPA acts as a false neurotransmitter, localizing in proportion to dopamine receptors in the striatum, and detected by PET. The monoamines are most commonly studied, because of their central role in the pathophysiology of major neurological diseases like Parkinson's disease, and psychiatric illnesses including depression and schizophrenia.

Application of PET and fMRI

The majority of functional neuroimaging at present uses $H_2{}^{15}O$ PET and BOLD-fMRI. Their applications are diverse, published throughout the neurological, psychological, physiological and general scientific literature, including many other parts of this encyclopedia. The early methods for neuroimaging, like PET and SPECT, required many seconds or minutes to acquire each brain image. During acquisition, subjects could perform many repetitions of the same task, or a complex task with many components. The overall activity might be due to any or all of these components.

The different tasks have some features in common, such as sensory stimulation (visual or auditory), motor actions (to indicate the chosen response, or learned motor sequences) or cognitive processes (reading, speech, working memory, long term memory encoding or recall, attention). The topic of research is reflected in critical differences *between* tasks. Areas of differential activation can be associated with the particular sensory, motor or cognitive elements of interest.

The different elements of a task might interact. For example the activation related to observation of object movement (versus static objects) might depend on whether or not attention was directed towards movement. To understand these interactions, different tasks must be designed that vary each factor independently of the others. This is known as a factorial design.

More elaborate designs include parametric variation of a factor, e.g. the speed of movement of visual stimuli, the number of items to be remembered, or the rate at which a task must be performed. The passage of time in a learning study may also be considered as a parametric modulator of activation.

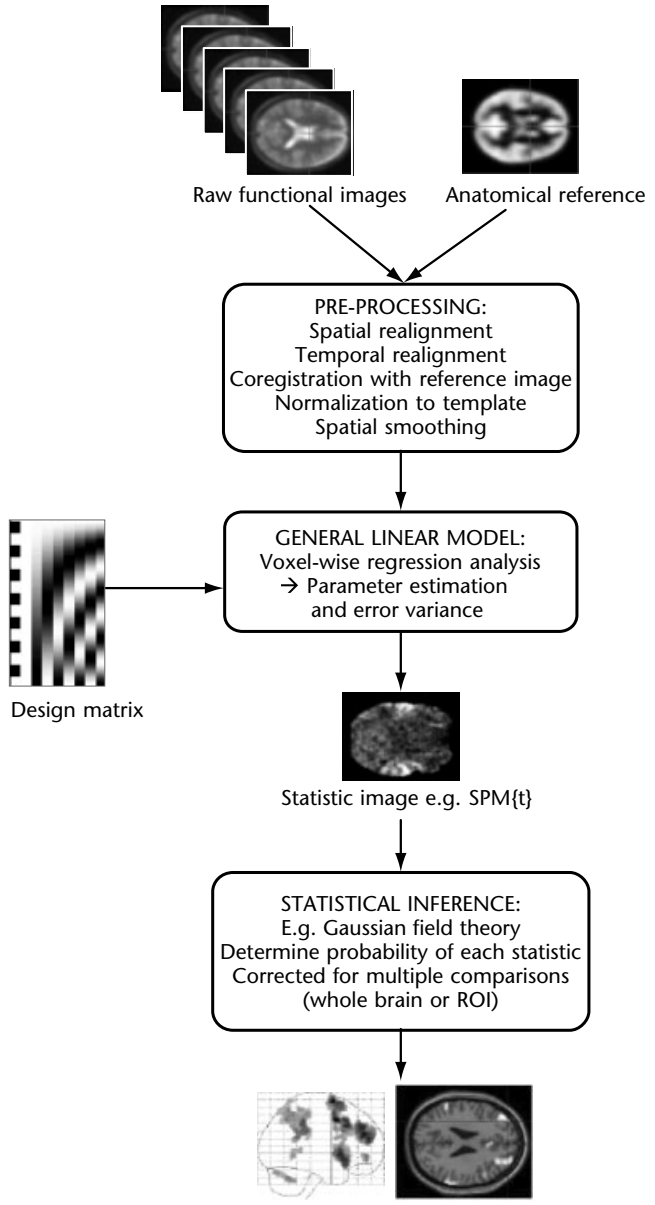

Figure 3. General scheme for analysis of functional and structural images. The three main stages are pre-processing, application of a general linear model, and statistical inference. Not all pre-processing steps are essential, but the interpretation and description of final results will vary for different pre-processing steps. The data are then subject to a general linear model, the basis for parametric tests including t-test, F-test, ANOVA, correlation, multiple regression, etc. In hierarchical models, such as random effects analyses, the application of a general linear model is repeated at each level of the hierarchy. Lastly, the probability of regional activations is determined, indicating where there are significant activations associated with the experimental conditions or tasks. Images courtesy of SPM, Wellcome Department of Imaging Neuroscience, London.

PRINCIPLES OF IMAGE ANALYSIS

A general scheme for analysis of functional or structural brain images is given in Figure 3. It can be divided into three main stages: pre-processing; application of a general linear model; and statistical analysis and inference.

Data Pre-processing

All forms of neuroimaging data undergo some form of processing before formal analysis. The minimum pre-processing is to reconstruct the raw data into a 3-D matrix, each data point representing a finite volume of brain tissue, called a voxel, for

each time point during an experiment. The subsequent processing stages will be illustrated using BOLD-fMRI data, but the principles may be generalized.

Pre-processing is aimed at allowing fair comparison of images, with optimal signal to noise ratio. To correct for movement between scans, the images are realigned to the same frame of reference. The realigned functional images may be coregistered with a structural scan of the subject, so that any regional task-related activity may subsequently be viewed in relation to the anatomy of the subject. When studying a group of subjects, it is preferable to accommodate the variation in size and shape of brains by 'warping' the brains to an international standard shape (an average shape of many normal brains). This process is called normalization. A third pre-processing step is often undertaken called smoothing, by which the data from each voxel are averaged with the data from the voxel's neighbors. Smoothing of data improves signal to noise ratio, at only a modest cost to spatial resolution. Smoothing data is necessary to use the theory of Gaussian fields to draw statistical inferences about regionally specific effects (see below). The fMRI data are often band-pass filtered during analysis. The filter may have two components: a high pass filter and temporal smoothing. This removes very low frequency effects such as the slow drift in BOLD signal over minutes.

The General Linear Model

A general linear model describes the activity of a voxel in terms of a weighted linear combination of explanatory variables (e.g. sensory, motor or cognitive events), plus some error. Given a series of images, it is possible to calculate the values of these weights, for each explanatory variable for each voxel, with minimal error. These best linear unbiased estimates of the weighting factors for each variable are known as the parameter estimates.

For accurate and meaningful parameter estimation, and subsequent statistics, it is essential to design the experiment carefully. Special consideration is given to how complex experimental tasks can be described in terms of the presence or absence of simpler explanatory variables such as stimulus presentation, memory encoding, or motor responses. Common statistical tests including t-tests, ANOVA (analysis of variance), multiple regression analysis, and correlation analysis are all based on general linear models.

Statistical Inference

The commonest statistics derived from the general linear model are the parametric t- and F-statistics. For t-tests, the magnitude of the parameter estimates must be considered against variability in activity due to chance alone, i.e. the error variance. To contrast the effects of two experimental conditions (e.g. activation in a task versus resting state) one can weight the parameter estimates, say $+1$ and -1, for the two conditions of interest. The statistic is calculable for every voxel in the brain producing a statistical parametric map, known as the SPM{t}. Statistical Parametric Mapping, SPM, refers to this general process of image analysis and is also the name of one of several software packages available for this process.

The F-statistic is the ratio of variance explained by inclusion of a variable in the model (or weighted combination of variables), divided by the error variance of the whole model. It may be used to compare models in a hierarchy of complexity, or to test a set of multiple linear hypotheses in a model. A map of the F-statistic can be drawn for the whole brain, called the SPM{F}.

To draw statistical inference, it is necessary to assign a probability value to the t- and F-statistic at each voxel. However, hundreds or thousands of voxels may have been scanned. Bonferroni correction for multiple comparisons is not appropriate because a voxel's data are not independent of the data in neighboring voxels. One solution is to consider the voxels to be a lattice representation of a continuously varying field across the brain. The theory of Gaussian random fields may then be used to make clear predictions about the expected features of the SPM{t} or SPM{F} (Worsley *et al.*, 1996), and assign a probability value to each voxel for a given contrast of experimental conditions.

There are different types of inference that can be drawn from the statistical parametric maps. There is a trade-off between regional specificity of the inference and the sensitivity. The most regionally specific test is to ask whether the t- or F-value at a voxel exceeds a threshold. For example, were voxels in the temporal cortex more active during reading than rest. In contrast, there is the omnibus test of whether the overall number of suprathreshold clusters of voxels is significant. For example, is the brain map different when reading compared with rest, without specifying where those differences lie. Of intermediate specificity and sensitivity are cluster level and set-level tests. The cluster level test determines the probability of spatial extent for each suprathreshold cluster. For example, when

comparing reading with rest, is the group of activated voxels in the temporal lobe significantly large. The set-level test determines the probability of the observed number of suprathreshold clusters that each exceed a specified size. For example, are there significantly more regions of activation above a certain size than would be expected by chance.

INTERPRETATION OF VARIANCE

General Principles

When studying a group of subjects under several conditions, there are many possible reasons for differential activation of a brain region. For example, it may be that the experimental condition is associated with different activity at that part of the brain. This is called 'condition variance'.

However, activation may differ because of structural brain differences; or because subjects perform the task differently; or that they have inherently different neurovascular coupling. These factors contribute to 'subject variance'. Even if these factors are controlled, the sensitivity and baseline of the BOLD-fMRI signal changes between scanning sessions. This leads to 'session variance'.

Session variance is generally large in comparison with condition variance in fMRI. Session by condition interactions may significantly explain changes in regional brain activation. If so, task-related activations for a given subject cannot be generalized from a single session to infer 'typical' activation patterns from this subject. In addition, differences of task-related activation between sessions might be due merely to session by condition interactions rather than the factor of interest (e.g. scanning before and after drug therapy).

Fixed and Random Effects Analyses

One often wants to extend inferences from particular subjects to the general population. A group of subjects may be considered to have been sampled randomly from the general population to which they belong, e.g. all men of that age, or all patients with a particular disease. This contrasts with the experimental conditions which are 'fixed' by the experimenter. Random and fixed variables must be treated differently in the analysis of variance of repeated measures, including neuroimaging.

For SPM{t}s, one calculates the ratio of the contrasted parameter estimates to a denominator variance term. If all variables are fixed (a fixed effects analysis), then the denominator term is the error variance within subjects (mainly noise from scan to scan). However, with a random variable like the selection of subjects, the appropriate denominator term must include the variance between subjects (random) as well as within subjects (fixed).

Models with both fixed and random effects are generally difficult to analyze. However, the balanced design of most imaging experiments enables a two-staged approach to mimic a mixed effects model. The first stage is a fixed effects model within each subject, to generate a summary image from each subject, such as the map of activation differences between reading and rest. These summary images can then be assessed across subjects in a second level (random) effects model. For balanced designs, the variance due to fixed and random effects is in the right ratio to assess the overall population effect.

In a fixed effects model combining data from several subjects, a significant activation may be due to a large effect in just one or two subjects, rather than a general effect across the group. However, it is still possible to make qualitative inferences about the population effects from a fixed effects model, if one stipulates that an effect is significant in all subjects. The refutation of the null hypothesis in all of the subjects is known as conjunction analysis. If a result is found in all subjects, even from a small group, it may be regarded as typical of the general population.

Group Data and Clinical Studies

The problem of extending inference to the subjects' general population is highlighted in clinical studies. The expression of disease will vary at a subject level, both between patients and over time in the same patient. If patients are rare or heterogeneous, how should they best be compared with control subjects, or studied over time? A random effects analysis may not always be possible. It requires a large group of patients (typically >12) who differ from the comparison group only in terms of the disease of interest. Many studies have used fixed effects models, and had to accept that the inference only extends to the particular patients studied. It is possible to use a conjunction analysis approach to show that each and every patient in a group differs from the control subjects with regard to a particular effect.

Ambiguity can arise when interpreting differences in regional brain activations in patient-control studies. These problems arise whether the patients have focal lesions, are subject to different drug therapies or are being studied during recovery

from disease. Interpretation depends on whether the performance, behavior and cognitive strategy in the patient group are the same as the control group. If a patient does not perform a task, or manipulations of the task suggest a different strategy is employed, then the normal pattern of brain activity cannot be expected. Neuroimaging cannot resolve whether the performance difference is attributable to the abnormal brain activity or vice versa.

ADVANCED MODELING TECHNIQUES

Event-Related fMRI

In early fMRI studies, the experimental paradigms were similar to those used in PET studies. Tasks were repeated during a specific 'block' or 'epoch' lasting approximately 30 seconds. fMRI can also characterize the BOLD response to transient events, such as a brief visual stimulus or single movement (Buckner *et al*., 1996). Although these events are transient, the BOLD response can be averaged across many repetitions. This has many advantages.

First, it exploits the excellent temporal resolution of fMRI, to identify separate patterns of brain activation caused by events even less than a second apart (Menon and Kim, 1999). Second, some cognitive and neurological processes can only be studied as occasional events, e.g. responses to unexpected or unusual events can only be studied if the events are rare, and not if they are recurrent in a block design. Third, some events cannot be controlled or predicted by the experimenter, e.g. correct versus incorrect responses to questions. The times of these events must be determined *post hoc*.

If stimuli can be presented individually, what is the best rate and order of presentation of different stimulus types? The rate of events may be defined by the stimulus onset asynchrony, SOA. With shorter SOAs, the BOLD response to one event becomes attenuated by previous events, but more events can be studied. If multiple event types are studied, the optimal SOA depends on the type of comparison to be made. In general, SOAs in the range 2–8 seconds are more efficient. Shorter SOAs are more efficient to determine differential responses between event types, whereas longer SOAs are more efficient to estimate the responses to each event type.

Effective Connectivity

Functional connectivity describes temporal correlations between spatially remote neurophysiological events. Effective connectivity describes the influence one area or neuronal system has over another. Functional connectivity between two areas may arise from effective connectivity, but it can also arise if there are common inputs from a third area.

Changes in effective connectivity are better understood when associated with particular experimental conditions. For example, the causal relationship between two regions' physiological activity may change under different psychological conditions. This is a psychophysiological interaction. There are many approaches to characterizing such interactions.

The first approach uses a general linear model. The model estimates the condition-specific covariance between the activation of a 'voxel of interest' and all other voxels. A significant difference in condition-specific covariance implies that the remote voxel covaried with the voxel of interest more under one experimental condition than another. This difference in covariance is not affected by the main effect of experimental condition, and is not dependent on an overall correlation between the voxel and the region of interest.

An alternative approach is to assess effective connectivity within a more restricted anatomical model. The anatomical model may be based on known primate anatomy; information obtained from structural neuroimaging studies (see below); or proposed on the basis of distributed activation patterns in functional imaging studies. Effective connectivity may be identified using structural equation modeling (Buechel and Friston, 1997). The model is used to calculate path coefficients (connection strengths) among the regions that best explain the variance-covariance structure of the data. The connection strengths take into account potential common inputs from other areas in the model. The significance of specific connection strengths may be tested by comparing two models, with and without exclusion or constraint of that connection. Connections are significant if their exclusion or constraint significantly changes the overall goodness of fit (measured by the chi-squared statistic, rather than t- and F-tests).

Structural equation modeling is a powerful and flexible tool for image analysis. Models can be used to compare connectivity under different experimental conditions. For example, administration of drugs or changing cognitive context may change the connectivity among regions, without changing overall activity within each region. Models can also be used to describe the contribution of one cortical region to changing connectivity between two others. For example, the covariance between

primary sensory cortex and association cortex may itself covary with parietal or prefrontal cortical activity, consistent with top-down modulation of sensory processing. There are, of course, limitations to structural equation modeling and other analyses of effective connectivity. Although demonstrating the influence of one area on another in the model, they do not prove that that model is the best of all possible models, nor that the connection is direct.

Causal influences are also suggested by the temporal order of activation in different regions, and experimental manipulation of activity by stimulation or lesion studies. Even event-related fMRI currently lacks the temporal resolution to show temporal precedence in distributed neural networks. This may be possible in combined studies, with fMRI and electrophysiological measures such as implanted electrodes, electroencephalograms (EEG) or magnetoencephalograms (MEG). In humans, direct experimental manipulation of cortical activity may be achieved by transcranial magnetic stimulation, TMS.

A caveat to the interpretation of connectivity from neuroimaging is that it refers to an excitatory or inhibitory effect of one region over the other at a systems level. Inferences cannot be made about the excitatory or inhibitory nature of the synaptic links, nor whether the connections are direct or polysynaptic.

STRUCTURAL NEUROIMAGING

Computational Morphometrics

The BOLD signal used for fMRI is based on the T2* MRI signal. In contrast, the T1 signal may be used to achieve very detailed anatomical information about gray or white matter. This may be used to examine subtle but systematic anatomic differences between populations, a process known as computational morphometry (Ashburner and Friston, 2000). It is possible, for example, to compare men and women, young and old, or patients and controls. Any of the information given by the structural brain images may in principle be used, but there are three common approaches.

Firstly, voxel-based morphometry, VBM, which compares the main tissue compartments of the brain. If brain images are placed in a standard anatomic framework, then at any given coordinate there is a certain probability of that voxel being gray matter, white matter or cerebrospinal fluid (CSF). The probability distributions for each tissue type for each subject may be entered into a general linear model, in the same way as functional imaging data above. If two groups are included, then for each voxel one can derive a statistic of the group difference, and thereby an SPM{t} of structural differences between the groups.

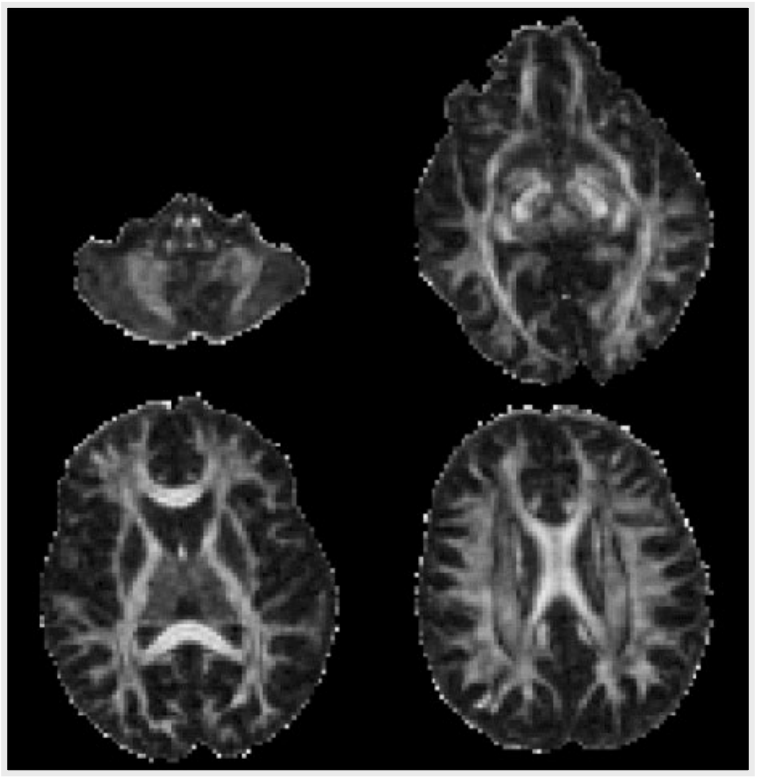
The second approach uses the information derived from the normalization (warping) of each brain image to a standard template image. Multivariate statistics may be applied to the deformation fields, to reveal global differences in brain shape between groups (deformation-based morphometry, DBM). In the third method, spatial derivatives of the deformation fields may be used to reveal significant differences in local shape or structure (tensor-based morphometry, TBM).

VBM, DBM and TBM can each be used to quantitatively characterize and compare structural brain MRI scans. The first to examine local differences in anatomy, the second to examine large-scale differences in shape and the third to characterize local shape differences. For some specific hypotheses, e.g. hippocampal gyral changes in Alzheimer's disease, one technique may be preferred. For other hypotheses, e.g. sex differences in cortical anatomy, these three methods are complementary.

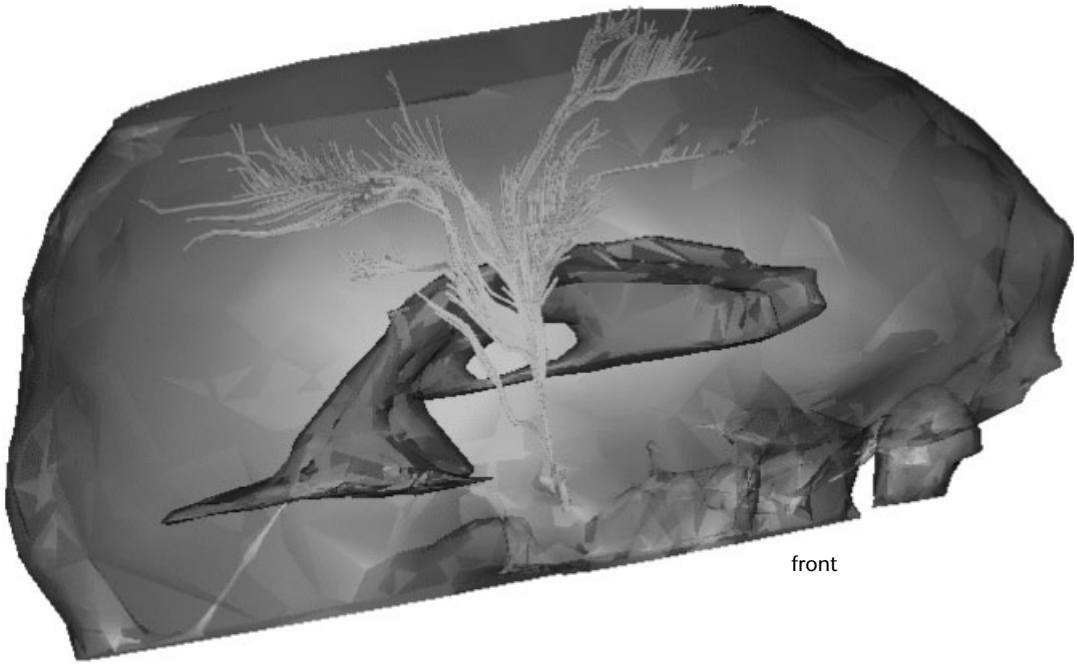
Diffusion Weighted Imaging

In parallel with characterization of functional connectivity by fMRI and PET imaging, methods have also been developed to determine anatomical connectivity. New techniques allow investigation of human brain connections *in vivo*. Several of these techniques depend on the property of anisotropy of water diffusion. Water diffusion in a magnetic field gradient leads to MRI signal dropout. The diffusion of water molecules along axons is greater than diffusion across the axon membranes. In an organized bundle of axons there will be asymmetric diffusion, called anisotropy. Anisotropy is high in normal white matter tracts, and low in gray matter, or disordered white matter.

The anisotropy may be measured for the whole brain, or specific regions, by diffusion tensor imaging, DTI. The diffusion tensor is a kind of matrix that contains information about the magnitude and direction of anisotropy for each voxel of the brain. The anisotropy may be displayed in terms of its magnitude or direction, or both. This provides an immediate impression of interconnected white matter tracts as in Figure 4a. Formal analysis of these images is the basis of tractography, which is the mapping of white matter tracts and nerves. If a tract runs between two voxels, then they will have similar anisotropy. Conversely, if two voxels have similar anisotropy, it is more likely that they



(a)



(b)

Figure 4. [*Figure is also reproduced in color section.*] (a) Anisotropy map through four axial slices of the human brain, with higher anisotropy indicated by lighter gray. The map clearly highlights the organization of the white matter tracts. (b) The anisotropy information may be used for tractography. In this example the likely connections from a 'seed' voxel in the pyramidal tract are shown in green from a right-lateral viewpoint, within a transparent brown cranium, extending upwards and fanning out as part of the corona radiata. The positions of the ventricles are shown in red. Images courtesy of Dr Geoff Parker, Institute of Neurology, London.

lie on the same tract than if the anisotropy is different. It is therefore possible to define how two brain regions are most likely to be connected, by finding the connecting route that minimizes the cumulative difference in tensors. This is known as a 'streamline' approach (Conturo *et al*., 1999). Alternatively, one can start with a 'seed' voxel, and link together neighboring voxels of similar tensors, building up a branching tree of likely connections. The results of this approach are shown in Figure 4b.

FUTURE DEVELOPMENTS

Progress in our understanding of integrated functional brain systems is fueled by improvements in the temporal and spatial resolution of neuroimaging, and the theoretical framework for analysis and interpretation of brain images. This is partly due to advances in the technology of image data acquisition, but also new analytical techniques and experimental designs, such as event-related fMRI. In the future, the analysis of functional imaging may directly incorporate prior information of cortical anatomy and human anatomic connectivity.

The integration of functional imaging with other techniques also promises a fuller characterization of integrated neural systems, with defined effective connectivity, dependent on specific neuropharmacological processes. For example, it will become easier to combine EEG with fMRI data, both by simultaneous acquisition and by mutually informative analysis of activation foci. This combination may offer the temporal resolution of EEG with the spatial resolution of fMRI (Dale *et al*., 2000). The addition of transcranial magnetic stimulation or new pharmacological agents in combination with fMRI or PET, will allow one to study the effects of experimentally controlled manipulation of brain function, to understand the normal human brain and the mechanisms of neurological and psychiatric disease.

Neuron Doctrine

Introductory article

Leonard K Kaczmarek, Yale University School of Medicine, New Haven, Connecticut, USA

CONTENTS

A simple statement of the neuron doctrine is that neurons are the fundamental units of the nervous system, and that the entire activity of the brain can be understood in terms of the actions and interactions of these cells. While this is generally accepted by current-day neurobiologists, theories of exactly how neurons achieve control over the workings of the brain have undergone multiple modifications since the concept was first introduced.

THE NEURON AS A CELLULAR ENTITY

The neuron doctrine, which was first formulated explicitly in a review article by Wilhelm Waldeyer in 1891, emerged through a debate at the end of the nineteenth century between the neuroanatomists Camillo Golgi and Santiago Ramón y Cajal. Although Golgi had developed a staining procedure that allowed an entire neuron to be visualized, together with its complex axonal and dendritic branches within the brain, his position in the debate was that the nervous system constituted a complex continuous syncytium of tissue. In contrast, Ramón y Cajal championed the concept that each of these 'Golgi-stained' structures with their complex arborizations represented a single functional unit (i.e. a single neuronal cell) (Figure 1). Although Golgi's accomplishments were far-reaching in many spheres of cell biology, and both men received the Nobel Prize for their work, it is Ramón y Cajal's name that is spoken in hallowed tones by today's neurobiologists.

A philosophical implication of the neuron doctrine is that it will become possible to explain fully the workings of the mind through an understanding of the way in which neurons work. Whether this is true or not, there are many more experimentally tractable questions that are related to the role of neurons in the brain. For example, what exactly constitutes 'a functional unit'? What aspects of the anatomical, physiological or chemical make-up of a neuron are central to its function? Over the more than 100 years since the neuron doctrine was formulated, views of how the combined activity of neurons gives rise to simple and complex patterns of behavior, as well as learning and memory, have become modified considerably, and there is no reason to believe that we are yet close to an answer.

If neurons as individual cells are the fundamental units of the nervous system, there must exist

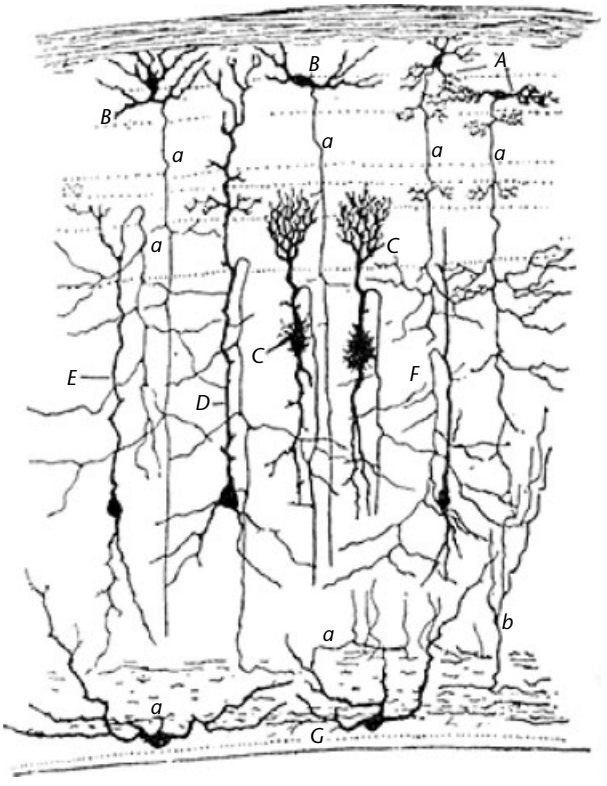

Figure 1. A drawing made by Santiago Ramón y Cajal, using the Golgi staining technique, showing different types of neurons in the optic tectum of a bird. (Reproduced by permission of the Cajal Institute, CSIC, Madrid).

mechanisms whereby they communicate. As is true of all cell types in the body, there is a host of chemical and mechanical ways in which neurons and other cells of the nervous system can influence their partners. These include soluble molecules known as growth factors, which in general instruct cells to grow, divide or even die, as well as molecules on the surfaces of neurons, which influence the properties of neighboring cells by direct physical contact. Nevertheless, the interaction between neurons that is most closely identified with the neuron doctrine is *synaptic transmission*. The term *synapse* was coined by Sir Charles Sherrington at the end of the nineteenth century, close to the time when the neuron doctrine itself was formulated. It refers to the connection between two neurons, usually at the end of the axon of one neuron where it is in close contact with the dendrite of the second neuron. At this site, unidirectional transfer of information occurs from the first neuron to the second one. Sherrington used the concept of synapses to explain how information is passed from a sensory organ to muscles in simple spinal cord reflexes, such as those that produce the withdrawal of a limb in response to strong mechanical stimulation of touch- or pain-sensitive neurons in the skin. It is now known that the synapse is a specialized site at the end of an axon where chemical neurotransmitters are released upon the arrival of a nerve impulse. These neurotransmitters diffuse across a narrow gap between the two neurons, and bind to neurotransmitter receptors on the second neuron. This in turn may excite the postsynaptic neuron, either triggering a nerve impulse in the second cell or increasing the probability that an impulse will occur. Alternatively, a neurotransmitter may inhibit the postsynaptic cell, thereby reducing the probability that a nerve impulse will occur.

NEURONS AS 'ON–OFF' SWITCHES

Some of the earliest studies of synaptic transmission were carried out at two very specialized synapses, namely the neuromuscular junction of vertebrates and the giant synapse of the squid. Indeed, the mechanism of the nerve impulse itself was first discovered as a result of studies of the giant axon of the squid. Transmission across the synapse on to the giant axon eventually results in the contraction of muscles that force water through the mantle of the animal. This allows squid to propel themselves through seawater at speeds that match those of fast automobiles. The occurrence of nerve impulses (action potentials) in both the presynaptic and postsynaptic neuron is 'all or none' – that is, if the neuron is excited sufficiently it generates an impulse whose form is independent of the initial stimulus. The impulse then propagates along the axon to its destination at the axon terminal. The release of neurotransmitter at the synaptic junction produces excitation of the postsynaptic neuron that is sufficient to drive another impulse in its axon. The properties of this synapse are generally similar to those of the neuromuscular junction, where the postsynaptic cell is a muscle cell rather than another neuron, and where the impulse results in contraction of the muscle. Both types of synapse are considered to be very 'secure'.

The mode of action of these two systems proved very influential in theories about how neurons may function within the brain. In particular, a neuron could be considered to be either active (i.e. conducting an impulse) or inactive. According to this line of thinking, the wiring diagram of the nervous system (i.e. the exact way in which the neurons are connected) is the single most important factor determining the way in which the nervous system functions. A variety of analogies could be drawn to provide an intuitive understanding of neuronal function. The wiring diagram of the nervous system has been said to resemble a telephone network. A key aspect of this view is that, because an individual neuron is either on (firing an action potential) or off (silent), knowledge of the biochemical and/or physiological properties of the component neurons is not particularly relevant to an understanding of the way in which the nervous system controls behavior. However, the strength of the synaptic connections between the neurons, and whether they are excitatory or inhibitory, is clearly of paramount importance, and studies of learning and memory have focused primarily on mechanisms that can alter the strength of the synaptic connections between two neurons. Indeed, the current most popular models for the investigation of learning and memory are phenomena termed long-term potentiation and long-term depression, in which specific patterns of stimulation lead to either an increase or a decrease in the strength of synaptic transmission.

According to the view of neuronal activity described above, in which a neuron can be considered to be either 'on' or 'off', binary logic can be applied to the elements of the neuronal network. As a result, many types of computer models have been implemented over the years to mimic the behavior of networks of neurons. While some of these models constituted real progress in engineering

and artificial intelligence, such simple models have so far proved to be spectacularly uninformative with regard to understanding real systems of neurons. This is partly because real neurons do much more than simply act as an 'on–off' switch. While no neurobiologist would dispute the importance of either connectivity or mechanisms that change the strength of synaptic connections, it is now evident that other mechanisms, related to the biological properties of individual neurons, are also key elements of neuronal function (Figure 2).

CONTROL OF BEHAVIOR BY NEUROPEPTIDES

The simple picture of the brain as a carefully wired circuit-board was dealt a very significant blow by the discovery of *neuropeptides*. These are basically a class of neurotransmitters whose function is similar to that of the 'classical' neurotransmitters that are released at synaptic endings, and which excite or inhibit the postsynaptic cells. Chemically they are larger and more complex than the classical neurotransmitters. More significantly, however, the action of these neuropeptide neurotransmitters is not delimited by the synaptic connections of the neuron from which they are released. Even more strikingly, the release of these substances is not usually dependent on the occurrence of single nerve impulses. Typically, a prolonged burst of neuronal firing is required to evoke the release of neuropeptides.

Neuropeptides are thought to be associated with relatively complex animal behaviors, rather than with simple reflexes. For example, they regulate feeding and reproductive behaviors. A very large number of neuropeptides have been identified within the brain, and some of these also function as hormones in other organs of the body. One of the first neuropeptides to have its role in animal behaviors thoroughly investigated was egg-laying hormone (ELH), which is released from certain neurons in *Aplysia*, a marine organism that, like the squid, has been widely used to investigate neuronal function. ELH is released by a train of impulses in the neurons, and brings about a long and complex sequence of reproductive behaviors that culminate in egg-laying. However, no specific synaptic connections are required for ELH to act on its target neurons. Instead, the neuropeptide simply diffuses away from the cells from which it was released until it encounters other neurons that have specific receptors for this transmitter. Another early example of neuropeptide action is that of luteinizing hormone-releasing hormone (LHRH) which, when it is released from certain neurons in rodent brain, brings about lordosis, a stereotyped pattern of sexual behavior. As with other neuropeptides, the neurons that respond to LHRH do not need to be connected synaptically to the neurons that release it.

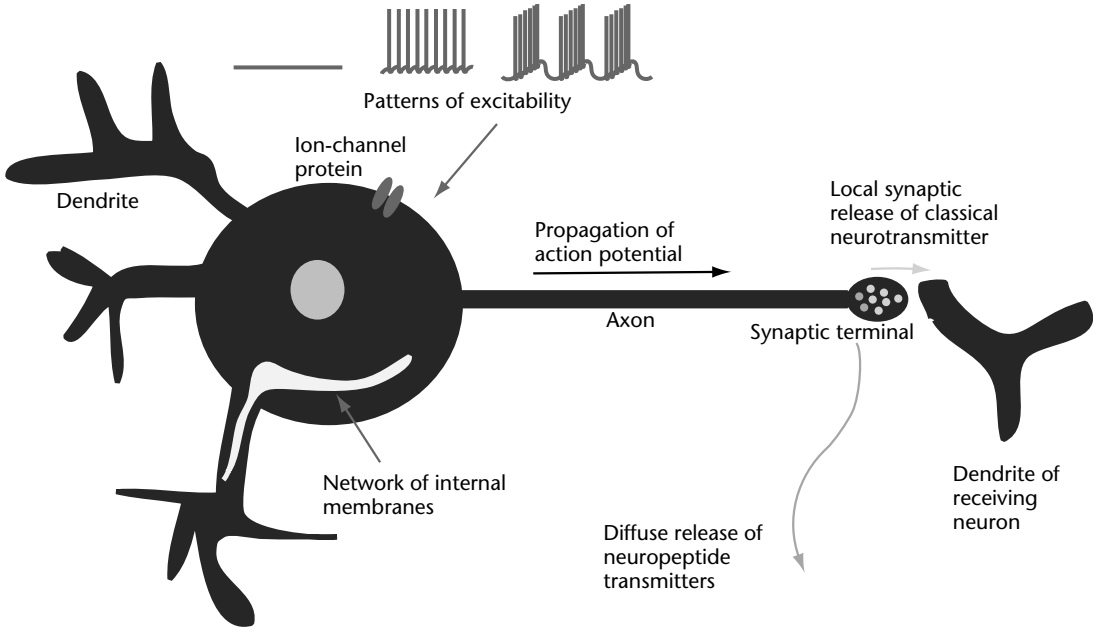

Figure 2. Schematic drawing of a neuron, showing some of the modes of neuronal information transfer described in the text.

Neuropeptides are found within neurons at all stages of sensory and motor processing within the brain, where they generally coexist with classical neurotransmitters. However, communication between neurons via their neuropeptide network does not depend on anatomical connectivity between the neurons. In many of these 'networks' the occurrence or timing of single neuronal impulses has no particular significance; these impulses exist simply as a mechanism to promote the secretion of the neuropeptides. The significant information now resides in which particular neurons bear receptors for the peptides and the exact way in which exposure to the neuropeptide alters the properties of these neurons (see below).

EACH NEURON HAS ITS OWN ELECTRICAL PERSONALITY

Another major modification to the simple 'on–off' view of neuronal function has arisen from a closer examination of the electrical properties of neurons within the central nervous system. These are much more varied than those of the squid giant axon or the neuromuscular junction. Indeed, even the concept of the nerve impulse as 'all or none' has changed. Although the propagation of an action potential down a long axon is indeed an 'all-or-none' event, the action potentials that occur in dendrites, cell bodies or synaptic terminals of a neuron can vary in their shape, height and width. The particular way in which a neuron is stimulated can produce changes in the shape of these action potentials. When these occur at synaptic endings, they alter the amount of neurotransmitter that is released. Changes in action potential shape at the cell body produce biochemical changes that determine how the neuron will respond to future simulation.

The shape of its action potential is not the only electrical feature of a neuron that is subject to change over time. Some neurons are entirely silent unless they receive an excitatory synaptic input from another neuron. In contrast, other neurons are capable of generating long spontaneous trains of action potentials in the absence of any synaptic input. Yet other neurons produce rhythmic bursts of impulses separated by brief periods of silence. Neurons with the latter feature can frequently be found in neuronal networks that generate rhythmic motor outputs (e.g. for locomotion or breathing). The way in which a neuron responds to sustained stimulation of its synaptic inputs is also varied. Some neurons only respond when they are first stimulated, and cease to generate impulses if the stimulation is maintained. This neuronal property underlies the adaptation that occurs in response to many types of sensory stimulation. Other types of neuron fire action potentials as long as they are being stimulated, while yet others continue to generate impulses spontaneously long after the initiating stimulus has ceased.

The most important feature of these electrical properties is that neurotransmitters and neuropeptides produce both short-term and long-term changes in these intrinsic firing patterns. In this case, the complex computational decisions that shape the output of the network are made within the neurons themselves, rather than at specific synaptic connections. The intrinsic electrical excitability of a neuron and the way in which this changes as a result of stimulation are both determined by the complement of *ion-channel proteins* that are found in the membrane of the cell. The relatively recent discovery of a huge number of genes that encode ion channels is testament to the importance of these intrinsic electrical properties. It has been estimated that a neuron selects its ion channels from literally billions of possible combinations.

ARE GLIAL CELLS ALSO NEURONS?

The neuron doctrine arrogantly ascribes the business of the brain to neurons alone. Yet neurons are not the only cell type in the brain. The *glial cells* that surround neurons are in fact far more abundant than the neurons themselves. Even before the neuron doctrine was formulated, glial cells had been named by the anatomist Rudolf Virchow as *neuroglia* or 'nerve glue', with the assumption that they exist primarily to hold the neurons together. Several different types of glial cells exist, and a variety of supporting roles have been convincingly attributed to them. Nevertheless, recent research has also suggested that one class of glial cells, termed *astrocytes*, may participate in extensive cell-to-cell communication. For example, the calcium ion concentration within a cell is known to be a key regulator of many cell functions, and in neurons it directly controls the release of neurotransmitters. Traveling waves involving rapid fluctuations of calcium ions have now been measured in networks of astrocytes that span wide areas of brain tissue. The significance of these waves of glial signaling is not yet known, but speculation abounds that they play a functional role in shaping the output of the nervous system, and that they may even play a role in learning and memory.

NEURONS USE MULTIPLE PATHWAYS FOR SIGNALING

To communicate across the relatively large distances (in cellular terms) between different regions of the brain, and between the brain and peripheral organs, the nervous system developed the mechanism of rapid axonal conduction of nerve impulses coupled to synaptic transmission. However, it is now evident that other mechanisms exist for the flow of information from one part of a neuron to another. These include an extensive array of membranes that lie within the cell itself. Composed of organelles termed endoplasmic reticulum and mitochondria, these membranes form an internal network within a single neuron. Information that is largely mediated by fluctuations in calcium ion concentration may be propagated from one site in a neuron to another across this network without invoking the traditional generation of nerve impulses. Indeed, this concept of extended internal membranes has been dubbed a 'neuron within a neuron'. In addition to this relatively rapid means of communication, slower biological processes that transfer molecules from the cell body of a neuron to its axon or dendrites, and vice versa, also exist. The way in which the nervous system adapts to its environment in the long term almost certainly involves these slower mechanisms of information transfer.

SUMMARY

The neuron doctrine, expressed as the belief that neurons are fundamental units of the nervous system, and that their activity controls both the behavior of humans and animals and the way in which they perceive their environment, is in good experimental shape. The anatomical, biochemical and physiological processes and the organizational principles that allow networks of neurons to do this are being determined by neuroscientists at many levels, ranging from the molecular to the behavioral.

Neurons, Computation in

Introductory article

James M Bower, University of Texas Health Science Center, San Antonio, Texas, USA

CONTENTS

Detailed knowledge of the complexities of single-neuron computation – the way in which single neurons process synaptic input – is essential to understanding the function of the brain itself.

INTRODUCTION

Arguably the most famous, and certainly one of the most influential, neuroscientists of all time was the Spanish neuroanatomist Santiago Ramón y Cajal. Working in the later nineteenth and early twentieth centuries, Cajal used an anatomical staining technique developed by the Italian biologist Camillo Golgi that – for reasons that remain mysterious – results in dark staining of only a small number of the many trillions of neurons found in the brain. Cajal spent his entire professional career drawing these labeled cells and carefully describing their sizes, shapes and distributions. An example taken from his studies of the cerebellum is shown in Figure 1. For this work, Cajal was awarded a Nobel Prize in 1906, a prize he shared with Golgi.

Cajal's work established some of the most fundamental assumptions underlying brain science. He demonstrated that the somewhat amorphous-looking brain tissue was actually made up of individual and separate neurons: this is now known as the 'neuron doctrine'. In the nineteenth century and even well into the twentieth, there were many philosophers and scientists, including Golgi, who believed that mental function could not depend on individual cells, but instead required what they called a 'reticulum' of directly interconnected processes. Cajal's claim that each neuron was a distinct entity with processes separated from other neurons by an actual physical space, now known as the synaptic cleft, was hotly debated until the mid-1950s when the invention of the electron microscope finally proved that Cajal had been right. The neuroscience literature is full of papers using modern tools to re-establish conclusions first drawn by Cajal using a simple microscope.

While Cajal's observation turned out to be correct, the neuron doctrine in its full form makes a much more fundamental and important assertion. As formulated in the famous 1891 review of Cajal's work by the German physician Wilhelm Waldeyer, Cajal's efforts led to the conclusion that 'the nerve cell is the anatomical, physiological, metabolic, and

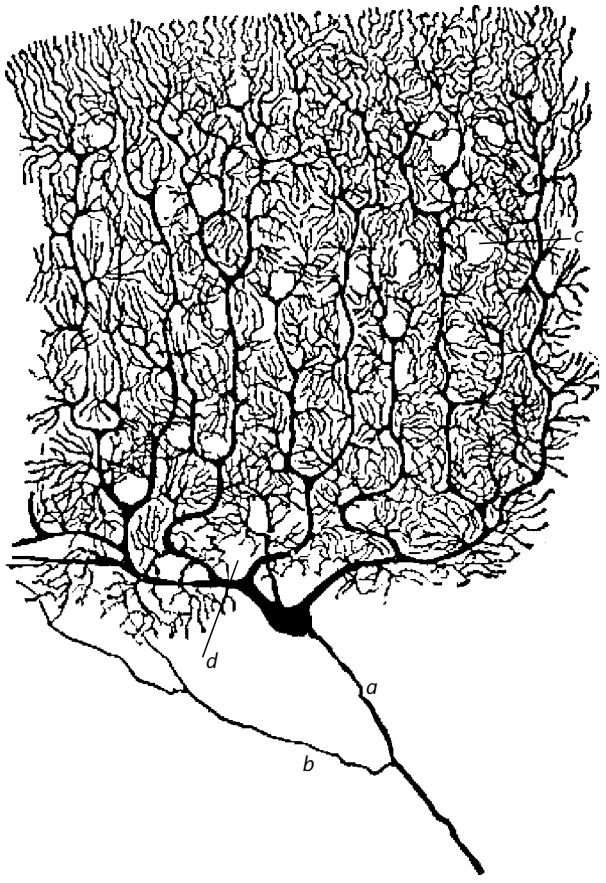

Figure 1. Drawing of a single Purkinje cell made by Ramón y Cajal in the late 1800s.

genetic unit of the nervous system.' Today we would add to that list that the neuron is also the brain's most fundamental computational unit. It is the electrical–chemical interactions within and between neurons that are believed to underlie all behavior, from the simplest to the most complex. Accordingly, the ultimate understanding of brain function will almost certainly depend on an understanding of how neurons act and interact.

INFORMATION PROCESSING IN NEURONS: THE TRADITIONAL VIEW

It can be argued that the development of neuroscience has been characterized by a slow and continuous growth in our understanding of the complexity and sophistication of the brain as a computational device. While this statement applies to all levels of brain studies, from behavior to molecules, it is perhaps nowhere as clear as in the study of the physiological and computational properties of single neurons. The traditional description of the neuron divides each cell into three distinct functional parts: the dendrite (from the Greek *dendron*, or tree), the soma or cell body, and the axon. The classical view of neuronal computation then follows from these divisions, with the dendrite receiving synaptic input from other neurons, the soma determining if the neuron should generate an output, and the axon conveying that signal in the form of an action potential to other neurons. Remarkably enough, Cajal inferred these relationships by looking at the shapes of neurons. At the time, the idea that dendrites received synaptic input, the soma synthesized the input and the axon distributed the results was known as the 'law of dynamic polarization', and remained highly controversial for many years. Once again, however, Cajal turned out to be basically right.

In the years between Cajal's publications and the 1960s, a great deal of attention was directed at efforts to understand the biophysical mechanisms underlying the generation and propagation of electrical signals along the axon. Primarily through the convenient use of a very large axon found in the squid (the 'giant axon'), a detailed understanding of the mechanism underlying this signal, also called the action potential, was obtained by the late 1950s. This effort was capped by a careful series of experiments performed by Alan Hodgkin and Andrew Huxley that led to a mathematical model for the generation of the action potential and resulted in a Nobel Prize in 1963. The mathematics used to describe this biophysical mechanism, known now as the Hodgkin–Huxley equations, remains at the base of most efforts to model neurons today.

To understand the action potential, or any neuronal process for that matter, one needs to realize that neurons are electrochemical devices. Critical to the function of neurons is the fact that their cellular membranes not only isolate the conditions of the inside of the cell from the outside, but also maintain those conditions through the selective and controlled passage of ions and other substances through the membrane. Charged ions such as sodium, potassium, calcium and chloride, which are particularly important to the electrical behavior of neurons, can move rapidly in and out of the membrane through physical channels that open or close under different electrical or chemical conditions. In addition, neuronal membranes contain ion pumps that control the intracellular concentrations of these important ions over the longer term.

In neurons, these membrane properties result in a maintained or 'resting' electrical difference at the soma between the inside of the cell and the outside of, on average, 65–75 millivolts, the inside of the cell being more negative than the outside. During the generation of an action potential, this resting membrane potential rapidly reverses polarity, with the inside of the cell briefly becoming more positive than the outside. Hodgkin and Huxley showed that this membrane potential 'depolarization' is driven by the rapid movement of positively charged sodium ions into the neuron through membrane channels specific for sodium. Under normal steady-state conditions, these channels are closed. When the channels are opened, positively charged sodium ions rush into the cell, driven by the difference in electrical potential (they are positive, the inside is more negative), as well as the fact that an ion pump maintains ten times less sodium inside the cell than outside. Observationally, once the action potential reaches its peak voltage (usually within a millisecond or less), membrane potential returns fairly rapidly to the resting level, with the inside once again more negative than the outside. Analysis by Hodgkin and Huxley demonstrated that this 'repolarization' of the membrane is driven by the movement of potassium ions out of the axon through their own set of membrane channels. Potassium moves out of the cell, following its own concentration gradient, because the same ion pump that maintains low levels of intracellular sodium maintains high levels of intracellular potassium. The flow of positively charged potassium to the outside of the cell leaves the inside more negative.

What Hodgkin and Huxley demonstrated was that the key to understanding this sequence of events lies in the factors controlling the opening and closing of the sodium and potassium channels. It turns out that sodium channels are sensitive to membrane potential, with a higher probability of opening as neuronal membranes are depolarized. As the membrane depolarizes, more sodium channels open, leading to an influx of positively charged sodium ions, producing more depolarization, causing more channels to open, and so on. It should therefore be easy to see why an action potential is a very fast, even explosive event. The return of membrane potential to the resting state is similarly dependent on the control of channel opening and closing. In this case, after opening in response to membrane depolarization, sodium channels automatically close after a short period of time. The return of the membrane to resting levels, however, is due to the voltage-dependent opening of potassium channels, which also open with membrane depolarization after a delay. Taken together, these channels result in a very rapid change in membrane potential, followed by a relatively rapid return to baseline conditions.

The feature of the action potential that is critical to its function in neurons is its seemingly automatic propagation down the axon once initiated. This propagation is also a consequence of the voltage dependence of the sodium channel. Specifically, depolarization at the beginning of the axon, driven by the sodium channel, results in a passive spread of electric current to adjacent axonal regions and the depolarization of that membrane. Sodium channels in these adjacent regions then start to open, further depolarizing the membrane, leading to depolarization of the next part of the axon, the opening of sodium channels there, and so on. In this way the action potential propagates down the axon, signaling the output of one neuron to many others.

NEURONS AS SYNAPTIC SUMMING DEVICES

The discovery that the sodium channel is sensitive to depolarization of the membrane also provided a ready and simple explanation for the influence of synapses on neuronal output. In general, synapses are found at the junction between the axons of one neuron and the dendrites or soma of another. When an action potential in one neuron reaches a synapse, neurotransmitters are released into the gap between the neurons, diffuse across that gap and influence another set of membrane ion channels in the postsynaptic neuron. These channels, which are different from the sodium and potassium channels already mentioned, open to allow positively charged ions (sodium and calcium, for example) into the postsynaptic cell. These positively charged ions result in a local depolarization of the postsynaptic cell membrane.

While brain function would be much easier to understand if a single synaptic depolarization of the postsynaptic membrane led directly to the initiation of an action potential in the next neuron, even early neurobiologists realized that a single input producing a single output did not allow much room for computing. Instead, action potential generation usually requires input from more than one synapse, and it is here that most neurobiologists believe the real core of neuronal computation is to be found. Not surprisingly, it is also here that one finds the greatest number of mysteries about how neurons work.

In the classical view of neuronal computation, shared by a remarkable number of neurobiologists and theorists even today, the fundamental operation performed by the dendrite of a neuron is a spatial and temporal summing of synaptic input. The idea is that sufficient synaptically driven depolarization of the postsynaptic membrane will lead to the initiation of an action potential. In its most common theoretical form, this type of cell is referred to as an 'integrate and fire' neuron. Such a neuron combines its synaptic input (usually by simple summation), and then 'fires' an output when a certain threshold is reached. This type of cell has formed the basis for many models of brain function, as well as most neural network models of information processing and cognition. It is also the most common description of neuronal computation found in textbooks even to this day.

While it is remarkable how many interesting models can be constructed from such simple neurons, growing evidence suggests that, in fact, many if not most neurons in the brain are not performing anything like a simple summation of synaptic inputs. Further, it is now clear that different types of neuron treat their synaptic inputs very differently. How neurons actually 'integrate' synaptic input is, at the moment, a very active and contentious area of research. The truth is that we are probably still very far from any real understanding of the true complexity of neuronal computation. The following sections will consider several features of neurons, currently largely ignored in higher-order theories and models to date, that are likely to be important in an eventual understanding of real neuronal computation.

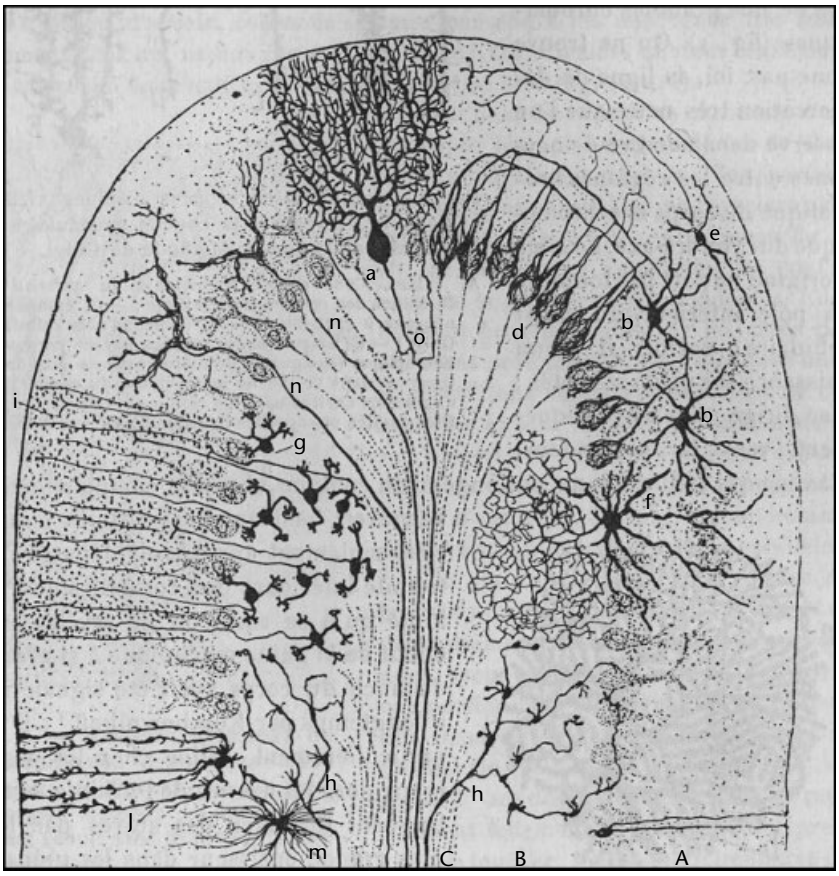

Figure 2. Drawing by Cajal of the different types of neurons found in the cerebellum.

NEURONAL FUNCTION IS RELATED TO NEURONAL SHAPE

When Cajal looked at his first stained tissue, he must have been amazed at the diversity of neuronal shapes, especially those of the dendrites. Considering either a single brain structure, or the brain as a whole, neurons come in a bewildering number of shapes and sizes. Figure 2 is an example of the cell types Cajal described in the cerebellum. As we have already noted, he believed that the shape of a neuron and especially of its dendrite directly reflected its function. In fact, the dendritic shapes and sizes he observed served as the basis for many of his and his contemporaries' speculations on how these neurons worked.

What is remarkable to note in the history of neuroscience is that from Cajal's day until very recently, many if not most theorists have simply ignored dendritic morphology. Instead, most discussions of neuronal computation have focused on the mechanisms of action potential generation. In fact, well into the 1960s many prominent neurobiologists believed that synapses on the distal dendrites of neurons had very little influence on neuronal output. Sir John Eccles (who shared the 1963 Nobel Prize with Hodgkin and Huxley for his work on the spinal cord) and others argued that the small depolarizations associated with such far-away synapses would dissipate as a result of the internal electrical resistance of the cells long before they could influence action potential generation. This assumption, of course, made it much easier to speculate about brain function.

In the 1950s, a physicist named Wilfrid Rall left the Manhattan project intent on applying physical principles and quantitative modeling techniques to neurobiological systems. Rall, who actually trained with Eccles, suspected that the complex geometries of neuronal dendrites held the key to neuronal computation. Taking advantage of his mathematical and analytical skills, Rall developed modeling tools that allowed, for the first time, quantitative studies of the consequences of dendritic morphology for synaptic integration. In a 15-year battle with Eccles and others, Rall applied techniques intended to predict how electrical signals would propagate through long-distance telephone cables

to show that dendritic synapses could, in fact, exercise considerable influence on action potential generation. He demonstrated not only that dendritic synapses have an effect on somatic output, but also that the complex geometry of neuronal dendrites provides a rich opportunity for complex computation. Using this approach, he began to study the interaction of excitatory and inhibitory synapses, a subject that is only today beginning to be taken seriously by many neural modelers. Through this pioneering work, Rall and his students confirmed Cajal's suspicion that the shape of a neuron had a profound effect on its function. While we are only at the very beginning of understanding this relationship, it is very likely that the geometrical complexity of a neuron's dendrite is a direct reflection of the complexity of its computation.

NEURONS ARE NOT PASSIVE CABLES

The discussion in the 1950s and 1960s about the role of dendrites in neuronal computation, as well as Rall's early modeling efforts, assumed that neuronal dendrites were passive electrical cables and did not themselves contain ion channels of the sort Hodgkin and Huxley had shown produced somatic action potentials. Over the last 20 years, it has become increasingly clear that many if not most dendrites are not passive but 'active'. Dendrites are now known often to have a bewildering set of ion channels responding not only to changes in membrane voltage but also to changes in the chemical state of the neuron or its surroundings. It has become equally clear that these active processes result in much more complex synaptic interactions than synaptic potential summation. Even studies of the ion channels underlying the action potential have made it clear that the idea of a simple threshold for neuronal activation is a considerable oversimplification of the real situation. In reality, there is no clear threshold, but instead the generation of an action potential results from the complex interplay of the probabilities of opening and closing of sodium, potassium and other ion channels.

While Rall himself suspected early on that the active properties of neurons would substantially change their computational properties, even his conclusions based on passive dendrites were controversial, and too far out of the mainstream to be taken seriously by many of the neurobiologists of the time. Nevertheless, in the early 1960s Rall introduced a new modeling technique that allowed single neurons to be represented in their full anatomical and physiological complexity. By breaking the cell and its dendrite up into many small compartments, it was possible to study the effects of arbitrary dendritic geometry and non-uniform ion channel distributions on neuronal computation. An example of this modeling approach is shown in Figure 3, which represents part of a compartmental model of a Purkinje cell, a type of nerve cell that occupies the middle layer of the cerebellar cortex. Rall's approach now provides the basis for modeling systems such as GENESIS and NEURON in which computational neuroscientists are discovering all kinds of new computational properties by constructing anatomically and physiologically realistic single-neuron models. Using these techniques, we are slowly realizing, once again, that our simplified notions of computation in neurons are going to have to change dramatically.

THE NEURON IN THE CONTEXT OF ITS NETWORK

The detailed analysis of neuronal anatomy and physiology allowed by compartmental modeling techniques has also made it clear that to study the computational complexity of any particular neuron, one must place that neuron in the context of its network. Thus, as Cajal suspected, and took great pains to illustrate (Figure 4), it is both the detailed structure of the neurons and the detailed geometry of their networks that determines how they compute. It is clear that neurons are not devices designed to receive arbitrary patterns of synaptic input. Instead, their structure anticipates the kinds of input that they naturally receive from their network. Slight changes in the spatial and temporal pattern of synaptic inputs can produce widely different neuronal output. This is especially true when the interaction of excitatory and inhibitory synaptic inputs is considered. For this reason, to understand the computational properties of an individual neuron, one will almost certainly need to construct an equally realistic model of the circuit to which it belongs. In this way, modeling at the neuronal level inevitably leads to modeling at the network level. Whether it will be possible to extract general principles from such models, or whether the computation will always be in the details, is yet to be seen. It seems certain, however, that oversimplifications of neuronal or network structure at the outset are likely to result in essential computational features of both being overlooked.

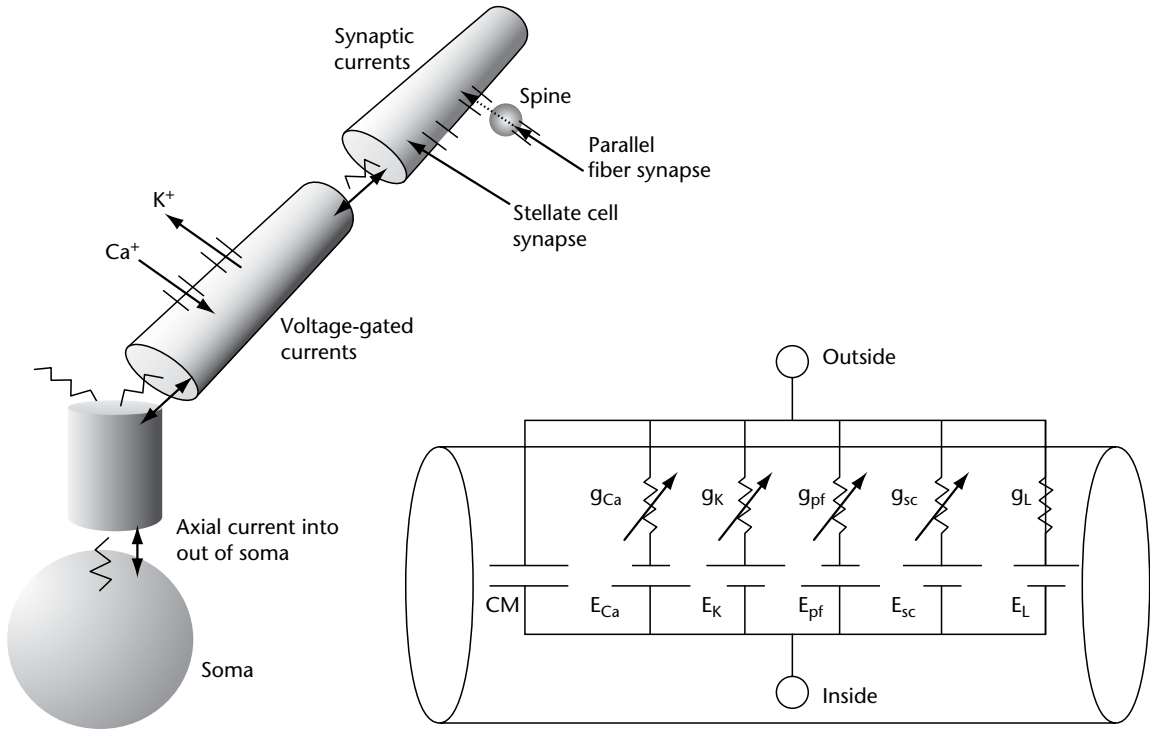

Figure 3. Representation of a neuron within a compartmental model. As shown on the left, the neuron is divided into a series of small compartments. On the lower right, the electric circuit diagram illustrates the way in which the electrical properties of membranes and ion channels are represented in each compartment.

EXAMPLE: A NEW PURKINJE CELL MODEL

In order to illustrate the potential complexity of single neuron computation, we will conclude with a brief description of an anatomically and physiologically realistic model of a Purkinje cell developed and studied by the author and his students over the last twelve years. As shown in Figures 1, 2 and 4, Cajal provided a remarkably detailed description of the morphological features of the cerebellar Purkinje cell, as well as its relationship to other neurons in the cerebellum. From anatomical analysis such as Cajal's, we know that the surface area of this cell's dendrite is one of the largest in the mammalian brain. It also has a remarkable geometrical shape, being flattened in one dimension like a fan. The cerebellar circuitry takes full advantage of the large Purkinje cell dendrite, providing it with between 100 000 and 200 000 synaptic inputs, believed to be the largest number for any neuron in the brain.

As befits a neuron of this size and complexity, we have modeled the neuron using almost 2000 individual compartments, several of which are shown in Figure 3. In these compartments we have included the electrical properties of the dendrite, such as its capacitance and resistance, as well as what information is available on the active properties of the membrane. Through the pioneering electrophysiological studies of the Purkinje cell by Mutsuyuki Sugimori and Rodolfo Llinas, we know that this cell's dendrite includes many different types of voltage-dependent ion channels and, in particular, has a very high concentration of voltage-sensitive calcium channels. From modeling and experimental work, we estimate that the current produced through these channels can be five times as large as that produced by the cell's hundreds of thousands of synaptic inputs. We also know from the work of Sugimori and Llinas that the ion channels in the soma are more complex than is assumed in most simple models of neurons. In addition to the standard sodium and potassium channels associated with the action potential, there are several other channels that also influence action potential generation. In fact, our model predicts that the soma of the Purkinje cell can generate action potentials on its own, without any synaptic input.

Given the complexity of the anatomy and physiology of this neuron, the construction of a model is the only way in which its function can be understood. The process used to construct this type of

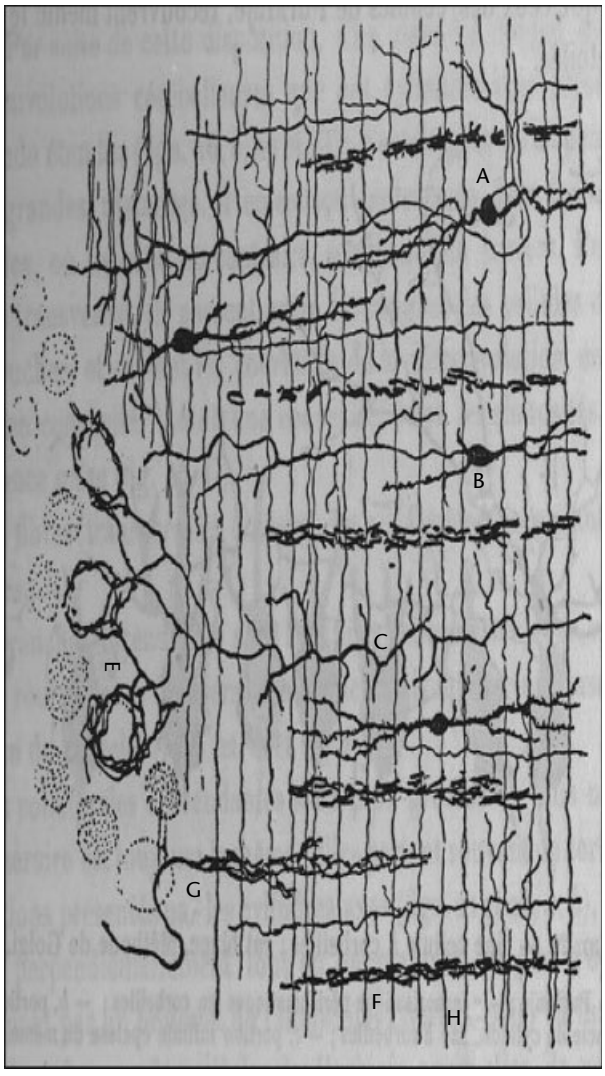

Figure 4. Drawing by Cajal of one aspect of the circuitry of the cerebellum. The cell labeled F is the dendrite of a Purkinje cell through which the long axons called parallel fibers are running.

model is as follows. First, one obtains a complete and anatomically correct description of the Purkinje cell. The cell is then divided into compartments following rules first established by Rall. The passive electrical properties of the model (membrane resistances and capacitances, for example) are then adjusted until they match the experimental data. At this point, mathematical equations that represent ion channels are added and adjusted until the model replicates real physiological responses. Typically, the data used to tune ion channel properties are obtained experimentally by injecting electric current directly into the cell's soma and looking at its electrical response. This technique, called voltage and current clamping, was used by Hodgkin and Huxley to understand the action potential and is very useful in assessing the basic electrical properties of the neuron. Once the model replicates these patterns of activity, model parameters are fixed, and synapses attached to the cell to start investigating model responses to synaptic input. The built-in realism of the model allows modeling results to be compared directly against experimental data, often contributing to the design of new experiments. While easy to describe, this iterative process is still ongoing after almost 12 years for the model described here.

Consequences of Dendritic Calcium Ion Channels for Purkinje Cell Function

It is asserted above that the presence of voltage-sensitive ionic membrane channels in dendrites has a profound influence on the processing of synaptic information. This point will be illustrated here by briefly considering the response of the Purkinje cell model to two of the different types of synaptic input.

One of the interesting and historically puzzling features of electrical activity in the Purkinje cell is that the soma of this neuron generates both classical action potentials and an unusual burst of activity known as a complex spike (bottom right graph in Figure 5). It was Llinas, working as a graduate student in Eccles' laboratory in Australia, who first demonstrated that the complex spike was associated with a special type of synaptic input arising from a single axon that wound its way around the central stalk of the Purkinje cell dendrite. We now know that each Purkinje cell is contacted by only one of these axons, known as a climbing fiber. That one axon, however, makes several hundred synaptic contacts with the central region of the Purkinje cell dendrite.

Figure 6 shows a computer simulation of the response of the Purkinje cell to activation of this one axon and its several hundred synapses. The top set of images of the modeled Purkinje cell shows changes in membrane voltage, while the bottom set shows changes in intracellular calcium concentration. Instead of a simple summing of postsynaptic potentials, the synaptically induced activation of calcium channels in the Purkinje cell dendrite results in an explosive calcium-dependent depolarization of the dendrite beginning in the central location of the climbing fiber synapses and extending rapidly out to the farthest tips of the dendrites. Climbing fiber synapses do not even extend to these regions of the dendrite. This enormous depolarization of the dendrite results in the generation

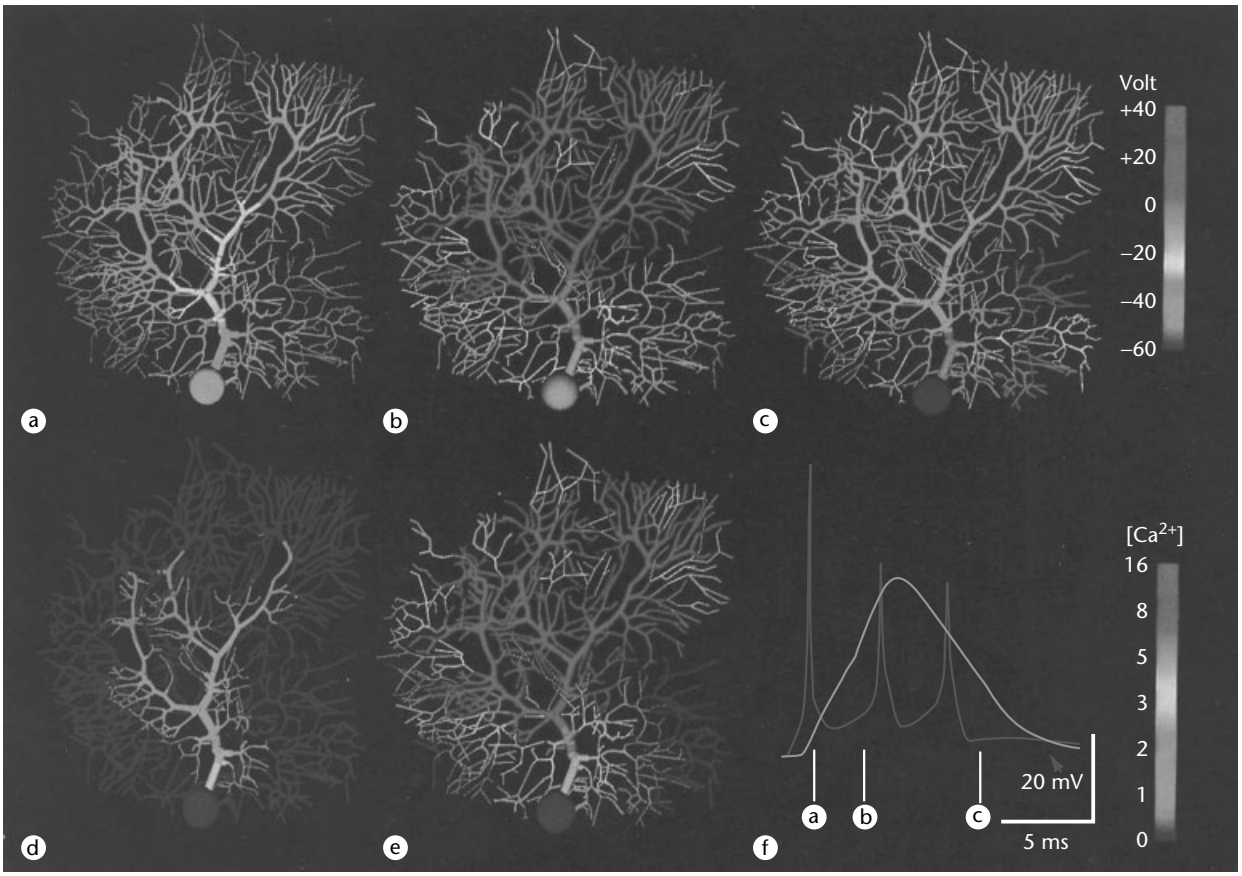

Figure 5. [*Figure is also reproduced in color section.*] Simulation results from climbing fiber activation of the Purkinje cell model. The upper images (a–c) use color to represent membrane potential, while the lower images (d, e) represent intracellular calcium concentration. Parts (b) and (e) were obtained at the same time and 2.5 milliseconds after parts (a) and (d). The voltage record shown in part (c) was obtained 7 milliseconds later than (b) and (e). The graph at the lower right (f) shows changes in membrane voltage in the dendrite (green trace) and at the soma (red trace) in response to climbing fiber activation and resulting from the active properties of the Purkinje cell dendrite. Figure reproduced with permission from De Schutter and Bower (1994) *Journal of Neurophysiology* **71**: 401–419.

of a burst of action potentials in the soma of the cell, as shown by the blue trace in the graph at the bottom right. In contrast to an integrate-and-fire neuron, the presence of active voltage-dependent channels in the dendrite of the Purkinje cell results in a single climbing fiber axon producing a massive depolarization of the dendrite, followed by a burst of generated action potentials rather than only one.

In addition to demonstrating the complex properties of the Purkinje cell dendrite, the modeling results in Figure 5 also indicate the importance of considering neurons in the context of the circuitry in which they are found. The climbing fiber input is a unique feature of the cerebellum, and it is clear that the anatomical and physiological structures of the Purkinje cell are organized accordingly. However, the results shown in Figure 6 illustrate that this cell's response to even a more traditional type of synaptic input is also profoundly affected by the active properties of its dendrite.

The results in Figure 6 were obtained by synchronously activating a small number of synapses on the most remote dendrite of the model. As discussed previously, before the work of Rall there was considerable controversy as to whether synapses this remote from the soma would have any significant influence on neuronal output. In the results shown here, we can see that activation of this dendrite is very effective in producing a somatic membrane depolarization. Analysis of the model predicts that the same dendritic calcium channels responsible for the explosive response of the Purkinje cell to climbing fiber activation are also responsible for this more subtle and constrained effect. In response to the climbing fiber input, these channels drive an explosive entry of calcium into the cell; whereas in this second case they serve

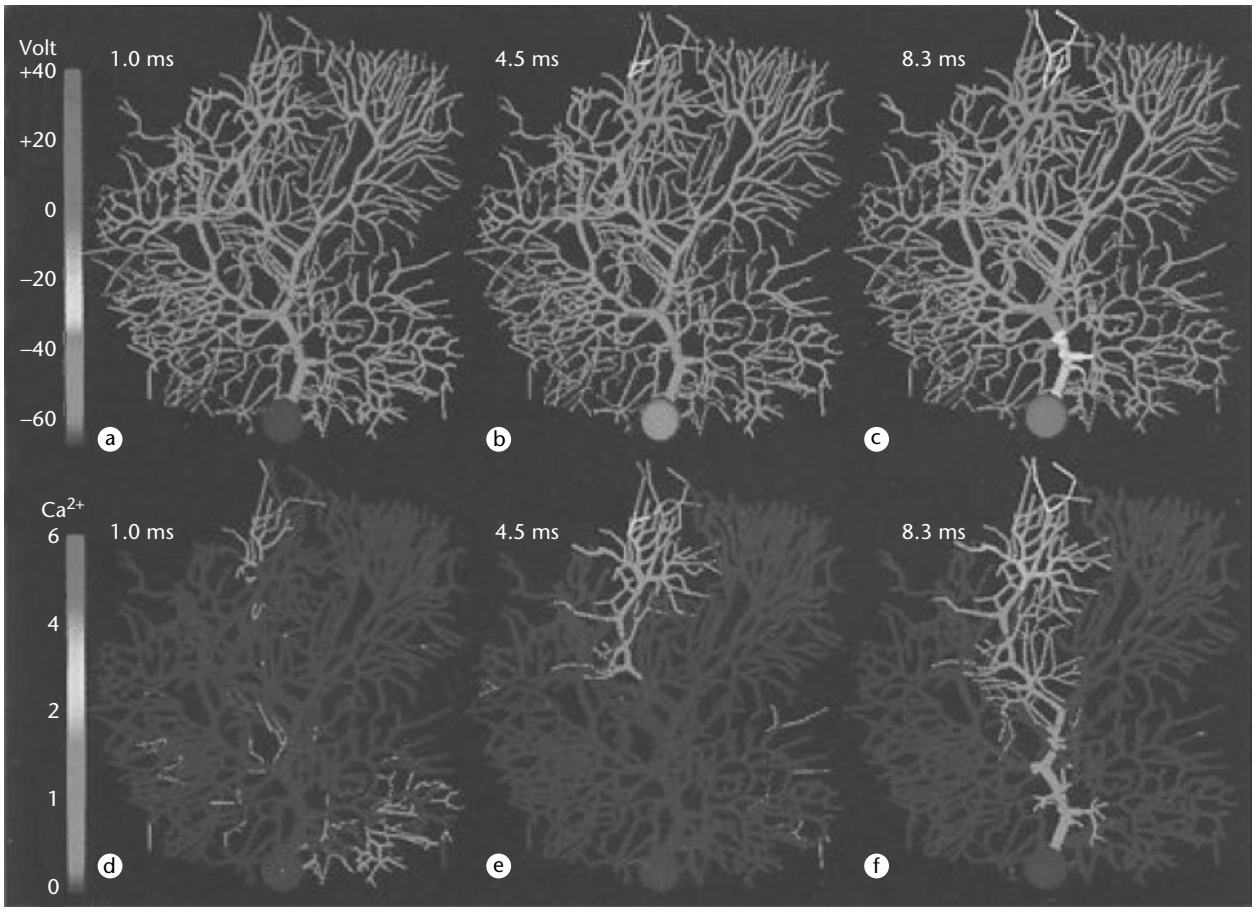

Figure 6. [*Figure is also reproduced in color section.*] The response of the Purkinje cell model to synaptic activation distant from the cell's soma. As in Figure 5, the upper images (a–c) use color to represent membrane potential, while the lower images (d–f) represent intracellular calcium concentration. Each set of images is labeled to indicate the time after the onset of synaptic activation at which they were obtained. This illustration shows the development of a calcium-dependent amplification mechanism that appears to assure that synapses some distance from the soma can still influence action potential generation. Figure modified from De Schutter and Bower (1994) *Proceedings of the National Academy of Sciences of the USA* **91**: 4736–4740.

to amplify the synaptic depolarization and route its influence to the soma. The difference has to do with the detailed distribution of the channels, the nature of the synaptic activation, and the detailed anatomy of the Purkinje cell dendrite. These relationships would not be apparent without a model.

While our study of this model to date has revealed many interesting new features of this neuron, the computational significance of these behaviors is more elusive. It is already clear that to elucidate this question, we must construct an equally detailed model of cerebellar circuitry. Whatever the Purkinje cell is computing, the detailed anatomical and physiological characteristics of its dendrite will be key, and hence realistic models are necessary. Given the dependence of the function of the brain on the computations performed by single cells, our understanding even of cognitive function may ultimately depend on analysis at this level of resolution.

Neurons, Representation in

Introductory article

Peter Földiák, University of St Andrews, St Andrews, Scotland, UK

CONTENTS

The brain uses the activity patterns of a large number of neurons to represent information about the world. The way in which information items are encoded in these patterns has fundamental consequences for information storage, recall, generalization and learning.

INTRODUCTION

A fundamental scientific problem concerns how to account for mental activity in terms of information processing in the brain, and how such information processing is in turn implemented by the functioning of nerve cells. The problem can be broken down into two distinct but interrelated questions. (1) How is information represented in the brain? (2) How are these representations transformed and manipulated in a way that eventually results in evolutionarily appropriate behavior? This article will focus on the first of these questions, with an emphasis on some general principles.

There are infinitely many ways of choosing a physical representation for a piece of information. For instance, numbers can be represented by notches on a piece of wood, by the positions of beads on an abacus, by ink marks on a piece of paper or by electrical voltages in a computer's memory. All of these representations are equivalent in the sense that the same meaning can be read out from them, and each item can be distinguished from other items. However, the representations differ significantly with regard to which operations are easy and which are difficult to perform using them. Addition on an abacus is easy, whereas multiplication using roman numerals on paper is difficult. Representations may vary with regard to what aspects of the items are made explicit in the representation (i.e. can be read out directly) and what other aspects are implicit (i.e. can only be calculated from it). These considerations will also be relevant when considering the encoding of information in the brain. Representation in the brain is determined both by the nature of the available biological 'hardware' and by the characteristics of the tasks that need to be performed.

Most computers today have one highly complex processing unit that is capable of performing a long series of complicated operations at high speed, receiving and sending out complex messages as inputs and outputs. In contrast, the brain's biological hardware consists of an enormously high number (approximately 10^{11} in humans) of relatively simple processing units, namely the neurons. Each neuron has a relatively simple range of internal states (such as 'inactive' or 'active') in comparison with the complex internal states of the central processing unit of a computer. An astronomical number (of the order of 10^{14}) of highly specific, adaptable connections between the units play a fundamental role in the computation, while the message transmitted on each individual connection is a sequence of electrical impulses that can also be regarded as simple by comparison with the messages that are sent within a conventional electronic serial computer. The millions of neurons, on the other hand, generate their outputs and send them to specific targets simultaneously, in parallel, thereby giving the system its computational power. Some of these fundamental functional properties can be abstracted in mathematical models and simulated on conventional electronic computers. These models, which are known as artificial neural networks, can give us some basic understanding of the nature of computational style and the capabilities of such highly, specifically and adaptively interconnected networks of simple units. Finally, the brain also differs from current general-purpose electronic computers in that although the system as a whole can exhibit highly flexible behavior, its processors are dedicated to specialized tasks. The central nervous system is organized into special-purpose areas and modules,

which are specialized and optimized by natural selection for representing certain aspects of the outer world and solving specific computational problems. Within these dedicated areas, each neuron is specialized even further. For example, the brain area specialized for processing touch information may have a neuron dedicated to signaling only when a light pressure is applied to the inner surface of the middle section of the left hand's ring-finger. The precise tuning of each neuron may change gradually to some extent over longer periods of time, but the neuron's response properties remain largely constant during a computation. In some early sensory areas at least, we may think of a neuron as a 'labeled line' with a fixed description on the label, while the activity of the neuron would indicate whether the label is applicable at the time. However, the appropriate description on the labels can often be difficult to formalize, and the labeled line analogy for many types of neurons may even break down completely.

The sensory system, and the visual system in particular, is perhaps the part of the brain that is most accessible to experimental study, as at least the stimuli that enter it are under the experimenter's control. Most of our knowledge of neural representation comes from sensory brain areas, and the rest of this article will focus on these areas.

In order to make sense of sensory representations in the brain, we need to consider the tasks that the sensory system has to solve. One of the main tasks is to reconstruct the causes of the physical signals that are provided by sensory receptors in terms of the significant objects and events in the environment. Light receptors can measure the pattern of light reflected from the surfaces of objects, and mechanical receptors in the auditory system can provide signals about the vibrations propagating through the air (i.e. the sounds that an object makes), but the relationship between these physical signals and the real objects and their properties is usually extremely complex. Why is the apparently simple and effortless act of recognizing a friend on the street computationally difficult? The reason is that the relationship between the identity of a friend and the pattern of light reflected from a face and falling on the retina can be extremely complicated, in view of the unlimited number of ways in which this pattern can change due to variations in the illuminating light, the position of the person in the visual field, distance, various occlusions, shadows, rotations and shape changes of the face itself due, for example, to altering facial expressions. Almost any simple measure of similarity can be smaller between different images of the same person than between images of this person and those of a very large number of other individuals whose facial surfaces differ only in tiny details. Such problems of recognition exist not just for vision but also for hearing and other modalities as well. In addition to simple pattern recognition of familiar objects or people, a more interesting problem is the classification of and appropriate response to novel, unfamiliar objects or situations. In these cases some type of description of the scene is necessary. A novel situation may show some resemblance to a previously encountered situation in certain respects, and it is not just the degree of similarity to an earlier situation, but also the nature or aspect of the similarity, that should determine the appropriate behavior in the new situation. It is these aspects of similarity that should form the basis of a high-level representation, making the 'meaning' or real-world causes of the stimuli explicit. Our goal is to understand how such a representation can be constructed, using the known neural machinery (mainly in the cerebral cortex of the brain), from the physical signals that come from the sensory receptors.

TUNING CURVES AND RECEPTIVE FIELDS IN DIFFERENT CORTICAL AREAS

Our most direct knowledge of the way in which neurons process information comes from neurophysiological experiments. Despite the huge number of neurons in the brain, it is possible to measure and record the electrical impulses from single nerve cells within the functioning neural system using microelectrodes. The single-cell recording method was developed in the 1950s, and has since been applied systematically to explore the relationship between stimuli and neural responses (or 'response properties') of neurons in different areas of the cerebral cortex.

The neural response in all cortical areas consists of electrical impulses (also called action potentials) of similar amplitude and shape. However, the timing and number of these impulses vary, and a large part of this variation is caused by changes in the stimulation that the neuron receives. The most commonly considered statistic of such a sequence of impulses is the total number of impulses or the rate of the impulses. Other measures of response, such as the time of appearance of the first impulse after a new stimulus, can also convey additional information in neurons.

Each neuron responds above its resting rate only when the stimulus has certain critical or 'trigger'

features. For instance, the earliest stages of visual processing take place in the retina, and in frogs this processing involves quite specific 'trigger features'. As frogs are interested in catching small insects, their retina has neurons that respond only when a small dark spot moves across a certain part of the visual field on a light visual background, just as would happen if a small bug was to fly across the frog's visual field against the background of the sky. Consequently, these specialized cells were called 'bug detectors'. Higher animals have retinas with less specialized retinal trigger features to allow more flexible and complex processing in the higher stages of the visual system.

After finding the critical stimulus features of a sensory neuron, the most interesting question from the viewpoint of the neural representation is how the neuron's response varies with various changes in the stimulus. In most experiments, the experimenter chooses to vary some properties or parameters of the stimulus, and then measures the changes in the neural response as a function of the stimulus parameters. The resulting function is called a tuning curve. The tuning curve often has a single peak at the point corresponding to the 'preferred' stimulus (i.e. the stimulus parameter that evokes the strongest response). The value of the tuning curve falls off as one moves away from the peak. If the tuning curve falls off sharply around this point, the neuron is considered to be narrowly tuned to this parameter; otherwise it is considered to be broadly tuned. The width of the peak can provide a measure of the breadth of tuning.

Another concept that is frequently used to describe neural representation is the receptive field. The receptive field of a sensory neuron is the space within the receptive sheet in which it transduces stimuli. For example, the receptive field of a somatic sensory mechanoreceptor (for touch) is the portion of the skin that is directly innervated by the receptor terminals. For a visual sensory neuron, the receptive field is the region of the visual field in which stimuli affect the activity of a neuron. The concept of the receptive field originates in studies of retinal ganglion cells. The trigger features of these cells are small spots of light (or dark spots), and the main parameter to which these neurons are tuned is the spatial position of the spot. Each ganglion cell receives excitation from a small group of photoreceptors, and receives inhibition from receptors in the surrounding small region (or vice versa). These are the excitatory and inhibitory zones of the receptive field. Such a center–surround organization means that these cells will not be optimally activated by a uniform field of light, but only by some change in the light intensity within their receptive field. The concept of a receptive field is clearly useful in the retina, as the responses of these ganglion cells to any stimulus can be predicted by the position of the light spot, or by the distribution of light across the receptive field. If it is inside the excitatory zone, a positive response can be expected, so here the receptive field refers mainly to a spatial region. However, even in the retina this concept starts to refer to more than just a spatial region, as it also begins to refer to the pattern of optimal stimulation within this region.

Tuning curves in the early stages of processing can be determined by the physical properties of the receptor cells. For instance, the touch-sensing (somatosensory) mechanical sensor has a particular location in the skin, and has a physical tuning determined by its anatomical construction and by the mechanical properties of the surrounding tissues. The tuning curves of the neural signals to position and pressure coming from these receptors are determined simply by these physical factors. The tuning curves of higher-order neurons are constructed neurally from these signals. Although the number of cortical neurons is higher than the number of receptors, many peripheral receptors converge on to a single sensory neuron in the central nervous system. Consequently, the receptive field of a central neuron is larger, and its response is more specific. These sensory neurons in turn converge on higher-order neurons. This process is then repeated, which leads to both a progressive increase in the receptive field size and a change in the trigger features of the neurons. The response properties of each neuron are shaped by the specific pattern of connections (and the pattern of connection strengths) from lower-level neurons, as well as by the pattern of inputs from other neurons at the same level of processing.

A major feature of cortical organization is that the cortex is divided into distinct cortical areas defined by anatomical and functional criteria. Cells within a particular area have a similar composition, neurochemistry, and input and output connectivity patterns, and their response properties may be similar. Neurons within an area can form continuous maps of visual space, and specific lesions or damage to cells within an area will lead to similar types of functional deficits.

PRIMARY VISUAL CORTEX

The primary visual cortex (or V1) is the first cortical stage where neural signals arrive from the eye, via

a thalamic stage (the lateral geniculate nucleus or LGN). The specific convergent connections from the LGN to V1, as well as connections within V1, give rise to novel trigger features. V1 neurons are no longer activated effectively by spots of light, and they require elongated features such as lines, edges or gratings of a certain orientation. These receptive fields are thought to be constructed by convergence from a row of LGN cells with receptive fields aligned along a certain orientation. Connections within V1 also have a role in shaping the response properties and the orientation tuning curves. V1 cells have a wide range of receptive field sizes, and the population of V1 neurons covers the whole visual field, more densely with smaller receptive fields near the center of the visual field, and less densely with larger receptive fields around the periphery. V1 neurons are tuned to several stimulus parameters simultaneously. For example, for an oriented line segment one could find optimal parameters such as position (receptive field size is of the order of 1 degree), orientation, length and width of the line segment (or density or spatial frequency of a periodic grating), spatial phase, flicker rate (response can be better to non-static images), direction of motion, and velocity. Some neurons in the input layers are driven preferentially by the left or right eye, while most other cells are driven by both eyes in a similar way. Some other neurons also show selectivity to particular color contrasts (color changes from a background), and some show selectivity to stereoscopic disparity (i.e. a difference in the position of an image of a point between the two eyes due to three-dimensional depth). Any given V1 neuron could be selective to a subset of but not necessarily all of these features. The neurons that are particularly sensitive to the spatial phase of a grating (or the position of a line segment) are called simple cells. Their response properties could be constructed mainly by convergent input from the LGN. Their input can be modeled as an appropriately weighted linear sum of LGN cell activities, with spatially separate excitatory and inhibitory receptive field regions. Here excitatory synaptic inputs would count as positive weights, and inhibitory connections would count as negative weights. V1 cells can of course only give positive responses, so any weighted sums that would be negative result in a zero response (effectively rectifying the response). Phase-insensitive neurons are referred to as complex cells, and they have larger receptive fields. Their responses could be constructed by convergent pooling of the responses of simple cells with similar tuning within the complex-cell receptive field, resulting in a nonlinear relationship between image components and the cell response.

The responses of V1 cells can also be modified by larger stimuli, probably reflecting neural inputs from other neurons within the area.

One of the most remarkable characteristics of the organization of V1 is the systematic and mostly smooth change in response properties as a function of position on the cortex. This may be necessary as neurons representing similar tuning values may need to interact more during processing. Thus placing neurons representing similar parameter values closer to each other on the cortex minimizes the length of the necessary connecting axons. There is in fact a continuous mapping of position of the receptive field in the visual field to cortical position, so that the left-hand side of the visual field is mapped at one side of the cortical map and the right-hand side is mapped at the other ('retinotopic map'). Other tuning parameters, such as orientation, are embedded in this map so that a small region (a 'hypercolumn') containing neurons that have similar receptive field positions is mapped in such a way that tuning parameters such as orientation preference change mostly smoothly across the hypercolumn.

EXTRASTRIATE VISUAL AREAS

Visual areas are organized approximately according to a hierarchical scheme. Pattern recognition is carried out mainly by the 'ventral stream', consisting of areas $\mathrm{V1} \rightarrow \mathrm{V2} \rightarrow \mathrm{V4} \rightarrow \mathrm{PIT}$ (posterior infero-temporal) $\rightarrow$ AIT (anterior infero-temporal). The major input to each of these areas is provided by the area that precedes it in this stream (with some shortcuts and inputs from other areas as well). The main characteristic of subsequent areas is an increase in receptive field size and the development of new trigger features. Increases in the receptive field size do not mean that the optimal stimulus has to get larger for these areas. Instead, the same feature size can be optimal for a higher area as in an earlier area, but the tolerance of the precise position within the receptive field (and of some other properties) is increased at each stage.

For instance, area V2 has cells that have similar tuning to those in V1, but some V2 cells are unoriented and respond to small spots of colored light ('spot cells'), while others respond to contours defined by non-luminance cues such as color borders, texture borders, borders defined by stereoscopic depth or illusory contours (which are like contours behind occluding surfaces). V2 is also likely to be a

significant stage in the processing of local curvature or combinations of orientations.

After V2, the two main visual streams diverge, with form and color being processed primarily by the ventral stream, whereas movement is processed primarily by the dorsal visual stream. The latter continues in areas V3 → MT → MST. MST cells are tuned to complex motions such as expansion/contraction or rotation. Many of these cells are influenced by stimuli beyond the classically defined receptive field. Their responses are suppressed when motion in the surround is in the same direction and has the same speed as in the center. Effectively, this means that MST cells are not driven by global motion, but only by motion relative to a background.

The next stage in the ventral pathway after V2 is V4, where receptive field size increases further. A large class of V4 cells shows tuning to color in a way that displays color constancy. This means that these cells are tuned to the color that a surface reflects (spectral reflectance – the fraction of light that the surface reflects at each wavelength), disregarding to a large extent the incidental changes in the color of the illuminating light. Other V4 cells encode well-localized shape primitives, particular combinations of colored shape primitives and contour features, such as angles and curves, independently of global shape configuration.

The last purely visual, high-level visual areas are in or near the inferior temporal (IT) cortex in monkeys. The cells in this region are sensitive to a variety of stimulus attributes, such as shape, color and texture. Posterior IT cells make complex discriminations of visual form, and have more complex shape tuning, yet they still respond quite well to shapes that are simpler than those that typically occur in the natural world. IT cells are often selective for configurations of several simple shapes with a specific relative spatial relationship. This is especially interesting, as the same cells are insensitive to the absolute position of these configurations within their large receptive fields. Some IT neurons respond to a given shape independently of the cues that define the contours or shape outlines in an image. They respond similarly to forms defined by light-intensity edges, or edges defined by color change, texture change or changes in stereoscopic disparity (cue invariance).

A large proportion of cells in the anterior IT cortex and in the neighboring area of the superior temporal sulcus (STS) are selective for complex, ethologically important patterns such as hands and particularly faces, and views of the whole body. In some cases, cells are tuned even more specifically to faces with a particular orientation, faces with certain characteristics, or the direction of gaze of the face within the stimulus image. IT cells have such large receptive fields that they include most of the visual field. Optical imaging of the surface of the IT cortex suggests that cortical maps in IT are organized in such a way that columns of neurons with related shape-tuning properties are located close to each other in the IT cortex.

These high-level visual cortical cells could be considered to have successfully solved the basic pattern recognition problem, as they respond to specific classes of objects while generalizing across many of the stimulus changes that are unrelated to the identity or 'meaning' of the object. Such representations provide useful inputs to semantic and polysensory areas involved in higher cognitive processes.

The response properties of IT cells can also change with experience. Extensive exposure to images of a set of objects will eventually increase the number of IT cells that respond to those objects. This indicates that the IT cortex plays a critical role not only in the representation and discrimination of objects but also in learning effects, object recognition and visual memory.

SPECIALIZATION AND GENERALIZATION

The example of the monkey ventral visual stream reflects some general computational principles. As one moves from lower to higher sensory areas, one can see that neurons in higher areas are more specialized (i.e. they are tuned to increasingly abstract combinations or configurations of lower-level features). These are not random combinations, but instead they are non-random co-occurrences, or 'suspicious coincidences' in the natural sensory environment of animals. The statistics of the sensory signals from the natural environment provide many different types of regularities or structure, and different stages of sensory processing are well adapted to this structure. For example, a 'face cell' in IT cortex is well suited to an environment in which facial features (e.g. eye shapes and mouth shapes) tend to appear and disappear together. The mechanism for specialization seems to be selective convergence of the signals from detectors of the coincident stimulus features. This convergence allows a higher-order neuron to respond only when a significant number of the appropriate lower-order features are present. The connections necessary for the appropriate convergence can

be learned by experience-dependent synaptic modification.

The other general principle that can be observed is that the tuning to those parameters of the stimuli which are related only to incidental conditions of image formation, or which are not related to real objects or events in the world, is gradually eliminated or generalized over. An example of such a non-object-related feature is the location of a feature within the visual field. The gradually increasing size of the receptive field in higher sensory areas illustrates the corresponding generalization. The most likely mechanism for such generalizations is also by convergence or 'pooling' of the signals about the appropriate set of specific lower-level features. The appropriate pattern of pooling connections can also be acquired through sensory experience, exploiting statistical structure in the normal sensory environment.

These principles do not seem to be unique to the visual system. Despite the quite different nature of the input from the somatosensory (touch) and auditory systems, the center–surround organization, and at later stages orientation and directional motion selectivity, seems to be present in these other modalities as well.

The concept of a receptive field was clearly useful at the earliest stages of sensory processing, where the major neural tuning properties were spatial. The concept has to be stretched to its limits in higher areas to include more pattern-specific information. The appearance of strong nonlinearity in responses, even during the first cortical processing stage, and the significant effect of specific long-range dynamic interactions from beyond the classic receptive field makes that concept of a well-defined and descriptive receptive field less justifiable.

STIMULUS–RESPONSE CORRELATIONS

There is a remarkably close relationship between sensory stimuli, neural responses and perceptual experience. In the previous sections we considered examples of the highly specific nature of this relationship between the stimuli and responses of cortical neurons. Even though these results strongly suggest that these cells take part in the perceptual decisions and experience, we cannot be certain of this without studying perceptual performance itself.

Humans, and in some cases other animals as well, can be asked to report their sensory experiences by simple behavioral decisions (e.g. the pressing of buttons depending on the detection or discrimination of stimuli). Performance in these psychophysical tasks can be highly informative about the nature of the actual mechanisms involved in perception, especially in difficult perceptual judgments, that are near the limits of the capabilities of the perceptual system. When stimulus levels are close to threshold, the observer makes errors with repeated presentations of the sensory stimuli. A sensory threshold can be defined as the stimulus level that supports a certain probability of making a correct decision. Thus, at their thresholds, perceptual judgments are subject to statistical variation.

Neural responses also show statistical variability, as the neural response is not identical even when the same stimulus is presented to the animal many times. This variability can have several sources. It may be due to factors internal to the neuron, or it may be due to fluctuations in the stimulus itself, noise in the receptor cells, or noise at any point in the neural processing pathway between the stimulus and the neuron.

Neural detection or discrimination thresholds can be determined for a population of cells using stimuli that are matched to the tuning characteristics of the neurons. The same stimuli can be used in a psychophysical task to determine perceptual thresholds. If the neurons as a group take part in the perceptual decision-making, their joint performance should be able to support the observed perceptual performance.

There are several models of the way in which information from multiple neurons can be combined to give perceptual levels of performance. The 'lower envelope principle' was proposed as an explanation for the detection of low-contrast gratings. Individual neurons in V1 have tuning curves to spatial frequency (related to the spacing of bars in a grating pattern). The peaks of the neural tuning curves also correspond to the spatial frequencies where the detection threshold curve has a minimum (i.e. where the cells' response can be used to detect the presence of a low-contrast grating most efficiently). This minimum lies at different spatial frequencies for different V1 neurons. However, subjects performing detection tasks have lower thresholds across a much wider range of frequencies than their individual neurons. In fact, the psychophysical threshold curve approximately follows the minima (or 'lower envelope') of the individual threshold curves of a population of neurons. The lower envelope principle therefore states that human perceptual performance in the detection task is always based on a single neuron (or a small subset of neurons), which has a

minimum threshold at the tested frequency. In other words, the hypothesis states that humans can select on each trial the neurons that are most sensitive to the particular stimulus, and can base their decision on these neurons. Although the lower envelope principle seems to be consistent with much of the psychophysical and physiological data, it assumes that the neural decision mechanism has completely accurate prior information about the parameters of the stimulus to be detected, and can also switch the decision mechanism to receive its signal from the right set of neurons without interference from other neurons. These seem to be unrealistic assumptions.

Alternative decision models combine signals from appropriately selected pools of neurons either by addition or by taking optimally weighted sums. The pooled response is normally less noisy and more reliable. Other statistical methods depend on the probability distributions of responses to determine the best decision of a statistically ideal observer of the neural responses. (*See* **Decoding Neural Population Activity**)

The strongest evidence for the involvement of a set of neurons in a perceptual task comes from experiments in which neural and psychophysical data are acquired simultaneously. In one experiment, neural impulses were recorded in humans (using microneurographic methods) from the fibers carrying information from the mechanoreceptive fibers of the hand. Psychophysical responses to pressure on the skin were recorded simultaneously. The psychophysical thresholds for the finger were similar to those based on the response of a single neuron. Furthermore, there was almost perfect trial-to-trial variation in that on trials when the stimulus failed to elicit a neural spike, detection was also missed, but when the spike was detected on a trial, the subject also detected the stimulus. This implies that in this case a single action potential in the fiber is sufficient to cause a conscious sensation. However, another neural fiber carrying mechanoreceptive information from the palm of the hand, was significantly more sensitive than the response of the human subject. This seems to imply that access of conscious decision-making to all incoming activity is not guaranteed. Moreover, electrical stimulation of a particular mechanoreceptive fiber caused the sensation of a light indentation at the location on the skin surface that corresponded to the previously determined receptive field of that particular fiber.

In another interesting set of experiments, responses from area MT of the visual cortex were recorded simultaneously with behavioral responses from a monkey in a direction discrimination task matched to the preferred stimulus of a directionally tuned motion-detector cell. For a population of cells, the distribution of ratios of neural and behavioral thresholds was close to 1, indicating that the level of sensitivity of single neurons was very close to the sensitivity of the monkey's response. The response of the monkey could, at least in theory, be based on the response of a single cell or a very small pool of cells. The trial-to-trial correlation between the neural and behavioral responses was small but significant. For repeated presentation of a given stimulus, the monkey tended to choose the preferred direction of the neuron more often when that neuron yielded a larger than average number of spikes. This implies either that the recorded neuron was one of a set of independently noisy neurons that contributed to the perceptual decision, or that there was a correlation between the variability of this cell and other cells that did contribute to the decision. Further evidence for the involvement of cells in perceptual decision-making comes from experiments in which the recording electrode was used to alter the activity of a relatively small group of cells by injecting a small current during the decision task. Stimulation of a column encoding upward motion induced a bias in the monkey's choices towards the upward direction. Such experiments establish that activity in directionally specific MT circuits of the monkey visual cortex underlies behavioral judgments of motion direction in the psychophysical task.

In conclusion, although there is a clear link between the activation of a relatively small subset of neurons and perceptual experience, it is difficult to infer precisely the number of neurons participating in even such simple perceptual tasks as were discussed above. While the sensitivity and reliability of individual neurons can be similar to the sensitivity and reliability of the whole behaving organism, it is not possible to conclude that we have identified the single neuron from the pool of many millions of neurons that actually performs the discrimination or detection task. Selecting the signal of the appropriate neuron to control the response for a particular task, as the lower envelope principle would assume, without interference from the irrelevant signals of millions of other neurons, must be an enormously difficult task. The imperfection and unknown noise that are introduced by this selection process must be compensated for by the improvement of the signal quality by the combination of responses from multiple neurons. Both the degree of improvement and the amount of signal

combination necessary for a given level of improvement are as yet unknown.

LOCAL, DISTRIBUTED AND SPARSE CODING

Despite having a relatively detailed knowledge of the response properties of most neurons in some parts of the visual system, due to nonlinearities and dynamic interactions we are still unable to predict reliably their responses to arbitrary novel stimuli. Most neurophysiological recording experiments from the visual cortex still use a relatively small set of simple abstract stimuli, so our knowledge of the way in which these cells respond to the type of complex and dynamic natural sequences of scenes that animals experience in their natural environment is to a large extent unknown. Furthermore, we would need simultaneous access to the activation patterns of whole populations of cells in order to describe the neural code. Single-cell recording techniques currently allow us to record only a relatively small number of neurons (often just one) at a time. Various functional imaging techniques may give us a vague idea of the involvement of brain regions in certain tasks, but their spatial and temporal resolution misses most of the computationally relevant details. A further problem concerns the way in which an experimenter chooses the range of stimuli to be tested on a neuron. This is a highly subjective and assumption-laden process, and it is almost certain to bias the results.

Despite these difficulties, there are some aspects of the neural code about which we can make some inferences. For instance, it seems to be a general observation in sensory areas that neurons have fairly specific tuning preferences, often to several parameters of the stimulus simultaneously. A random selection of natural stimuli will therefore relatively rarely cause high activation in a given sensory neuron, which means that neurons are narrowly tuned across the set of all possible stimuli. A separate but related issue concerns the distribution of activity across the whole population of neurons for a given stimulus, which determines the amount of sparseness. A code is sparse when the number of active units divided by the total number of units is low. Due to the limitations of the recording techniques, we have no way of observing sparseness directly. However, on average, the more narrowly tuned the neurons are across the stimuli, the smaller the number of neurons that is expected to be active for a given stimulus. To encode the same information with fewer active neurons, the visual system must eliminate the statistical redundancy (i.e. the uninformative replication) in its coding. For instance, the center–surround organization of retinal ganglion cells eliminates responses except at the boundaries of visual surfaces. This type of organization has also been found in higher visual areas. For instance, the responses of motion-sensitive cells in area MT are suppressed by the same motion in the surround, so they only respond when the motion involves solely the receptive field of the cell. These types of specific suppressive effects have been found in all cortical areas where they were tested, presumably resulting in a significant decrease in the number of active cells.

A sparse code is useful because it combines the advantages of local and fully distributed codes. It allows the discrimination of a much higher number of states than local codes, and it allows generalization based on the overlap of representations, while still keeping the mapping from the representation to an output pattern relatively simple and easy to learn by means of simple learning algorithms. A neural network model that aimed specifically to maximize a measure of sparseness trained on natural images resulted in localized wavelet-like receptive-field profiles that resemble V1 simple-cell profiles. Finally, a sparse code may be a desirable way of encoding information, as the number of real causes of any given sensory stimulus is probably much lower than the total number of potential causes of all possible natural images. Each image could then be encoded as a relatively small subset of active units corresponding to the current causes.

Neuropsychological Disorders, Animal Models of

Introductory article

Gordon Winocur, Rotman Research Institute, Toronto, Canada

CONTENTS

Animal models are important to the study of brain damage and neurological disease. When brain function is affected, there are direct psychological and cognitive symptoms that must be taken into account to achieve a full understanding of the disease.

PROS AND CONS OF ANIMAL MODELS

Animal models are an essential part of medical science and have contributed significantly to our understanding of various diseases. Indeed, the treatment of serious illnesses, such as cancer and diabetes, would still be very primitive without the knowledge derived from animal research. This approach is possible because humans and other animals (especially mammals) share important anatomical and physiological characteristics, so that meaningful generalizations across species are possible. Apart from practical considerations, the use of animals is necessitated on moral and ethical grounds; it is obviously unacceptable to subject humans to unproven experimental procedures and treatments, no matter how promising they might be.

In the study of brain damage and neurological disease, we must consider psychological and cognitive symptoms as well as physical ones. Thus, for example, in studying Alzheimer disease (AD), in addition to describing the neuropathological changes that characterize the disease, it is necessary to identify parallel behavioral changes (e.g., memory loss), because of their obvious importance for diagnosis and treatment. With the emergence of the discipline of neuropsychology – the study of relationships between brain function and behavior – sensitive tests have become available to study changes in cognitive abilities suffered by humans with brain damage. Of equal importance is the progress that has been made in devising tests that measure similar processes in animals, and allow for the development of models that represent these changes.

When properly used, animal models of neuropsychological disorders can be instructive on several levels. If the model actually duplicates the disorder it is meant to represent, it can provide valuable information as to cause, symptoms, and treatment. Unfortunately, because our knowledge of complex neurological diseases is limited, it is virtually impossible to model all aspects of a disease. Consequently, we must often resort to creating artificial, approximate models. This can be accomplished by physiological or biochemical manipulations that can involve, for example, surgical destruction of brain tissue or genetic alterations. In such cases, it is usually necessary to focus on some subset of symptoms or causative factors; but even a partial characterization, if accurate, can lead to significant progress. An important measure of the success of a model is the extent to which it expresses cardinal behavioral features of the disease.

Animal models can provide valuable insights into the mechanisms of diseases. For example, we are becoming increasingly aware that heredity and environmental factors interact in complex ways in the expression of certain diseases. Only by carefully controlling genetic make-up, environmental influences, and related experiential factors (e.g., early trauma, stress) can their effects be assessed. Similarly, as neurological diseases progress, new and distinct neuropathological markers appear, along with new cognitive symptoms. Typically, the type of control needed to study these relationships can be exercised much more readily in animal populations than in humans. Although the advent of sophisticated neuroimaging techniques has created new opportunities in human research, properly-constructed animal models represent the best hope for this line of investigation.

Another advantage of animal models is that they are well suited to preclinical experimentation with drugs and other treatments. Apart from the study of short- and long-term benefits of a treatment, animals allow for the study of side effects that could compromise its effectiveness. Unfortunately, it is often easier to reduce cognitive impairment in brain-damaged animals than in comparable human populations, and therein lies a limitation of animal models. Nevertheless, demonstrating that a particular drug can effectively relieve a major symptom in any form of the disease is usually an important step in the right direction.

There are other problems with trying to model neuropsychological disorders in animals. For example, some have argued on compassionate and even scientific grounds that alternative methods (e.g., computer modeling) are preferable. It goes without saying that animal researchers must follow procedures that are as safe and humane as possible and that safeguards must be in place to protect animals from maltreatment. While a certain amount of controlled pain is sometimes inevitable, it is kept to a minimum, and practice is guided by the principle of the 'greater good'. As long as we are prepared to attach special significance to the quality of human life, there is little doubt that the benefits of animal research outweigh the costs.

It may be argued that, because neuropsychological problems are not necessarily life-threatening, animal sacrifice is not warranted. In reality, just as animal research has contributed significantly to the development of drugs for treating serious mental illnesses (e.g., schizophrenia) and alleviated much suffering in the lives of patients, animal-based findings can lead to the discovery of cognitively enhancing medication. One must not underestimate the misery of those suffering a dementing disease, and the accompanying psychosocial problems that take an enormous toll on the quality of an individual's life. The argument that cognitive disorders do not represent a serious enough health problem to justify animal experimentation must be considered against the plight of the many elderly individuals, stroke victims, and AD patients, who are mentally imprisoned within a shrinking cognitive world.

The neuropsychological investigation of cognitive disorders in brain-impaired humans is still in its infancy, but, thanks to a growing recognition of the problem and the development of new technologies (e.g., sensitive tests, structural and functional brain imaging), great strides are being made. This article will review advances in the use of animal models. It first reviews developments in assessing cognitive deficits associated with brain damage. The emphasis here is on the circumscribed damage that results, for example, from brain surgery, cardiovascular disease (e.g., stroke), or head trauma. We then look at the unique features and cognitive symptoms of neurodegenerative diseases, with AD, Parkinson disease (PD), and Huntington chorea (HC) as specific examples.

ASSESSING COGNITIVE IMPAIRMENT IN ANIMAL MODELS OF BRAIN DAMAGE

We would ideally want to use the same tests to measure cognitive function in animals and humans. While this is possible to some degree, several factors – most prominently, cross-species differences in cognitive capacity – render this approach impractical. In addition, animals and humans have different ways of doing things and are biased towards different types of information. As an obvious example, humans are predisposed to make extensive use of language, monkeys respond primarily to visual information, and rodents rely heavily on olfactory and spatial cues. A more realistic strategy is to administer tasks that are appropriate to each species' stimulus–response characteristics, but that require the same cognitive processes for successful performance. Thus, for example, we assume that short-term memory (STM), the ability to retain small amounts of information for short durations, is distinct from long-term memory (LTM), where information is stored for long periods of time, but that both are part of the cognitive make-up of all relatively sophisticated animals.

In most cases, even circumscribed brain damage produces variable patterns of cognitive deficits. However, memory loss is a common feature of most neuropsychological disturbances. For this reason, and to exemplify the modeling approach in animal research, this review will focus on memory as a primary domain of cognitive impairment associated with brain damage. The challenge, as with all forms of cognitive assessment, is to devise tests that measure memory impairment in ways that are appropriate to each species.

The development of suitable tests for studying the effects of brain damage on memory function was stimulated by attempts to reproduce features of human amnesia in animals. In a pioneering investigation of neurological patients in the 1950s, Brenda Milner and her colleagues at the Montreal Neurological Institute discovered that damage to the hippocampus, a major structure deep within the medial temporal lobe (MTL) of the brain,

produced a profound memory loss for experiences subsequent to the injury (anterograde amnesia). In general, the impairment was restricted to conscious recollection of specific events (e.g., a news event that occurred several days ago), whereas memory for general knowledge (e.g., that the sun rises in the east and sets in the west) or learned skills (e.g., chess) was relatively intact. There was also evidence of time-dependent retrograde amnesia, in which experiences that occurred a relatively short time before the hippocampal damage were forgotten, while much older memories were retained.

Milner's studies were conducted on epileptic patients who underwent surgical removal of hippocampal tissue to reduce the frequency and severity of debilitating seizures. However, similar patterns of memory function are observed in patients who suffer hippocampal damage as a result of neurological diseases, such as herpes encephalitis, an inflammation of the brain that selectively attacks the medial temporal lobe. Also, vascular infarcts that block the supply of blood, glucose, and oxygen to the hippocampus will produce ischemic damage and similar memory deficits.

Research with various clinical populations has revealed that other structures also contribute to memory function. In addition to implicating other brain regions, such as the frontal lobes (FL), the basal ganglia (BG), and various thalamic nuclei, this work has demonstrated important differences between the contributions of the different regions. As we will see later, the BG are involved in a form of (procedural) memory that supports learning and remembering non-episodic information. By comparison, the FL are essential when recalling information that is dependent on strategic search and retrieval operations.

The importance of the thalamus – a subcortical structure within the diencephalon – for memory emerged from studies of Korsakoff syndrome, a condition that is associated with chronic alcoholism and vitamin B deficiency. Korsakoff patients often suffer extensive neuropathology, but the profound memory loss that they experience seems to relate to damage to specific (anterior and dorsomedial) nuclei in the thalamus. Studies of patients with restricted damage to the thalamus, resulting from stroke or tumor, confirmed the link, although their memory profile is different from that associated with MTL damage. Thalamic patients suffer a more generalized impairment, which can include STM and LTM function, and even extend to certain types of learning. On the other hand, when damage is restricted to the thalamic region, premorbid memory appears to be intact.

Thus, rather than comprising parts of a single, integrated memory system, as was once thought, the hippocampus and thalamus probably control different memory-related cognitive processes. Animal studies have contributed significantly to the resolution of this issue. To model selective brain damage in animals, lesions are produced in various ways, such as passing electrical current through the structure, aspirating tissue, or infusing neurotoxins that destroy neural cells. Ischemic damage, similar to that seen in stroke patients, is typically produced by temporary occlusion of major arteries that supply blood to targeted brain areas. Extensive behavioral testing, involving a wide range of tasks, has been conducted in different species of animals (e.g., monkeys, rats) with selective hippocampal or thalamic lesions produced by these procedures.

Animal research has confirmed that lesions to either structure produce comparable degrees of memory loss for specific information, such as the location of food rewards. However, when more sensitive tests are administered, it becomes apparent that the hippocampus and thalamus mediate different cognitive processes. On tests that provide separate measures of general learning ability, STM, and LTM, the memory problems of thalamus-damaged animals were related to difficulties in learning the task. This pattern, which is also observed in thalamic amnesic patients, suggests that the thalamus is involved in the early stages of learning and possibly in attending to relevant task-related information. By comparison, when tested on similar tasks, animals with hippocampal damage generally exhibit good rule-learning ability but are reliably impaired when required to recall specific responses after extended delays, or when distracted by interfering influences. There are several views of hippocampal function, but this pattern suggests that the hippocampus participates in transferring information from STM to LTM, a process that is sometimes called 'consolidation'.

Memory function is also affected when the FL are damaged, but, again, in different ways. Patients with FL lesions resulting from injury or disease do not suffer generalized memory loss, but they have difficulty recalling information without the benefit of external aids, or when a conscious effort is required to locate the information in their memory. Thus, they may recognize a familiar picture, but the picture is not likely to conjure up memories of experiences associated with the scene. It is difficult to characterize FL function in precise terms, but there is broad agreement that the structure is involved in strategic processes that direct thought

and goal-oriented behavior. This function is important not only for free recall, but also for other cognitive activities that require the organization of information and behavioral planning. Therefore, FL patients are also impaired in complex learning tasks, in solving problems, and in organizing daily routines.

Our understanding of the functional significance of the FL, as well as their interactions with other brain regions, has been advanced significantly by animal research involving a variety of tasks. One such task involves conditional associative learning (CAL), in which different stimuli must be associated with different responses. Thus, if stimulus A is presented, the individual must perform response A; if stimulus B is presented, response B, and so on. Both humans and monkeys with FL damage are severely impaired on this rule-learning task. Rats with FL lesions are also impaired in a Skinner-box version of CAL, but, depending on the task requirements, other structures are also important. Thus, while rats with FL lesions are impaired in learning the basic rule, rats with hippocampal lesions learned it as well as normal controls. Increasing the delay between stimulus presentation and the opportunity to respond does not affect FL-damaged rats, but the hippocampal group's performance deteriorates sharply. This dissociation is significant because it shows that the primary effect of the FL lesion was on the strategic aspect of the task – that is, in using relevant information to learn the rule and select correct responses. In contrast, the behaviour of the hippocampal rats confirmed that the hippocampus is involved in relatively straightforward memory processes.

The above examples illustrate the feasibility of devising animal tests that measure memory processes analogous to those affected by focal lesions to the MTL, diencephalic, and FL systems. Investigators have used these tests to confirm the precise function of specific brain regions, and to show how localized functions are integrated within a multiple-systems model. This type of research has created a strategy for studying the complex pattern of lost and spared memory function following brain damage. It is a strategy that has already led to important insights into the nature of memory disturbances, and it has practical implications for the development of treatment programs.

ANIMAL MODELS OF ALZHEIMER DISEASE

Alzheimer disease, the most common cause of dementia, affects about 10% of people over the age of 65, and as much as 40% of the population over 80. The early manifestations are seemingly innocent bouts of forgetfulness, but as the disease progresses, memory lapses become more frequent and other forms of cognitive impairment begin to appear. Over a period of years, attention, learning ability, language and speech skills decline as part of a deterioration of general intellectual function.

In line with the early symptoms of memory loss, AD begins with abnormalities in the hippocampus, which spread to other regions of the brain. Apart from considerable neuronal loss, certain pathological features are unique to AD, although their precise relation to the disease is uncertain. Cardinal features include intracellular accumulation of neurofibrillary tangles that result from changes in the protein *tau*. Normally, *tau* molecules provide internal support to nerve cells, but in AD, they become twisted and clog the cells, causing them to die. There are large extracellular deposits of neuritic plaques formed by an overproduction of β-amyloid protein, which is normally involved in cell membrane function. In large numbers, the plaques trigger an inflammatory response, which may initiate the sequence of events that ultimately leads to cell death.

AD is accompanied by depletion of several neurotransmitters, although most attention has focused on acetylcholine (Ach) and cholinergic neurons of the basal forebrain and septal and hippocampal regions. Cholinergic activity normally declines in old age, but the loss is substantially greater in AD patients. It has been estimated that the brains of AD patients lose as much as 70% of the Ach-synthesizing enzyme, choline acetyltransferase, and up to 90% of the normal supply of Ach. There is little doubt that these changes contribute significantly to the severe memory loss associated with AD.

The nature of AD presents several obstacles to developing a comprehensive animal model of the neuropsychological component. AD does not occur naturally in animals, and certain essential features that affect brain function (e.g., neurofibrillary tangles) have not been reproduced reliably in non-human species. Also, because AD is progressive, it is difficult to capture all the cognitive and related psychological impairments that are expressed as the disease passes through its various stages. In light of these considerations, most attempts to model AD have focused on the early stages, where the pathology is less complex and where memory loss is the primary cognitive symptom.

Investigators have used surgical techniques and pharmacological manipulations to demonstrate that disruption of cholinergic systems in animals produces cognitive deficits similar to those seen in AD patients. Lesions to the medial septum, hippocampus, and nucleus basalis of Meynert (NBM) in the forebrain result in significant reductions in cholinergic activity and cognitive deficits in nonhuman primates and rodents. These experiments often involve conditional learning tasks, such as CAL (described above). On such tasks, animals with lesions to the area of the medial septum and hippocampus typically learn the basic responses within normal limits, but their performance deteriorates when challenged to remember specific information that is critical to response selection. In CAL, this occurs when a delay is introduced between the stimulus and the response. In contrast, lesions to the NBM, the primary source of cholinergic input to frontal cortex, interfere with basic rule learning, but increasing stimulus–response intervals does not add significantly to the deficit. These are important findings because they show that the two branches of the cholinergic system are involved in different functions that are also implicated in AD. The evidence directly links the septal–hippocampal region to the type of memory function that is affected in AD, whereas the NBM–frontal system appears to control strategic or attentional processes that are essential for various kinds of new learning.

In the 1970s, researchers found that drugs, such as scopolamine and atropine, that block cholinergic receptor function at the synaptic level severely disrupt memory function in young adult humans. An equally important finding, and one with clinical implications, was that performance deficits can be reversed by cholinergic agonists (e.g., physostigmine) that promote Ach synthesis. The same effects have been demonstrated in young adult rats and monkeys.

These results provided direction for treating the cognitive problems associated with normal aging and diseases such as AD. In fact, studies showed that cholinergic drugs (e.g., physostigmine, donepezil) were often very effective in overcoming learning and memory deficits in aged animals or in animals with damage to cholinergic brain regions. Currently, such drugs are the only pharmacological treatments approved for AD, and while their effectiveness is limited, they provide relief and hope to many patients, where only a few years ago there was none.

Animal models have also been useful in studying the connection between β-amyloid and cognitive impairment in AD. Given the large deposits of β-amyloid in AD brains, it is not surprising that its presence correlates with neuronal damage and cognitive impairment. Similar relationships have been reported in rats infused with β-amyloid protein in various brain regions, especially the hippocampus. Importantly, the pattern of cognitive impairment associated with β-amyloid build-up is similar to that seen in early AD. In one study, the performance of aged dogs on a battery of learning and memory tests was related directly to β-amyloid levels in the brain. A significant correlation was detected on tests where successful performance depended on remembering specific information. On the other hand, tasks that emphasized stimulus–response rule learning were less affected by age and β-amyloid levels.

Similar results have been reported in investigations of strains of 'senescence-accelerated mice' that are specifically bred to produce β-amyloid deposits that correlate with learning and memory deficits. It follows that it should be possible to limit such deficits by reducing β-amyloid levels. Although not yet attempted in humans, there are indications that this is a promising line of investigation. Several studies have shown that injecting antibodies to β-amyloid into senescence-accelerated mice significantly reduces their memory deficits.

New and exciting possibilities for studying AD emerged from the discovery that some forms of the disease can be traced to genetic mutations and that these mutations can be introduced into the brains of mice. For example, an abnormality on chromosome 19 that results in underproduction of APOE4, a protein involved in cholesterol production, has been linked to over 60% of AD cases. When similar APOE4 deficiency was created in transgenic mice, scientists discovered AD-like pathology that included abnormalities in β-amyloid production and impaired cholinergic function. These mice also exhibited learning and memory impairment that was directly linked to reduced Ach levels in the hippocampus and FL.

APOE4 is a susceptibility gene for late-onset AD. This means that not everyone who carries it will necessarily acquire the disease. Other recently-discovered genes have proven to be stronger predictors of early-onset familial AD, although these genes account for only about 5% of the total number of AD cases. An especially important discovery was a mutation of the amyloid precursor protein (APP) on chromosome 21. APP is normally involved in producing the β-amyloid protein, but in its mutant form it leads to the development of amyloid plaques. Transgenic mice carrying this

mutation develop AD-like neuropathology that includes deposits of plaque and abnormalities in the *tau* protein (which, as indicated above, is implicated in the formation of neurofibrillary tangles). APP mice also show cognitive deficits that correlate with biochemical and pathological abnormalities symptomatic of AD. The model was enhanced when the investigators showed that the constellation of symptoms increased with the age of the animals, as would be expected in a progressive disease like AD. Mutations of other genes (e.g., presenilin 1 on chromosome 14, presenilin 2 on chromosome 1) have been similarly linked to forms of AD. Behavioral work in this area is just beginning, but the encouraging early results raise hopes that this approach will be useful in relating the developmental pattern of cognitive deficits to the progression of neuropathological symptoms of AD.

ANIMAL MODELS OF BASAL GANGLIA DISEASE

The basal ganglia, located centrally in the forebrain, are a group of structures that include the caudate nucleus (CN) and putamen (known together as the neostriatum) and the globus pallidus. These structures form part of the extrapyramidal motor system that regulates movement in all parts of the body. The BG and, most notably, CN are also involved in cognitive functions. The CN has direct connections with the FL, so that damage to the CN often produces cognitive symptoms similar to those seen in patients with FL lesions. We focus here on two degenerative brain diseases – PD and HC – that attack the BG and produce motor and neuropsychological disturbances.

PD, which affects about 0.1% of the population, originates in the substantia nigra of the upper brain stem, and spreads along dopaminergic pathways to the BG and ultimately to the FL. The earliest symptom is loss of fine motor control, but as the disease progress, patients suffer generalized motor slowing, tremor, rigidity, and speech and swallowing difficulties. A variety of cognitive symptoms are also part of the disease. PD patients sometimes develop a form of dementia that includes memory and intellectual loss similar to that of AD. Nondemented PD patients typically exhibit a neuropsychological profile that reflects damage to CN and its frontal connections. The defining cognitive deficit in PD is impairment in procedural learning, as expressed in various problem-solving and skill-learning tasks that require strategic planning. While learning ability is affected in PD, straightforward memory function is relatively spared. When PD patients do experience memory difficulties, it is usually for inaccessible memories and can be traced to interruption of CN–frontal pathways.

HC is a relatively rare genetic disorder that results from an abnormality on chromosome 4. It is characterized initially by involuntary, jerky (choreiform) movement of fingers and toes, which later spreads to most regions of the body. Cognitive and psychiatric problems are common in HC, including dementia and changes in mood and personality. Initially, the disease attacks the CN and putamen; it then spreads to other brain regions including the FL.

In the early stages of HC the cognitive profile resembles that of nondemented PD patients. Thus, HC patients are impaired in learning and remembering new skills and procedures but not necessarily in consciously recalling specific experiences. This point is illustrated in experiments in which HC patients are compared with MTL or diencephalic amnesics on tests of skill learning and specific memory function. Such experiments reveal a double dissociation, in which HC patients display procedural learning deficits but normal memory, while the opposite pattern is observed in amnesic patients.

It is important to note that procedural-learning tasks on which PD and HC patients are typically impaired often have a substantial motor component. Consequently, one has to be careful not to confound effects of motor disabilities in assessing neuropsychological test performance. Careful study has shown that the cognitive and motor symptoms of these diseases, as well as those with focal lesions to CN, are largely unrelated, and linked to different brain systems.

Scientists have attempted to model the cognitive symptoms of PD and HC by studying the effects of damage to CN in animals. Early research focused on the disruptive effects of CN lesions on spatial-learning tasks in which animals had to perform a series of turning responses to locate an object in their environment. Deficits on such tasks mirror the disorientation problems of PD patients, and have been related to the requirement that critical associations be formed between specific stimuli and discrete responses. Other studies have shown that CN lesions disrupt performance on a variety of discrimination-learning tasks where positive and negative stimuli are associated with different responses. These findings parallel those of studies with humans, and provide strong evidence that the CN is a critical part of the neural system which forms stimulus–response associations: a

process that is essential for many rule- or skill-based procedural-learning tasks.

Attempts to develop more specific animal models of PD and HC have utilized neurotoxin lesion techniques that selectively destroy neurotransmitters directly linked to the diseases. Thus, to mirror PD, investigators have infused dopamine antagonists, such as 6-hydroxydopamine, into the CN, causing selective damage to dopamine cells. With respect to HC, similar experiments have been performed with various pharmacological agents (e.g., kainic acid, quinolinic acid, 3-nitrapropinic acid) that produce changes in CN similar to the pathology of HC. Such research has confirmed that even selective damage to CN produces generalized stimulus–response learning deficits. It is not yet clear whether traditional lesion techniques will be sufficient to capture the range of symptoms of PD or HC, and other strategies need to be explored.

The development of models using transgenic mice has been a major advance in studying HC. These models have the important advantage of taking into account the genetic basis of the disease. Mice carrying the human HC gene display motor disturbances and many of the neuropathological features of the disease. Behavioral studies with these mice are just beginning, but early results indicate a deficit pattern consistent with that observed in other animal models and in HC patients. Of particular importance is the observation that these mice develop progressive impairments that reflect the progression of the disease to other regions of the brain, and specifically to the FL.

A promising model of PD has emerged from tragic and unusual circumstances. In the 1980s, William Langston, a neurologist working in California, reported that over 200 drug addicts developed parkinsonian symptoms after mistakenly injecting themselves with a substance, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyradine (MPTP). MPTP is a powerful neurotoxin that selectively attacks the substantia nigra, destroying dopaminergic pathways that connect this region to BG. The entire group developed typical signs of PD, including the motor and cognitive disturbances. MPTP does not produce PD-like symptoms in rodents, but monkeys show virtually the full range of pathological signs and motor deficits within three days of injection.

Investigations of MPTP effects have consistently revealed learning and memory deficits on tasks that are sensitive to impairment in the FL and CN brain regions: a pattern that is consistent with human findings. An important feature of the MPTP model is that the cognitive deficits correlate with dopamine depletion and respond to treatment with dopamine agonists. Thus the tragedy of the MPTP-exposed drug addicts has led to a primate model that may lead to major breakthroughs in understanding and treating a menacing brain disease.

With respect to treating BG diseases, there has been some progress in recent years. Again, animal models have played a central role. In PD, the most common treatment is to prescribe dopamine agonists like levadopa and deprenyl, which temporarily reduce the symptoms in most patients. More invasive treatments, such as surgical destruction of anatomically-related subcortical structures (e.g., thalamic nuclei), can be effective in reducing motor symptoms. HC is sometimes treated with dopamine antagonists to restore BG function, but the benefits tend to be modest. Because of its genetic origin, advances in genetic engineering and the development of transgenic-mice models of HC offer greater prospects for success.

Another radical treatment, which takes a very different approach to restoring lost brain function, involves grafting or transplanting live neural tissue. In the most common application, brain cells are extracted from aborted fetal tissue and transferred to damaged sites in the host brain. Properly implanted, the cells migrate to appropriate locations and begin to function both physiologically and neurochemically. Behavioral experiments, in which cholinergic or dopaminergic brain cells were transplanted into brain-damaged or aged animals, have shown that learning and memory function can also be restored. This technique has proved to be especially effective in the MPTP monkey model of PD, where CNS transplantation of dopaminergic cells reduced the motor and cognitive symptoms of the disease. Indeed, the results have been so encouraging that the procedure has been attempted on PD patients, but with mixed results.

CONCLUSION

Animal models are becoming as important to the study of neuropsychological deficits following brain injury as they are to any other medical condition. Substantial progress followed the emergence of surgical, pharmacological, and genetic techniques that produce, in animals, the neuropathological and cognitive changes reliably seen in patient populations. Equally important was the need for sensitive behavioral tests that assessed cognitive impairment associated with localized damage, and dissociated specific deficits from those

resulting from coexisting damage to other regions. Important advances in these areas led quickly to improved understanding of underlying mechanisms, and to experimental treatments that promise to alleviate functional deficits associated with brain injury of various etiologies. This article has focused on the use of animal models of cognitive deficits associated with focal brain lesions and such neurodegenerative diseases as AD, PD, and HC. These examples serve to make the point with respect to major neurological problems, but the list could be extended to include Down syndrome, multiple sclerosis, and neuropsychiatric diseases (e.g., schizophrenia, obsessive–compulsive disorder) that have cognitive symptoms.

Animal models have their limitations, and the practice, with respect to neuropsychological disorders, has its critics. Nevertheless, the benefits derived are incontrovertible, and as they continue to accrue, the central role of animal models in this research enterprise will be assured.

Neurotransmitters

Introductory article

Gary L Wenk, University of Arizona, Tucson, Arizona, USA

CONTENTS

Neurotransmitters are chemicals that are released in tiny amounts by neurons in response to an action potential.

INTRODUCTION

Neurotransmitters are chemicals that are released in very small amounts from neurons in response to the arrival of an action potential. Once released, the neurotransmitter travels across the synaptic cleft that separates one neuron from the next in order to transfer information. Almost everything interesting that relates to information processing is thought to rely upon the action of the neurotransmitters.

The first neurotransmitters to be discussed are those that form diffuse regulatory pathways. These pathways originate in the brainstem region; they include those releasing the neurotransmitters acetylcholine, dopamine, noradrenaline (norepinephrine), serotonin, and the various neuropeptides. These projection pathways consist of small clusters of cell bodies that mostly reside within the brainstem and send branching axons to terminate in multiple and widespread areas of the brain. Thus, a single neuron may modulate the activity of a large number of target cells. The diffuse pathways contrast with other neurotransmitter pathways which provide a rapid, point-to-point innervation to specific neurons.

PRINCIPLES OF CHEMICAL NEUROTRANSMISSION

It is important to realize the fact that behavior influences and is influenced by the neurotransmitter function within the brain. Specificity of neurotransmitter action is fundamental to normal brain function. This specificity is achieved by either localized release within a discrete area (anatomic specificity) or by limited receptor distribution (chemical specificity). Anatomic specificity is imparted through spatial sequestration of transmitter–receptor interaction; i.e. the actions of the neurotransmitter are restricted to the space of the synaptic cleft. Chemical specificity is dependent upon the moment-to-moment composition of interstitial fluid that surrounds the neurons at a given receptor population, and hence neurotransmitters may act at sites distant from their release. The two main things that you need to know about what a neurotransmitter is doing are (a) where it is released, and (b) what the receptor does in response to the presence of the neurotransmitter. Simply stated, neurotransmitter systems that innervate specific brain regions influence the function of that brain region. For example, because noradrenaline (norepinephrine) innervates the hippocampus it has a role in hippocampal function, and because the hippocampus has a role in memory, so then does noradrenaline.

CLASSES OF NEUROTRANSMITTERS

With the introduction of sophisticated histological techniques in the early part of the twentieth century, neuroanatomists were able to map neuronal pathways on the basis of transmitter content. Only the 'classical' neurotransmitters – acetylcholine and the monoamines – are discussed in detail here; owing to the multiplicity of neuropeptide neurotransmitters (over fifty have been identified to date), these substances are considered only in general terms. Finally, the two major amino acid neurotransmitters, glutamate and γ-aminobutyric acid (GABA), are introduced.

An important concept to keep in mind when considering the role of the various neurotransmitters in the brain is that they occur at very different levels of concentration. The neuropeptides exist at nanomolar levels, the classical neurotransmitters exist at 100 to 1000 times the concentration of

neuropeptides, and the amino acid neurotransmitters exist at concentrations 100 to 1000 times greater than that of the classical neurotransmitters.

In addition, the manner in which the brain produces and discards the various neurotransmitter molecules in each class is quite different. The neuropeptides are processed from much larger polypeptides and are not reused after release from the synaptic terminal. In contrast, the classical neurotransmitters, such as acetylcholine, dopamine, and noradrenaline, begin as simple amino acid nutrients from the diet and are modified by a series of enzymes prior to being released. Once released, these transmitters are largely used again by a process called reuptake; essentially, the neurotransmitter is removed from the synaptic cleft and repackaged into a new synaptic vesicle. Finally, the amino acid neurotransmitters glutamate and GABA are obtained from the diet and are not modified at all prior to being stored in synaptic vesicles and then released into the synaptic cleft. These differences also highlight another difference in the nature of these neurotransmitter systems: the neuropeptides are metabolically expensive to produce and use compared with the amino acid transmitters.

RECEPTOR SUBTYPES

Most of the neurotransmitter receptors are proteins that float within the neural membrane. They are the targets of action of the neurotransmitter molecules as well as of drugs that influence brain function. They respond with specificity to the neurotransmitters, have a finite rate of operation (the speed with which they transmit information) and are saturable (they have a finite maximal effect). The binding of neurotransmitter molecules to the receptors is reversible.

There is usually more than one type of receptor within each neurotransmitter system. For example, there are at least five different dopamine receptors and two different receptors that respond to acetylcholine. The dopamine receptors all respond to dopamine, but the nature of the response varies considerably: for example, some dopamine receptors open ion channels directly, while others activate a series of second messenger systems. The different subtypes of neurotransmitter receptors are distinguished also by the drugs that interact with them: for example, the two subtypes of acetylcholine receptor are distinguished by the fact that one responds to nicotine while the other responds to muscarine.

Receptors are further distinguished by whether they lead to an increase or decrease in neural function. For example, serotonin might bind to one of its receptor subtypes and produce stimulation, while binding within the same brain region to a different subtype of receptor might lead to inhibition of the activity of the postsynaptic neuron. Therefore, it is impossible to state that a particular neurotransmitter is either excitatory or inhibitory; this response depends entirely upon the nature of the receptor.

NEUROTRANSMITTERS IMPORTANT IN COGNITION

Acetylcholine: Learning, Memory, and Attention

Acetylcholine is an important neurotransmitter throughout the animal kingdom. In mammals, four major classes of acetylcholine-containing (cholinergic) neurons have been identified.

The first category includes neurons that are contained entirely within the peripheral autonomic nervous system; all postganglionic parasympathetic neurons and some specialized postganglionic sympathetic neurons (innervating sweat glands and some blood vessels) are cholinergic.

The second category of cholinergic neurons are those that originate within the central nervous system (brain and spinal cord) and project to the periphery; these include the skeletomotor neurons and the preganglionic neurons of the parasympathetic and sympathetic nervous systems.

The final two categories of cholinergic neurons are contained entirely within the central nervous system: local circuit or interneuronal cholinergic neurons, and cholinergic projection pathways. Cholinergic interneurons are found in the striatum and retina. The other cholinergic cells of the central nervous system are within the basal forebrain. The basal forebrain region includes the medial septal area and the nucleus basalis. Cholinergic cell bodies in the medial septal area project axons to the hippocampal formation; those in the nucleus basalis innervate the amygdala and send a topographic projection to the entire cortical mantle; and those in the reticular formation and periventricular area send a major projection pathway to the thalamus.

Acetylcholine is synthesized in neurons that express the enzyme choline acetyltransferase using two precursors from the diet. The first, choline, is found in many foods, particularly those that contain lecithin (a common food additive). The acetyl

group used to produce acetylcholine is obtained from glucose. Acetylcholine is synthesized in the axonal terminal within the cytoplasm and is then actively transported into synaptic vesicles for storage and release. Each synaptic vesicle contains approximately 5000 to 10 000 molecules of acetylcholine. The regulation of its synthesis is controlled by end-product inhibition: higher levels of acetylcholine within the terminal inhibit production. The production of acetylcholine is also controlled by the availability of both of its precursors. Giving additional choline alone will not produce or release more acetylcholine; therefore, it is not possible to enhance cholinergic function by eating a diet high in choline. Once released, acetylcholine is metabolized by the enzyme acetylcholinesterase into choline and acetic acid. Most of the choline released into the synaptic cleft is taken back up into the terminal and used to produce new acetylcholine molecules.

Cholinergic neurons are implicated in several forms of higher-order behavior. Most notably, the inputs to hippocampus, amygdala, and cortex appear to participate in sleep, learning, memory, and attention. The general function of any neurotransmitter can sometimes be inferred from the consequences of its loss from the brain or from the consequences of pharmacological manipulation. For example, drugs that impair cholinergic function, such as hyoscine (scopolamine) and atropine, also impair memory; drugs that enhance cholinergic function, such as physostigmine, tend to enhance learning and memory abilities. In addition, a characteristic feature of Alzheimer disease is the marked loss of cholinergic cells within the basal forebrain that roughly parallels the decline in cognitive function.

Noradrenaline (Norepinephrine): The Arousing Transmitter

Noradrenaline (norepinephrine) belongs to the class of neurotransmitters known as catecholamines (this group also includes dopamine and adrenaline). Catecholamines have been identified as neurotransmitters in a variety of species ranging from insects to humans. This transmitter is used for intercellular communication in both the central nervous system and peripheral nervous system.

Almost all of the postganglionic sympathetic neurons are noradrenergic; i.e. they use noradrenaline as a major transmitter. Within the central nervous system, there are several discrete cell clusters (nuclei) of noradrenergic neurons and all of these are located in the lower brainstem and pons. The locus ceruleus is the largest cell group with at least half of all central noradrenergic cells being located at this site in the caudal pontine central gray matter (in humans, about 12 000 cells per side). The noradrenergic cells of the locus ceruleus send axons that terminate throughout the brain and spinal cord (mainly ipsilaterally) to innervate all areas of the brain. Within the locus ceruleus, the more caudally located cell groups send descending projections to the brainstem and spinal cord, whereas the more rostrally located cell groups innervate the forebrain and telencephalon, with the exception of the basal ganglia.

The production of noradrenaline and the other catecholamine neurotransmitters is from dietary precursors and requires five different enzymes. These enzymes are very similar to each other and are produced by genes that lie close together, somewhat like beads on a string. These enzymes exist within the brains of all five classes of vertebrates and several invertebrates. The high degree of nucleotide homology between these enzymes suggests that they may have evolved from duplication of a common ancestral gene.

It is important to appreciate that not all of these synthetic enzymes are expressed in every catecholamine neuron. When more than one enzyme is expressed in a neuron, their regulation is usually linked in a coordinated fashion leading to the production of a specific neurotransmitter. Occasionally during embryogenesis, selected enzymes are transiently expressed and then disappear. This is why some neurons begin life containing noradrenaline but later on contain dopamine.

The main rate-limiting enzyme in the production of the catecholamine neurotransmitters is tyrosine hydroxylase. Therefore, the production of noradrenaline requires the amino acid tyrosine from the diet. For this reason, the content and balance of dietary amino acids is important for synthesis of the brain's major neurotransmitters. Shifting the concentration of different precursor amino acids in the diet can alter the uptake of each nutrient into the brain and may limit or alter neurotransmitter production. With a balanced diet, uptake of all amino acids is fairly constant and in correct proportion. However, too much of one amino acid will offset the metabolism of the others.

Once released from the terminal, noradrenaline acts upon a distinct class of receptors whose classification, as with many other transmitter systems, is based on anatomical and pharmacological criteria. Noradrenergic neurons are thought to govern the activity of preganglionic autonomic neurons and to participate in neuroendocrine regulation. In

addition to the brain, the chromaffin cells of the adrenal medulla also release noradrenaline into the bloodstream upon exposure to stressful stimuli.

Noradrenergic pathways within the central nervous system have been implicated in virtually all aspects of brain function from homeostatic processes to advanced behaviors such as learning and memory. Locus ceruleus projections may also mediate selected feeding behaviors and a global-orienting and arousal function to environmental stimuli. Drugs that enhance the function of noradrenaline, such as amphetamines, also enhance arousal.

Dopamine: The Rewarding Transmitter

Although dopamine is the predominant neurotransmitter in species that evolved prior to molluscs, this neurotransmitter has a rather limited distribution within the central nervous system compared with the other classical neurotransmitters.

Dopamine is used by several pathways within the central nervous system. The tuberohypophysial system (also known as the tuberoinfundibular system) consists of cell bodies in the arcuate nucleus of the hypothalamus and periventricular nucleus that project axons to the median eminence and the intermediate and neural lobes of the pituitary and control the release of prolactin. Another dopamine projection system originates in the ventral mesencephalon. The mesocorticolimbic dopamine neuronal system is composed of cell bodies located in the ventral tegmental area which send projections primarily to frontal lobe structures, including the nucleus accumbens, olfactory tubercles, amygdala, septal area, and the prefrontal, cingulate, piriform, and entorhinal areas of the cortex. The nigrostriatal pathway consists of cell bodies in the substantia nigra that send axons to the striatum (caudate and putamen).

These dopaminergic systems serve different functions. For example, the nigostriatal system regulates postural reflexes and inhibition of motor output. The mesocorticolimbic dopamine system is a critical element of brain reward pathways, whereas the tuberoinfundibular dopamine system governs pituitary hormone release.

Decreased levels of dopamine in the nigrostriatal pathway result in Parkinson disease, the symptoms of which include tremors, spasticity, and akinesia (difficulty in initiating or stopping movements). In contrast, increased levels of dopamine in the forebrain are associated with stereotypy in rats and schizophrenia in humans. One of the best understood actions of forebrain dopamine is its role in reward and euphoria. Virtually every known drug or rewarding experience stimulates, directly or indirectly, the forebrain dopamine neurons. This system is stimulated by the consumption of all known addicting substances, such as cocaine, heroin, and nicotine. Interestingly, its activity is not influenced by ingestion of caffeine.

Serotonin: The Most Complicated Neurotransmitter System

Serotonin or 5-hydroxytryptamine is found in many non-neuronal sites such as platelets, mast cells, and enterochromaffin cells. This amine is also used by central nervous system projection pathways that provide diffuse innervation throughout the brain and spinal cord.

There are nine major serotonergic nuclei and these are located in the midline areas of the pons and upper brainstem. The more caudal nuclei project to terminal fields within the brainstem and spinal cord. The rostral nuclei send diffuse ascending projections throughout the telencephalon and cerebellum; many of the terminal fields are overlapping. All areas of the forebrain receive input from these nuclei.

Serotonin was first found in serum and determined to have tonic effects on the cardiovascular system, which explains its name. It is found in the gastrointestinal tract of virtually every animal species examined and has also been found in the venom of amphibians, wasps, and scorpions – its effects upon the vasculature (vasodilation) assist in the action and absorption of the venom. Even planaria have serotonin receptors.

In humans, approximately 90% of total body serotonin is found in the gut, about 8% is found in platelets and mast cells in the blood, and only about 1–2% is located in the central nervous system, most of it within the pineal gland, which is not really part of the nervous system. The remainder is found in the raphe nuclei within the reticular region of the brainstem. Ascending pathways from these nuclei pass via the medial forebrain bundle to innervate the limbic structures, hypothalamus, septum, cingulate gyrus, cerebellum, superior colliculi (to influence vision), hippocampus, and neocortex. Serotonin terminals also make contact with glial cells and blood vessels; this might explain the role of serotonin in the onset of migraine headaches.

Although serotonin neurons represent less than 0.01% of neurons in the brain, their axonal terminals ramify widely to innervate almost every region of the brain. Serotonin neurons have a regular, slow spontaneous firing rate (about 0.5 to 2.5 spikes per

second) which suggests that they are constantly dribbling serotonin everywhere in the brain. This pattern of activity does not suggest that real information transfer is occurring. It is thought that these neurons provide only modulation of other neural activity within the region they innervate. This may explain why it has been so difficult to define a specific function for this neurotransmitter system. The spontaneous activity of these neurons is slowed significantly during slow wave sleep and eliminated completely during dream sleep. Undoubtedly, serotonin neurons play a role in the control of sleep onset and maintenance. Serotonin is also involved in adjusting the sleep–wake cycle to the photoperiod and regulation of the circadian rhythms.

The production of serotonin requires the amino acid tryptophan as a precursor from the diet. Uptake of tryptophan depends upon the level of other amino acids in the blood. A high-carbohydrate diet enhances tryptophan uptake into the brain. Approximately 1% of the tryptophan taken up into the brain is converted by the enzyme tryptophan hydroxylase into the transmitter serotonin. The production of serotonin is tightly controlled. It is known that lack of tryptophan in the diet will impair the formation of serotonin, but the presence of additional tryptophan does not lead to increased function of these neurons in spite of the fact that the action of the synthetic enzyme tryptophan hydroxylase is not rate-limiting. Any excess serotonin molecules that are produced appear to be metabolized within the cytoplasm, not released. Synthesis occurs within the neuronal terminals, so tryptophan hydroxylase is made in the cell body and shipped to the terminals.

Once released, serotonin can act upon a large variety of receptors: at least fourteen have been identified thus far. Pharmacologists have developed many different drugs that target these receptors; these drugs have been used to treat anxiety and depression as well as migraine headaches. Many naturally occurring drugs such as mescaline, dimethyltryptamine, and psilocybin can also influence serotonergic receptor function and produce hallucinations. The termination of action of serotonin, as for dopamine and noradrenaline, is by reuptake. Catabolism by various enzymes is a minor component in the termination of the action of serotonin.

Elevation of brain hippocampal levels of serotonin has been associated most often with impairment of learning and memory abilities. Lesion of the serotonin neurons can induce hyperactivity and hyperresponsivity to novel stimuli and increased motor activity. Serotonin neurons may also have a role in feeding behavior, thermoregulation, and sexual behavior. Serotonergic pathways are also implicated in mediating arousal behaviors. Finally, abnormal serotonergic transmission is thought to underlie psychiatric disorders such as major depressive illness and obsessive–compulsive disorder.

Neuropeptides

Most peptides that serve as intercellular messengers within the central nervous system range in size from 3 to 50 amino acid residues. More than 50 neuropeptides have been identified to date and there is no doubt that countless more will be discovered. Neuroanatomists have described multiple peptide pathways throughout the central and autonomic nervous systems and several peptides are known to exist within the dorsal root ganglion sensory neurons. Many peptides found within the nervous system are also produced in non-neural tissues such as the gastrointestinal tract and endocrine system.

Neuropeptides exert potent effects upon a variety of processes when administered into the brain, and specific peptides are thought to be involved in mediating several diverse functions. It is well established, for example, that certain peptides known as hypothalamic releasing hormones are the primary regulators of pituitary hormone secretion. Interestingly, some of the hypothalamic releasing hormones are also distributed outside the hypothalamus in brain areas controlling behavioral and autonomic outputs. On the basis of brain distribution and actions, some neuropeptides are believed to play a unique part in homeostatic processes by integrating appropriate endocrine, autonomic, and behavioral responses to environmental stimuli.

Amino Acid Neurotransmitters

The neurotransmitters discussed above are released throughout the brain and are, in general, involved with modulation of neural activity within the brain regions they innervate. For example, they may increase the likelihood of a memory, but are not responsible for the actual molecular mechanisms underlying the neural plasticity. In addition, these transmitter molecules are produced primarily for the purpose of neuronal communication. In contrast, some amino acids have multiple duties within the central nervous system. These amino acids are used for intermediary metabolism related

to protein synthesis or neuronal repair as well as for neurotransmission.

The two most important amino acid neurotransmitters that have been identified are glutamate and GABA. Neurons that contain and release glutamate and GABA are found throughout the central nervous system. Chemically these two neurotransmitters are very similar: indeed, glia actively convert glutamate into GABA, and vice versa, by the addition or subtraction of a molecule of carbon dioxide. This chemical similarity related to the presence or absence of carbon dioxide is a common phenomenon in nature; for example, some mushrooms contain both ibotenic acid (which acts like glutamate in the brain) and muscimol (which acts like GABA in the brain). As expected, ibotenic acid and muscimol differ only by a molecule of carbon dioxide.

Glutamate

Glutamate and GABA are the brain's major excitatory neurotransmitters, providing point-to-point innervation of brief and fast excitatory input. Almost everywhere that glutamate is released it produces a strong postsynaptic excitation. This excitation can lead to either a change in function of the synapse, often called neuroplasticity, or to the destruction of the postsynaptic neuron. These two actions of glutamate have different roles in the brain at different times of life, and are influenced by the response of specific glutamate receptors to the presence of elevated levels of glutamate.

For example, during development and maturation of the brain, elevated extracellular levels of glutamate may lead to the pruning of excess neuronal synapses or the destruction of selected neurons. The loss of excess synapses and neurons is thought to improve information transfer and processing within the maturing brain. After these processes are completed, the brain alters the way in which it uses glutamate and exerts greater control over the concentration of glutamate within the synaptic cleft. During adulthood, extracellular levels of glutamate are carefully controlled in order to avoid overstimulation of its receptors and the inappropriate destruction of postsynaptic neurons. With advanced aging, extracellular levels of glutamate once again may become involved with the degeneration of selected neural systems.

Recent research has focused upon pharmacological methods to attenuate the degenerative actions of glutamate in order to slow the progress of neurological disorders such as Alzheimer and Huntington diseases.

GABA

Gamma-aminobutyric acid neurons can be found throughout the brain. They exist mostly as small interneurons that provide local circuit control of regional neural networks. However, there are also a few prominent long pathways that release GABA. The widespread nature of these underlies an interesting feature of this neurotransmitter system, which is that a large percentage of synapses are influenced by GABA and are therefore inhibitory. This feature underlies an important proclivity of neural function, that most neural processing involves inhibition rather than excitation.

Receptors for GABA come in two types that are distinguished by the type of drugs that bind to them. These receptors serve as binding sites for drugs that depress central nervous system function. Alcohol, barbiturates, and the benzodiazepine drugs (e.g. diazepam) all bind to GABA receptors, enhancing their function and thereby increasing the level of inhibition in neural networks throughout the brain. The consequence is a slowing a neural activity and the subsequent loss of consciousness.

COTRANSMISSION OF NEUROTRANSMITTERS

It is now known that a single neuron may contain several transmitters in different combinations. Most, if not all, neurons contain two or more different neurotransmitters, such as a neuropeptide in combination with a classical neurotransmitter. Depending on the neuronal firing rate, coexisting transmitters may be released separately or together. Cotransmitters may either potentiate or attenuate each other's effects. For example, the neuropeptide galanin is present in acetylcholine-containing neurons that innervate the hippocampus; the release of galanin appears to attenuate the action of acetylcholine upon the postsynaptic neurons within this brain region.

Although the functional significance of coexisting transmitters is as yet not completely understood, a clear implication is the enormous potential for highly specific and differentiated intercellular communication.

CONCLUSION

Neurons communicate with target cells and other neurons through chemical means. A large number of chemically diverse compounds serve as neurotransmitters in the central and peripheral nervous

systems. Many neurons contain more than one transmitter substance. Projection pathways typically contain the classical transmitters (acetylcholine, noradrenaline, dopamine, serotonin), while the peptide transmitters coexist within these neurons. Many neuropathological disorders are associated with reductions or excesses of particular neurotransmitters. The rich diversity of neurotransmitter substances underscores the complexity of neural communication and also provides pharmacological opportunities to modify information processing within the central nervous system.

Non-Alzheimer Dementias

Introductory article

Esma Dilli, University of British Columbia, Vancouver, British Columbia, Canada
Bruce L Miller, University of California School of Medicine, San Francisco, California, USA

CONTENTS

Significant degenerative disorders other than Alzheimer disease that cause dementia include the frontal temporal lobe dementias, Parkinson-like dementias, and prion-related diseases.

INTRODUCTION

The most common type of dementia is Alzheimer disease; however, there are other significant degenerative disorders that cause dementia. These non-Alzheimer dementias vary in their symptomatology and treatment. Therefore, understanding the pathophysiology and anatomy of these dementias will help to provide the most effective treatment for these patients. Non-Alzheimer dementias can be categorized into frontal temporal lobe dementias, Parkinson-like dementias, and prion-related dementias. Each of these categories can be further divided according to the location of the disease process in the brain and/or the signs and symptoms surrounding the disease.

FRONTAL TEMPORAL LOBE DEMENTIA

Frontal temporal lobe dementia (FTLD) is the third most common type of dementia after Alzheimer disease and Lewy body dementia. It accounts for approximately 16% of all patients with primary degenerating dementia. There are three subtypes of FTLD, which are characterized by their presenting symptoms as well as by the involvement of the frontal temporal lobe: frontal temporal dementia, progressive nonfluent aphasia, and semantic dementia.

Frontal Temporal Dementia

Frontal temporal dementia (FTD) causes a gradual deterioration in behavior and language. The behavioral signs include social inhibition and disordered social conduct such as a decrease in manners, social graces, and decorum. Also, patients demonstrate an early impairment in the regulation of personal conduct where they act passively, or talk too much and constantly interrupt others. Other behavioral features of FTD include loss of insight and distractibility. Difficulty with planning and organizing at home or work reflects the decrease in executive function in the frontal lobe. Hyperorality, weight gain, altered preference for food (such as craving sweet foods only) and/or excessive smoking and alcohol consumption may be due to a combination of frontotemporal dysfunction and a decrease in the amount of brain serotonin. Stereotyped perseverative behaviors such as hand rubbing, collecting items, and impulse shopping are also common symptoms. People with FTD demonstrate lack of concern for others and emotional blunting. Criminal behavior such as theft is higher in FTD patients (10%) than in Alzheimer patients (1–2%), reflecting the socially inappropriate behaviors that are present in FTD. Some people with FTD also develop amyotrophic lateral sclerosis (ALS). Around 60% of FTD cases occur sporadically and the other 40% are familial. Approximately 80% of these familial cases are autosomal dominant. Mutations in the tau gene on chromosome 17 account for a small percentage of familial cases.

Although there is no cure for FTD, treatment is available to alleviate its symptoms. Antidepressant drugs such as selective serotonin reuptake inhibitors (SSRIs) can be used to treat the depression as well as reducing compulsions, disinhibition, and hyperorality.

Progressive Nonfluent Aphasia

Progressive nonfluent aphasia is a disorder of expressive language. Patients present with word-finding deficits, trouble in organizing their thoughts, and slowing of word output, which can lead to stuttering. Speech is sparse (decreased word output and phrase length) and effortful. Patients

have problems both expressing and understanding the grammatical elements of speech. 'Anomia' is the term used for the difficulty in naming manifested by inability or slowness to find the correct word. Other signs that suggest progressive nonfluent aphasia are difficulty with reading and writing, as well as impaired repetitions. People with progressive nonfluent aphasia also display verbal apraxia (speech disarticulation). The behavioral changes emerge late in the disease, and usually present as apathy, depression, and social withdrawal. Insight and personal awareness remain intact in these patients. Memory is relatively spared in the early stages of the disease. The brain atrophy is usually asymmetrical and involves the left frontal temporal lobe. The pathology of progressive nonfluent aphasia shows a classical FTLD pattern.

There is no cure for progressive nonfluent aphasia, but speech therapy can be used to improve verbal apraxia.

Semantic Dementia

Semantic dementia is a temporal variant of FTLD causing progressive deterioration of semantic knowledge about people, objects, facts, and words. People with this disorder lose the meaning of words even though they might be able to read, repeat or spell the words phonetically. They perform poorly on tests that require conceptual knowledge such as picture naming, category fluency (e.g. the patient is asked to name all the words in a particular category such as animals) and word–picture matching (matching written or spoken words to pictures). Difficulties in naming (anomia) and impaired verbal comprehension are common complaints. The speech is fluent and grammatically correct with normal flow, but empty in content. Phonology, syntax, and other nonverbal aspects of speech are preserved. Memory for day-to-day events (episodic memory) such as remembering recent personal events and appointments is well preserved, unlike the loss of recent memory in Alzheimer disease. Visuoperceptual and spatial abilities, and nonverbal problem-solving, are commonly preserved until late in the disease. However, as the syndrome progresses a number of patients develop visual deficits such as prosopagnosia, the inability to recognize a familiar face such as that of a relative.

Neuroimaging typically reveals bilateral focal atrophy of the inferolateral temporal neocortex, especially the left anterior temporal cortex, with sparing of the hippocampus. Because the hippocampus is involved in the acquisition and storage of recent episodic and semantic memory, patients with semantic dementia have better recall of recent autobiographical memory while Alzheimer patients have better recall of past events. Most postmortem studies show non-Alzheimer pathological changes with either nonspecific neuronal loss, gloss or spongiform changes.

PARKINSON-LIKE DEMENTIA

Lewy Body Dementia

Lewy body dementia (LBD) is the second most common type of dementia after Alzheimer disease, being responsible for approximately 15–25% of all cases of dementia. It usually begins in the fifth to seventh decade of life, and is twice as common in men than in women. Patients show a progressive cognitive decline with deficits in attention and visuospatial ability. The symptoms include fluctuating alertness, recurrent visual hallucinations (seeing things that are not real) and motor symptoms of Parkinson disease. Patients demonstrate a significant degree of cognitive impairment such as progressive loss in memory, language, visuospatial construction, and reasoning.

Visual hallucinations occur in about 60–80% of people with LBD and are usually recurrent, well formed, and detailed, with themes of people and animals. The hallucinations can occur at any time but are often worse during times of acute confusion. Auditory hallucinations are less common than visual ones in LBD. The neurochemical basis of the hallucinations involves an imbalance between acetylcholine and dopamine. Besides the visual and auditory hallucinations, people with LBD also present with other neuropsychiatric symptoms, such as delusions (including paranoid delusions) and depression. Rigidity and slowing of movement are common in LBD. Slow, shuffling gait, stooped posture, mask-like face, and hypophonic speech are also signs of the parkinsonism typical of LBD. Other clinical features include a history of recurrent unexplained falls or loss of consciousness.

Lewy bodies are the main histopathological feature. Classic LBD shows tau-negative, spherical, red-staining neuronal inclusion bodies. These Lewy bodies stain for ubiquitin and α-synuclein. They may be single or multiple within the neuron and may vary in size. Other associative pathological features of LBD include Lewy-related neuritis, plaques, neurofibrillary tangles, regional neuronal loss of substantia nigra, locus ceruleus and nucleus basalis of Meynert, and microvacuolation. There is no known etiological or risk factor for

LBD. There are a few rare familial cases of LBD related to an autosomal dominant pattern of inheritance. Lewy body disease usually ends in death; mean survival is 3–9 years after diagnosis.

The visual hallucinations may be alleviated by cholinesterase inhibitor agents such as donepezil. If extrapyramidal motor signs are prominent in an individual with LBD, moderate use of antiparkinsonian drugs to enhance dopamine function can be helpful, but may exacerbate psychotic symptoms. It is important that people with LBD avoid neuroleptic tranquilizer medications, which might worsen the parkinsonian symptoms. Therefore atypical antipsychotic neuroleptic medications are recommended to alleviate the psychotic symptoms of hallucinations and delusions.

Progressive Supranuclear Palsy

Progressive supranuclear palsy (PSP) causes progressive nonfluent aphasia due to frontal lobe degeneration. The incidence is approximately 1 in 100 000. Around 8% of people diagnosed with clinical Parkinson disease eventually present with PSP. The onset of the disease is often in the sixth decade (age range 45–75 years). Patients often present with supranuclear ophthalmoplegia (inability to move the eyes). At first the patient has difficulty in looking up and down; later, as the disease progresses, there is deterioration in horizontal voluntary eye movements. This impairment can affect the patient's daily activities such as reading, cooking, or walking. Patients with PSP also have an increased incidence of repetitive falls. Other symptoms of PSP include hypophonia (low volume in speech) and dysarthria due to weakness and loss of control of throat and mouth muscles, related to a condition called 'pseudobulbar palsy'. The patient may also complain of stuttering, and have trouble swallowing and chewing (dysphagia). The parkinsonian symptoms of PSP include axial rigidity (slow and stiff movement) of neck and trunk with relative sparing of the limbs. The axial rigidity is particularly demonstrated with abduction and lateral rotation of the neck. Additional motor symptoms of PSP consist of hyperextended gait and little or no tremor.

The behavioral symptoms of PSP include profound apathy, loss of motivation, problems with planning and organization, and irritability. However, patients appear less frustrated and disinhibited than people with FTD. Dementia is present in most patients. They tend to become forgetful and slow in their thinking. On physical examination, the patient with PSP shows square wave jerks (small, inappropriate saccades that intrude on steady fixation) and decreased saccade velocity. In contrast, people with corticobasal ganglionic degeneration show preserved saccade velocity but an increase in saccade latency on the ipsilateral side of the apraxia. This distinguishing feature can be assessed by an electrooculogram (EOG), which tests eye movement velocity and latency.

The cause of PSP is unknown, but rare familial clusters have been described in which the pattern of inheritance appears to be autosomal dominant. Postmortem examinations show bilateral loss of neurons and gloss in periaqueductal gray matter, superior colliculus, subthalamus, red nucleus, pallidum, dentate nucleus, and oculomotor nuclei. The cerebral cortex is relatively spared. Positron emission tomographic scans show dorsal frontal hypoperfusion, while magnetic resonance images show midbrain atrophy.

There is no cure for PSP; however, levodopa can be effective in reducing the motor symptoms. In addition, speech therapy and encouraging the patient to eat soft food and drink thick liquids may be helpful in coping with the swallowing difficulties. Death usually occurs around 5–7 years after diagnosis.

Corticobasal Degeneration

Corticobasal degeneration is a rare, sporadic, progressive neurological disease characterized by a combination of parkinsonian and cortical symptoms. It often begins in the sixth decade. The symptoms begin initially on one side of the body then spread to affect both sides. This asymmetric pattern is a distinguishing feature of this disease. These asymmetrical motor deficits include focal dystonia (abnormal posture) and 'alien hand' – a combination of abnormal hand postures, involuntary movements, and changes in muscle tone. The early motor involvement in corticobasal degeneration includes bradykinesia and rigidity, poor coordination, and dysequilibrium (impaired balance). Additional motor symptoms are myoclonus and apraxia (loss of ability to make familiar purposeful movements). Additionally, patients show left or right parietal lobe deficits.

Corticobasal degeneration usually starts in the parietal lobe and spreads to the basal ganglia. The pathological changes include neuronal loss, gliosis, neuronal inclusions, and achromasia (ballooned neurons) in the superior frontal gyrus and parietal cortex. The absence of amyloid plaques and of neurofibrillary tangles differentiate this disorder from Alzheimer disease. Astrocytic plaques and

tau proteins are also present. The substantia nigra shows neuronal loss with gliosis.

There is no treatment to slow the course of corticobasal degeneration, and the symptoms of the disease are generally resistant to therapy. Antiparkinsonian drugs do not produce any significant or sustained improvement in the motor symptoms. Clonazepam may help the myoclonus. Occupational, physical, and speech therapy may help in managing disability. The course of corticobasal degeneration results in death, usually 6–8 years after diagnosis.

HUMAN PRION DISEASES

Human prion diseases are transmissible spongiform encephalopathies involving proteinaceous infectious particles that lack nucleic acids (DNA or RNA). The disease is due to biochemical modification of the prion protein (PrP) that is normally present in human cells. The normal PrP is converted to an abnormal isoform, which results in aberrant folding of the protein structure. The normal prion protein contains more of the tertiary α-helix conformation, while the abnormal prion protein contains more of the β-sheet tertiary conformation. There are five types of human spongiform encephalopathies: kuru, Creutzfeldt–Jakob disease (CJD), fatal familial insomnia, Gerstmann–Sträussler–Scheinker disease, and variant CJD.

Kuru

Kuru is a transmissible prion disease that occurs only in certain inhabitants of Papua New Guinea, and is believed to be due to cannibalism. The brains of patients with this disease show unicentric plaques.

Creutzfeldt–Jakob Disease

Creutzfeldt–Jakob disease is a rapidly progressive, fatal prion disease that can be familial or sporadic in its development. Eighty percent of the sporadic cases occur in the age range 50–70 years, and 10–15% of the familial cases are autosomal dominant. The mean survival is 5 months, with death occurring within 1 year in 90% of the sporadic cases. There are three separate groups of symptoms that appear early in the disease. One group consists of generalized systemic symptoms such as fatigue, poor sleep, and loss of appetite. The second is nonfocal neurological symptoms which include memory loss and confusion. The final group is focal neurological symptoms consisting of ataxia and aphasia. All patients later present with myoclonus, behavioral changes, and dementia. The diagnosis of CJD requires an EEG showing periodic complexes in the wave pattern, a distinct protein band in cerebrospinal fluid, and the presence of dementia and myoclonus in the patient. Neuropathological examination shows spongiform degeneration, neuronal loss, astrocytosis, and amyloid plaques in 5–10% of sporadic CJD cases.

Fatal Familial Insomnia

Fatal familial insomnia is a rare fatal prion disease usually due to a mutation in the prion protein gene. The onset is usually in people aged 35–61 years. Death occurs 7–36 months after the initial symptoms, which consist of untreatable insomnia, progressive dysautonomia (hypertension, irregular breathing, tachycardia) and motor signs such as ataxia and myoclonus. The family history, the symptoms, and the EEG recording (showing a slow background activity without the periodic complexes that occur with CJD) make up the diagnosis.

Gerstmann–Sträussler–Scheinker Disease

Gerstmann–Sträussler–Scheinker disease is a fatal autosomal dominant spongiform encephalopathy in which patients present with ataxia associated with other cerebellar signs. The incidence is approximately 5 per 100 million, making this disorder very rare. Pathological examination of the brain shows multicentric amyloid plaques that form in the cerebellum and cerebrum.

Variant CJD

Variant CJD (vCJD) is another fatal progressive prion disease which has characteristic differences from sporadic CJD. This prion disease is due to ingestion of meat that contains the bovine spongiform encephalopathy agent. The mean onset of the disease is at age 29 years, which is earlier than that of sporadic CJD. The duration of symptoms is longer in vCJD and patients survive approximately 14 months. In addition, people with vCJD present with psychological symptoms first, while people with sporadic CJD often develop the dementia first. Cerebellar signs are almost always present in vCJD, whereas only 40% of people with sporadic CJD show cerebellar signs such as ataxia. People with vCJD do not show periodic complexes in the EEG.

Nootropic Drugs

Introductory article

Warren H Meck, Duke University, Durham, North Carolina, USA
Christina L Williams, Duke University, Durham, North Carolina, USA

CONTENTS

Nutrients and other chemicals that amplify cognition are sometimes called 'nootropics'. These 'smart drugs' are thought to work by one of two basic processes, either by influencing glucose metabolism and blood flow in the brain, or by elevating the levels of one of the many neurotransmitters or neuromodulators that are known to play a role in attention, memory and decision processes.

CRITERIA THAT MUST BE MET BEFORE A DRUG CAN BE ESTABLISHED AS NOOTROPIC

The term 'nootropic' was coined by the pharmacologist Cornelius Giurgea in the 1970s (its origin is Greek, meaning 'acting on the mind'). In terms of chemistry, nootropic drugs are a highly heterogeneous group. Giurgea argued that to qualify as a nootropic, a drug had to exhibit the following characteristics. There must be reliable evidence of enhanced cognition, especially under conditions of disturbed neural metabolism resulting from hypoxia, electroconvulsive shock or age-related changes. Nootropic substances must also increase the efficacy of tonic cortical/subcortical control mechanisms and facilitate information flow between the cerebral hemispheres. The prophylactic effects of the drug were also taken into consideration (i.e. the importance of enhancing the general resistance of the brain to physical and chemical injuries was emphasized). Finally, the drug had to be devoid of any other psychological or physiological effects, including addictiveness or neurotoxicity. In order to streamline these criteria, most neuroscientists now define nootropics as a class of drugs that act as cognitive enhancers and which have no undue side-effects or toxicity.

One group of nootropics works by improving cerebral blood flow, and may be used to improve the deficits in attention, language or memory that are commonly seen following the neurological damage associated with stroke. The damage is often caused by constriction of the arteries that supply blood, and therefore oxygen and glucose, to the brain. Consequently, drugs that increase cerebral blood flow and reduce hypertension might be expected to 'improve the performance' of otherwise energy-starved neurons. This is why propranolol, phenytoin and hydergine are used as smart drugs. Because drugs such as hydergine also act as free-radical scavengers, they may be effective in preventing strokes and combating age-related neuronal insults.

The calcium-channel blockers, such as verapamil, diltiazem, nifedipine, nitrendipine and nimodipine, are another group of potential smart drugs. They are widely used to treat hypertension, and thus might affect cognition by increasing cerebral blood flow, but they also block the entry of calcium ions into neurons. A key stage in the molecular cascade of memory formation appears to be the opening of membrane channels through which calcium ions flow. In aged rodents, the mechanisms that open and close these calcium channels seem to become defective, and consequently calcium accumulates to dangerously high levels inside the cells. The calcium-channel blockers might improve memory by countering this effect. Ginseng, that all-purpose elixir of life, contains an agent that blocks calcium channels.

There is some evidence that calcium-channel blockers, glutamate agonists, serotonin antagonists and certain piracetam derivatives can help laboratory animals to learn highly specific tasks if the drug is injected around the time of training. Yet in many cases it is not always clear how the drugs act. Some may work by interfering with the molecular events that lead to memory formation, while others may affect the animal's general level of arousal. Clearly, even the simplest psychological tests involve many

more aspects of performance than merely learning and memory. Drugs that alter sensations of hunger or thirst, or which reduce sensitivity to pain or simply make a participant more active, could all improve performance. For these reasons it is important to separate the effects of a drug on different memory processes (e.g. encoding, consolidation and retrieval) as well as its effects on different types of memory (e.g. episodic and semantic).

A third group of nootropics has been developed as a result of discoveries about the neurochemical deficits associated with Alzheimer disease. One of the characteristic features of that disease is progressive loss of memory function. Post-mortem studies of the brains of Alzheimer patients show dramatic destruction of neurons, particularly the basal forebrain neurons which secrete or utilize the neurotransmitter acetylcholine. Research conducted during the 1970s in humans and other animals also provided evidence that acetylcholine might be a key neurotransmitter in memory formation. For example, acetylcholine-receptor-blocking drugs (e.g. atropine and scopolamine) that act by reducing the effective level of brain acetylcholine also impair memory in young healthy subjects. In the early 1980s, these types of observations gave rise to the 'cholinergic hypothesis' of memory loss. If memory loss was due to low levels of acetylcholine or to loss of functioning within the cholinergic system, then researchers reasoned that what was needed were smart drugs to increase the brain's supply of acetylcholine and to amplify its actions. As a result of this reasoning, several smart drugs were developed, including piracetam, together with food additives that are potential metabolic precursors of acetylcholine, such as choline and acetylcarnosine.

Clinical trials have provided convincing evidence that some drugs (e.g. the acetylcholine-enhancing drug tacrine) may be of help in the early stages of Alzheimer disease. In addition, the results of several naturalistic studies suggest that perimenopausal estrogen replacement may reduce the risk of developing Alzheimer disease by up to 50%, although other studies did not find this benefit. Preliminary results from one large epidemiological study suggest that estrogen replacement may delay the memory deficits that are associated with normal aging.

However, additional controlled clinical trials are needed to determine how and under what circumstances estrogen replacement has nootropic effects. Estrogen influences language skills, mood, attention and a number of other functions in addition to memory. Estrogen receptors are present in several regions of the brain, including those involved in memory (such as the hippocampus), and increases in synapse formation (i.e. increased brain plasticity) with estrogen treatment have been observed. In addition, estrogen may in effect raise the levels of certain neurotransmitters within the brain. These include acetylcholine (implicated in memory), serotonin (implicated in mood), noradrenaline (implicated in mood and other autonomic functions) and dopamine (implicated in attention, interval timing, motor coordination and reward). However, it is important to note that the evidence for these beneficial effects of estrogen on cognition is still preliminary.

EXAMPLES OF SUBSTANCES THAT HAVE BEEN CLAIMED TO IMPROVE MEMORY IN NORMAL SUBJECTS

Although some drugs do improve memory in different tasks in normal human subjects, many neuroscientists are careful to point out that the brain is a very complex system, and that cognition results from the coordination of many processes. It seems unlikely that a single chemical could improve memory. However, some experimental results suggest that there are certain drugs which improve memory. The nootropics that have been studied can be divided into several different categories as follows.

- Cholinergic agonists (e.g. strychnine and picrotoxin as well as nicotine and related substances) act by influencing or emulating the release of acetylcholine in the hippocampus. It is known that this neurotransmitter plays an important role in synaptic plasticity.
- Stimulants (e.g. caffeine and amphetamine) probably act by increasing the effective level of dopamine and/or norepinephrine, which leads to increases in alertness and attention, which can in turn improve memory consolidation.
- The piracetam family of compounds (e.g. piracetam, aniracetam, oxiracetam and others) serve as representative AMPAkine agents for which the hippocampal AMPA-glutamate receptor is often the target for effects on memory. The AMPAkine agents cover a broad class of drugs and vary widely in terms of brain penetration and efficacy. A number of the compounds in this class increase synthesis of neuronal membrane lipids such as phosphatidylinositol, phosphatidylcholine and phosphatidylethanolamine. AMPAkines appear to act by influencing synaptic strengthening or formation.
- Substances such as *Ginkgo biloba* extract and acetyl-L-carnitine may support increased attention or neural health in adults. These chemicals are thought to improve blood flow in cerebral structures and to facilitate memory.

- Hormones such as estrogen, vasopressin, epinephrine, norepinephrine and ACTH probably act by modulating the cholinergic input to the hippocampus from the basal forebrain although, as mentioned above, estrogen may directly modulate synaptic plasticity. Each of these substances may have a separate role in the brain and in the periphery, depending on their site of origin and their ability to cross the blood–brain barrier.
- The last category includes essential nutrients such as choline, folic acid, vitamin B_{12} and vitamin E. Choline in particular, which is a major component of cellular membranes and the precursor of the neurotransmitter acetylcholine, appears to affect the early development of brain structures involved in attention and memory through metabolic imprinting. This process results in organizational changes in the way in which acetylcholine is synthesized, released and recycled – leading to lifelong enhancement of cognitive processes and resistance to age-related memory decline.

EVALUATION OF EVIDENCE FOR THE ABOVE-MENTIONED EXAMPLES

For the most part, nootropics act at the level of cellular or intracellular mechanisms such as gene expression, transmitter release and associated changes in neural plasticity. It is at this level that adjustments can affect higher-level processes such as memory encoding. To date, most studies have been conducted with laboratory animals rather than with humans, and most of the human studies have focused on treating dementia or aging because of the lack of effect in healthy individuals. However, positive results have been obtained for healthy adults, and given that the memory systems of a wide range of animals appear to be quite similar, there is good reason to believe that memory-enhancing substances could work in healthy humans. There is also reason to believe that some aspects of brain aging could be slowed or potentially ameliorated.

There are fewer substances that are known to improve other aspects of cognition. Although we are well aware that drugs such as nicotine and the stimulants (e.g. caffeine, amphetamine and acetyl-L-carnitine) improve reaction time and attention, it is less clear whether higher-level processes such as intelligence or creativity are influenced by drugs. This may be because intelligence and creativity are difficult to measure. There might be whole classes of chemicals we have not yet found that influence higher-level cognition, although it is best to remain cautious about this.

The effects of nootropics can be highly individual, possibly linked to the amount of glucose, oxygen and steroids in the bloodstream and also to brain neurochemistry. For example, caffeine appears to improve recognition and recall differently depending on the level of internal arousal and the time of day. Nootropics need to be tuned to the brain chemistry of their users in order to be effective.

Finally, it is well known among researchers that the timing of drug administration can be an important factor. In many cases the drug has no effect if it is given before or during the learning experience, and is only effective if given after a certain time. Other drugs only work if they are administered before the learning experience. In fact, some drugs can even be given before birth. It has been found that if the diet of pregnant animals is supplemented with choline, their offspring will exhibit enhanced memory capacity and precision throughout their entire life. This appears to be due to permanent alterations in the septal–hippocampal pathway. Whether or not it would be a good idea to try this treatment in humans is an open question (it might be interesting to compare the children of mothers who eat choline-rich and choline-poor diets).

There are also the problems of dose response and pharmacokinetics. High doses of the drugs do not necessarily improve performance, and in fact they usually decrease it. The memory improvement typically follows an 'inverted U-curve', where there is an optimal dose that is dependent on the ways in which other environmental and genetic factors are affecting the participant's neurochemistry, as well as drug absorption and metabolism. Primarily for this reason the phrase 'the dose makes the drug' was coined – that is, the same drug can have very different behavioral effects depending on the dose and how it interacts with the contextual factors that determine pharmacokinetics.

It is important to note that in addition to the benefits provided by nootropics, it is likely that some of these improvements in cognition come at a price. For example, caffeine has been shown to improve sustained attention and vigilance, but it impairs the ability to deal with contradictory or uncertain stimuli. If we learn too well, we might remember details at the expense of general knowledge or abstraction ability. Enhanced memory capacity would be expected to lead to increased interference unless information was also stored with greater precision. All of these problems suggest that while nootropics can enhance memory, using them optimally is much less straightforward than merely swallowing a smart pill with one's coffee or orange juice in the morning.

PROSPECTS FOR THE FUTURE DEVELOPMENT OF NOOTROPICS

It is known that nootropic drugs and cognitive training are complementary and probably act on different systems. In general, it seems that improving the hardware (e.g. neural networks) can give rise to a quantitative improvement, while improving the software (e.g. hierarchical structures) can bring about a qualitative improvement. A well-integrated combination of nootropic drugs and cognitive strategies could become very powerful. It is likely that the future of cognitive amplification will be found in the gradual combination of different behavioral and pharmacological tools into unified systems, where cognitive science and neurobiology provide mutual support for each other.

CONTENTS

Object recognition is a process through which sensory inputs reactivate distributed neural networks subserving memory of objects in the temporal and other association cortices.

INTRODUCTION

Imagine yourself looking at an apple on a dish (Figure 1). Without conscious effort, you will perceive a red round object on a white background and recognize it as an 'apple', a kind of fruit with sweet and sour taste. It may remind you of the story of Adam and Eve, or of the discovery of the law of gravity by Isaac Newton. You might even think of a particular type of personal computer by means of association with the word 'apple'. Thus, visual information is automatically processed to lead to the percept of an object, which should be recognized with reference to the memory in our mind. Furthermore, knowledge or personal experience related to the object can be retrieved by association.

What, exactly, is happening in your brain while you are looking at an apple? The red light entering your eye is focused on the retina, where optical sensation is converted into neural signals. Retinal output is relayed to the lateral geniculate nucleus of the thalamus and transmitted to the primary visual cortex (V1) which is located at the posterior pole of the brain (Figure 2). In V1, individual neurons are activated only when a restricted part of the visual field (receptive field) is stimulated. Within their receptive fields, V1 neurons detect elementary visual features such as orientation of the outline of the apple, or the wavelengths of light reflected from the apple. Various visual features detected in V1 undergo hierarchical and parallel-distributed processing along two major cortical visual pathways. A dorsal visual pathway from the occipital to the parietal lobes is specialized for spatial and motion perception and for the visual control of actions, e.g. rotating and cutting the apple. A ventral visual pathway from the occipital to the inferior temporal (IT) cortex is specialized for identification of objects. Different features such as shape, color or texture of an apple are analyzed in discrete neural modules, and are reintegrated to give a unified percept of a whole apple. This integration occurs in the IT cortex, the final stage of the ventral visual pathway. The IT cortex plays a central role in visual identification as well as recognition of objects. Electrical recording of neuronal activity provides compelling evidence that visual long-term memory is coded as coordinated activities of neuronal populations in the IT cortex in primates.

However, many questions remain. How are different classes or depths of categories organized? Are neural activities better correlated with the physical properties of an object, or with subjective percept of the object? How is representation of a newly learned stimulus generated in the adult IT cortex? What is the mechanism underlying reactivation of neural representations in the IT cortex by

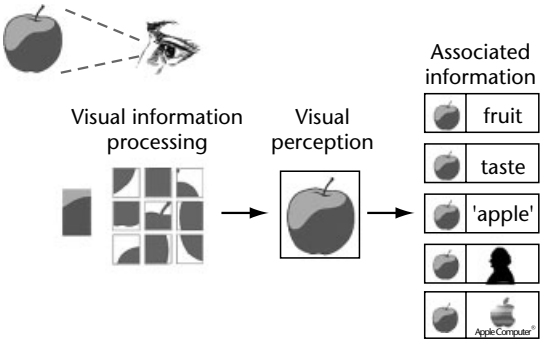

Figure 1. Object recognition.

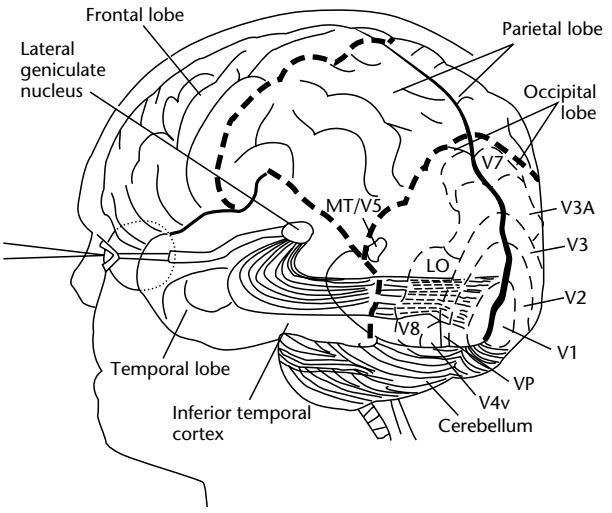

Figure 2. Human visual pathway. Starting with the eyes, the pathway extends to V1 through the lateral geniculate nucleus. The visual cortex is divided into visual areas V1, V2, etc. The inferior temporal cortex has a central role in object recognition. association? The following sections include recent evidence that partly answers these questions. It should be emphasized here that recognition is a process through which retinal input ultimately reactivates distributed neural networks subserving memory of objects in the temporal and other association cortices.

FAILURE OF RECOGNITION FOLLOWING BRAIN DAMAGE

Behavioral studies of humans with brain damage provide important insights into the organization of neural modules that participate in visual object recognition. Klüver–Bucy syndrome is a mosaic of behavioral abnormalities following extensive brain lesions to bilateral temporal lobes including medial temporal lobe structures. In addition to emotional, sexual, and personality changes, people with this syndrome exhibit a characteristic failure to recognize objects in front of them. Although they have normal visual acuity without any visual field defect, they behave as if they are 'blind' to the objects. Instead, they tend to put everything into their mouth in order to identify it by oral contact. Thus, visual recognition of objects can be selectively impaired without loss of elementary visuosensory functions, and without inability to identify the same object by other sensory modalities. This symptom is called visual agnosia. Agnosic patients can 'see' a visual image and sometimes even draw a copy of it, but cannot tell what it is or how to use it. A typical cause of visual object agnosia is ischemic infarcts in the IT cortex or adjacent occipital visual association cortex (Figure 2). This contrasts with the finding that more posterior-occipital lesions often affect visual sensation itself (cortical blindness). These clinical findings suggest that object recognition and basic visuosensory functions may be dissociable processes implemented in different anatomical structures.

Agnosia sometimes disproportionately involves certain object categories more than other categories. Various types of category-specific agnosia have been reported. Some patients who can recognize 'living things' are relatively impaired in the recognition of 'nonliving things' which are most typically exemplified by small, easily handled, manufactured objects. Other patients have the reverse problem: a patient who can quickly recognize a saw or a screwdriver will become distressed by attempts to recognize animals and foods, and may hesitatingly answer, 'Perhaps they are some kind of animal or plant.' Visual agnosia specific to letter strings is also reported. This syndrome is called alexia. Patients with alexia cannot read normally, despite normal visual capabilities, and despite their ability to understand spoken language and to write. Typically, they read words letter by letter, spelling each word before identifying it. Interestingly, some patients with alexia can easily read single and multiple digits without error. These findings indicate that distinct neural machinery exists for different categories.

A special type of agnosia is prosopagnosia, which renders people incapable of recognizing personal identity on the basis of face but spares their ability to identify someone from their voice or the visual characteristics of their gait. People with prosopagnosia have the ability to recognize common objects. Furthermore, they can assign faces to the 'face' category and correctly recognize various facial expressions on the faces they fail to identify individually.

Identification inability within a category such as seen in prosopagnosia does not seem to be restricted to faces. When people with prosopagnosia try to recognize nonface objects that are unique to themselves, for example their own pets, houses or cars, their failure is generally as marked as it is for faces. Moreover, there are case reports of a bird-watcher who had lost the ability to differentiate visually between birds, and of a farm worker who could no longer recognize his cows. These reports suggest that focal brain damage interferes with the

patient's ability to perform within-category identifications without affecting the recognition of the generic class to which the stimulus belongs. This suggests that a distinct system exists for the purpose of identification.

The variety of deficits in the visual processing of objects reviewed here suggests the existence of multiple systems for recognition. However, naturally occurring lesions tend to be several cubic centimeters in size and located according to the vagaries of vascularization rather than functional distinctions. Moreover, purely focal cognitive impairment is rare in clinical cases; patients often have other neurological deficits. For these reasons, the precise localization of the area responsible for specific perceptual processing is difficult to determine solely from currently available lesion data.

BRAIN MODULES FOR OBJECT RECOGNITION IN HUMANS

Imaging Studies in Humans

Functional activation studies in normal volunteers supplement the lesion data in identifying the neural correlates for the object recognition system at a finer spatial resolution. Functional magnetic resonance imaging (fMRI) and other neuroimaging methods enable comparison of regional brain activity while the person tested views various types of objects. Comparison of the activity evoked by faces with that evoked by nonface objects has identified a region in the fusiform gyri (part of the IT cortex) that responds preferentially to faces rather than objects, especially in the right hemisphere (Figure 3). This area is called the fusiform face area (FFA). Furthermore, regional brain activity in FFA does not increase when the person studied views photographs of 'scrambled' faces, houses and hands, suggesting that this is a face-specific brain area. In the field of orthography, one study comparing passive viewing of letters with passive viewing of digits found segregated regions responding to letters that were localized in the left fusiform gyrus. The parts of the visual association cortex implicated in these studies are consistent with the locations of lesions observed in prosopagnosia and alexia.

Some researchers claim the existence of a brain area that specifically processes geographic entities and locations, which is not suggested by the commonly observed dissociation in agnosic patients. A region in the parahippocampal cortex responds specifically to buildings or places in a local environment (Figure 3). This area is called the parahippocampal place area (PPA). There are thus anatomically separate modules selectively processing different categories, such as faces, letter strings, and geographic locations.

An enduring question concerning face perception is whether faces are the only objects processed by the FFA. The fact that some people with prosopagnosia cannot perform within-category identification in nonface categories indicates that the FFA is not restricted to processing faces. Gauthier and colleagues propose that this putative 'face area' might be the result of our extensive experience with faces. They found that expertise with homogeneous sets of stimuli newly created for the experiment (Figure 4) recruits face-selective areas in

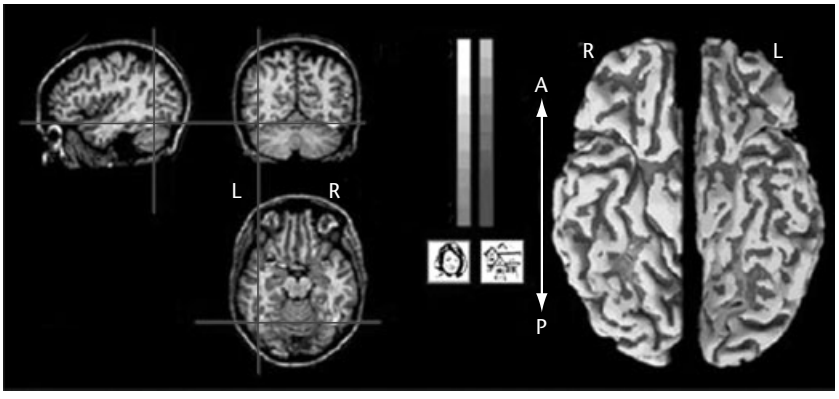

Figure 3. Example of face- and building-related regions in one observer. Preferential activation to faces versus buildings (orange) and to buildings versus faces (blue), shown on sagittal, coronal and axial slices (left), and on a three-dimensional reconstructed brain (right). Figure 4. 'Greebles': a homogeneous set of nonface unfamiliar stimuli specially created for research into the 'face area' of the brain. Modified from Gauthier I, Tarr MJ, Anderson AW, Skudlarski P and Gore JC (1999) Activation of the middle fusiform 'face area' increases with expertise in recognizing novel objects. *Nature Neuroscience* **3**(8): 764–769.

the fusiform area (FFA) and occipital lobe (OFA). They extended this finding to other homogeneous categories. Study participants who were experts on birds or cars were subjected to fMRI in two task conditions: (1) identification of faces, cars and birds in homogeneous categories, and (2) coarse categorization of familiar objects. Homogeneous categories activated the FFA to a greater extent than did familiar objects. Moreover, in the face-selective areas in the right hemisphere, significantly greater activation was observed in experts than in novices. This suggests that the level of categorization and expertise, rather than geometrical properties of objects, determines the specialization of the FFA.

In summary, neuroimaging methods have clarified that anatomically distinct regions may serve for the recognition of different categories, such as face, letter strings, and places in the local environment. The specificity for face in FFA may be the result of our extensive experience with faces.

OBJECT RECOGNITION IN MONKEY IT CORTEX

Evidence from Lesion Studies

Macaque monkey preparations provide efficient animal models to investigate detailed anatomical and functional architectures responsible for visual recognition of objects. The Klüver–Bucy syndrome was originally described in the monkey. As in humans, monkeys with bilateral temporal lobe resection appear indifferent to objects that are presented visually, even if there is no sign of visual acuity impairment, visual field defects or deficits in modalities other than vision. The monkeys have the compulsion to examine all objects by sniffing and by oral contact. The visual aspects of this syndrome proved to be caused by small lesions limited to the temporal neocortex, but not by resection of the amygdala, hippocampus or other medial temporal lobe structures. These findings indicate that in both humans and macaques, the IT cortex serves as the center for visual recognition of objects.

By forming focal lesions systematically in monkeys, it is possible to further characterize the functional organization of the IT cortex. Lesions in the posterior part of the IT cortex cause severe impairments in visual pattern discrimination. The deficits are more marked when the object to be discriminated is presented in a different size, position or angle. On the other hand, lesions in the anterior part of the IT cortex produce milder visual discrimination deficits, and the performance may be relatively invariant to physical transformations of the visual pattern. Anterior IT lesions are also reported to impair the ability to retain an object's identity for up to several minutes, or the ability to associate objects with other objects. Thus, it is likely that the posterior part of the IT cortex is involved in more sensory aspects of visual perception, while the anterior part is involved in more mnemonic and associative aspects of object recognition.

Neuronal Selectivity for Stimulus Features

To determine how objects are represented in the neural network of the IT cortex, we can examine the stimulus-coding properties of single neurons. The activity of single neurons can be monitored by recording their electrical activity using an extracellular microelectrode.

The majority of IT cells respond to visual stimuli. Many IT neurons are selective for various stimulus attributes, such as color, texture or shape. Of particular interest is the sensitivity of IT neurons to stimulus shape. Although shape selectivity in earlier visual areas such as V4 has also been reported, only in IT is this selectivity notably observed. Neurons in this area respond selectively to various natural or synthetic objects, or to mathematically constructed two-dimensional patterns, such as Fourier descriptors. Groups of cells in IT also respond to the sight of biologically important objects such as faces or hands. A population of

neurons that selectively respond to disparity-defined three-dimensional shapes has also been reported.

The stimulus features necessary for maximal activation of the cell can be determined by reducing the complexity of an effective visual stimulus. Maximal activation of the neurons in IT cortex is usually achieved by moderately complex stimuli, such as star or T shapes. The properties of IT cells change significantly along the anteroposterior axis of the IT cortex. In the most posterior part of the IT cortex, neurons prefer simple stimuli and have their receptive fields constrained to the contralateral side, like those in area V4. In the most anterior part of IT, neurons rarely respond to such simple stimuli and have larger receptive fields extending to the ipsilateral side. In addition, a group of IT neurons preserve their selectivity for particular shapes even if the size, position and orientation of the shapes are changed.

In summary, IT neurons possess suitable properties for coding visual objects in a efficient way, such as a large receptive field, complex shape selectivity, and invariance to size, position or orientation. This tendency becomes more pronounced in neurons towards the anterior part of the IT cortex.

Functional Architecture of IT Cortex

Columnar organization is a well-established property of many different cortical areas. In the early visual system, the clustering of neurons responding selectively to simple stimulus attributes, such as position in the visual field, ocular preference, orientation of line segments or direction of movement, is observed. In the IT cortex, modular organization is less related to retinotopic organization and reflects instead similar preferences for combinations of shapes and other stimulus attributes. A pair of neurons (within 100 μm) that were recorded simultaneously using a single electrode had more similar feature selectivity than neurons recorded using different electrodes (more than 1 mm apart). Fujita and colleagues found neurons with similar stimulus selectivity when electrodes were advanced nearly at a right angle to the cortical surface over a distance of 0.6–1.4 mm, whereas when electrodes were advanced obliquely they did so only over a distance of 0.2–0.5 mm (Figure 5). In the latter type of penetrations, there were two or three separate clusters of neurons that showed similar selectivities. All of these results support the conclusion that the anterior IT cortex consists of modules in which neurons with similar selectivities cluster across cortical layers. Optical recording studies have further confirmed the clustering of cells that respond to a moderately complex feature, and demonstrated that similar but different stimuli activated partially overlapped spots. The averaged diameter of individual spots roughly coincides with the width of columns inferred from the single unit recording experiments.

In summary, neurons with similar selectivities cluster in a columnar pattern in the IT cortex. Various calculations, such as those of similarity for categorization and difference for identification between objects, may be performed in these columnar modules.

Generating the Mnemonic Representation

The stimulus selectivity of IT neurons can be acquired through learning in adulthood. Sakai and Miyashita have demonstrated the effects of associative learning in adults on the stimulus selectivity of IT cells. In a visual stimulus–stimulus association task, monkeys were required to retrieve a visual stimulus specified by another visual stimulus from long-term memory. Recordings made during this task identified a class of neurons exhibiting significantly correlated visual responses to arbitrarily assigned picture pairs (Figure 6). Thus, the stimulus selectivity of IT neurons can be acquired through learning in adulthood. Moreover, the activation of IT neurons can link the representations of temporally associated but geometrically dissimilar stimuli.

The plasticity of stimulus selectivity was recently supported by other studies. In adult monkeys trained to discriminate between complex visual stimuli, the proportion of IT cells maximally responsive to some members of the stimuli used for the training was significantly greater than that observed in the control untrained monkeys. Some researchers found a compact cluster of cells that responded selectively to the visual stimuli used in the task that the monkeys had learned: this suggests that specific visual experience induces development of clusters of anterior IT neurons with similar stimulus preferences. The implication of dynamic reorganization of columns after learning are consistent with Gauthier's proposal that the putative 'face area' in the human brain may be the result of our extensive experience with faces.

Supporting evidence for the associative effect on IT neurons has been accumulating. Guided by a theoretical conjecture that the modification of response properties for temporally associated stimuli might also be a mechanism for learning to associate different three-dimensional views of the same

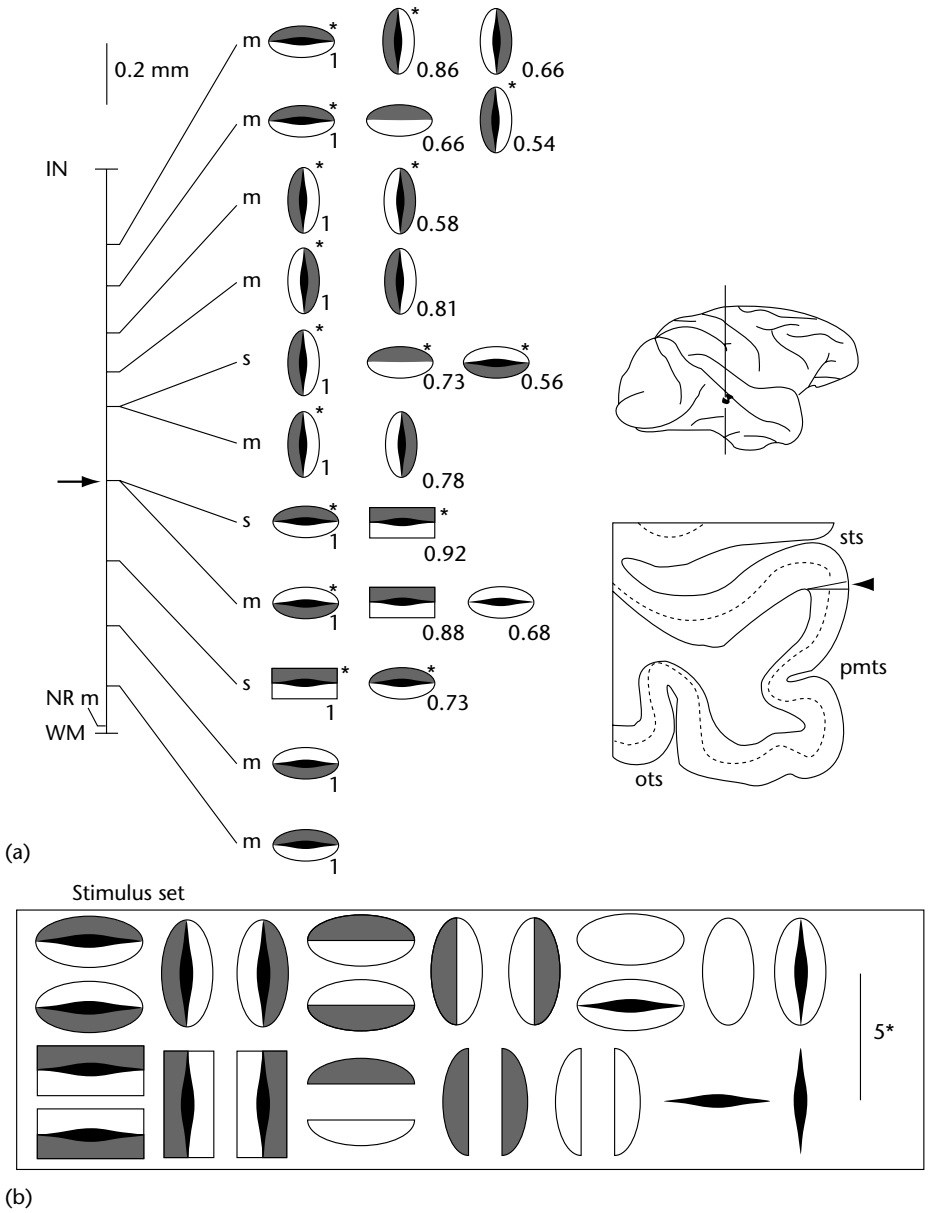

Figure 5. Response strength profiles of inferior temporal (IT) cells or multiple units recorded in a penetration directed vertically to the cortical surface. (a) The penetration is reconstructed on a coronal section through the IT (arrowhead in right panel); pmts, posterior middle temporal sulcus; sts, superior temporal sulcus; ots occipitotemporal sulcus. A schematic drawing of the recording track (left) shows recording depths; IN, site where the first neuron was recorded in this penetration; WM, entry into white matter; NR, no response. The effective stimuli for the cell, seventh from the top (arrow), was determined first; then other cells distributed throughout the gray matter along this penetration were tested; s, single cell recording; m, multiple cell recording. Numbers show response magnitude relative to the maximal response. (b) Set of 24 stimuli used for the experiment, which included effective stimuli for the cell and their modifications. object, some researchers found that IT neurons indeed responded more consistently to different three-dimensional views of the same object than would be expected by chance. Furthermore, when visual stimuli are shown in a fixed temporal order repeatedly, the few images that evoke activity in a given neuron are often neighboring stimuli in the sequence, suggesting this activity could work as a vehicle for generating long-term visual associations.

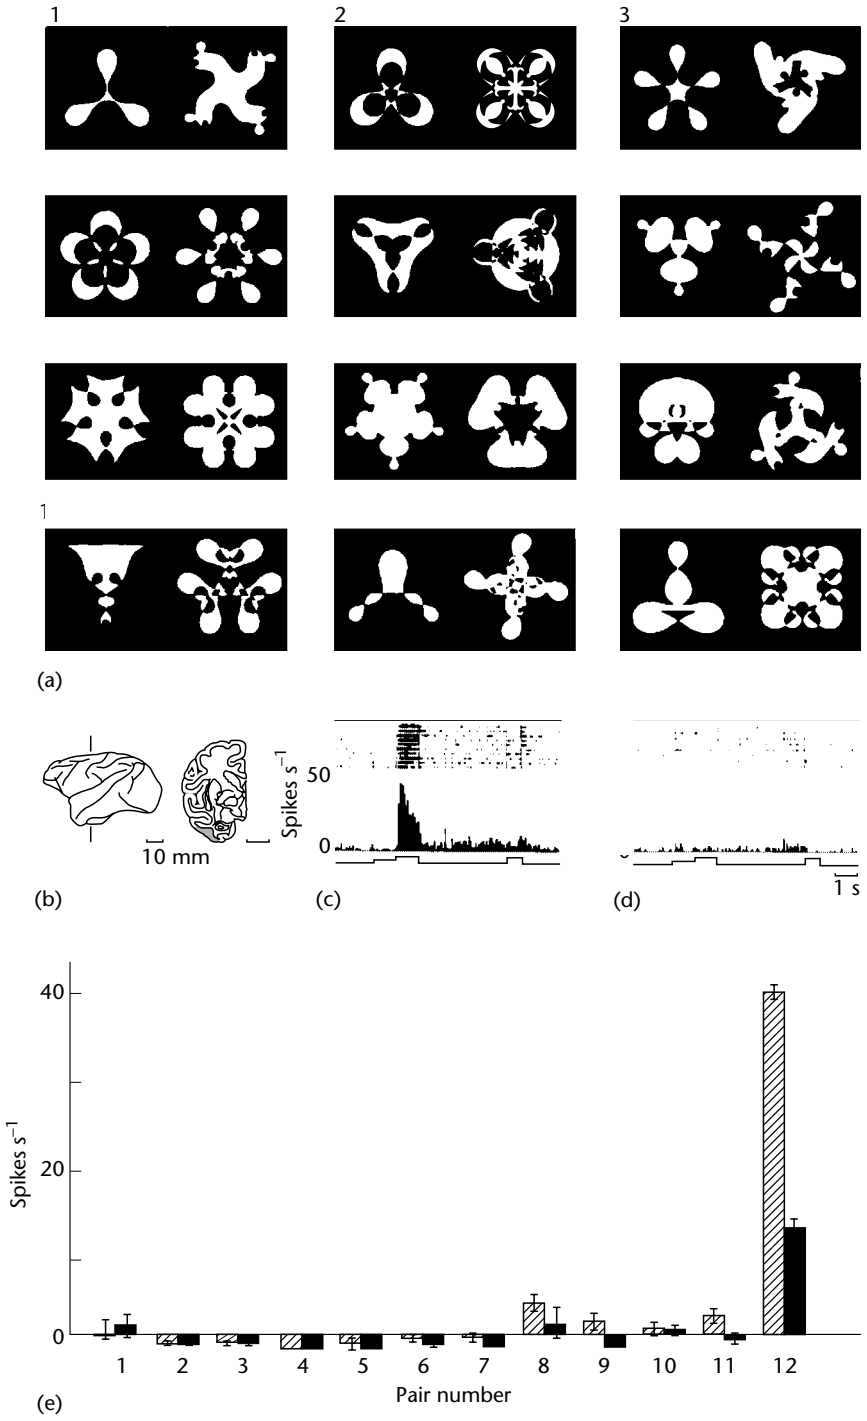

Figure 6. Stimulus sets used for the pair association task and responses of a pair-coding neuron. (a) Twelve pairs of Fourier descriptors used as stimuli in the task. (b) Location of recorded neurons. Left, lateral view of a monkey brain. Right, cross-section indicated by a vertical line on the lateral view. The stippled area represents the range of recording sites. (c) Rastergrams of neural discharges in each trial (upper panel) and spike density histograms (lower panel) obtained from a single neuron. Bin width 80 ms. Trials were collected for cue 12. (d) Trials for cue 7, which elicited no response at all in the same cell as in (c). (e) Mean discharge rates for each cue presentation relative to the spontaneous discharge rate (denoted by arrowhead) in the same cell as in (c) and (d). Modified from Sakai K and Miyashita Y (1991) Neural organization for the long-term memory of paired associates. *Nature* **354**: 152–155.

It has thus been clarified that IT neurons have the ability to establish new linkages between different stimuli that have arbitrary but cognitively meaningful connections through dynamic reorganization of the columnar architecture.

Active Representation and Subjective Perception

A striking feature of neural representation in the monkey IT cortex, compared with other earlier visual areas, is that single-unit activities are more contingent upon subjective perception. When different images are presented to the left and right eyes, the individual does not perceive a combination of the two images, but rather perceives each image alternately. By presenting a stimulus that evoked strong responses from a recorded cell to one eye, and a control stimulus that did not activate the recorded neuron to the other eye, Logothetis and colleagues compared the responses of IT cells with the monkey's reported perception. Only a small fraction of the cells in V1 responded consistently with the monkey's report. This proportion increased moderately in V4, and nearly all the IT cells responded consistently with the monkey's perception. These results indicate that the conscious perception of objects is better correlated with cell activities in IT than in earlier visual cortices.

In human studies using functional brain imaging, cortical regions whose activity is related to rivalrous perceptions have been systematically investigated. The extrastriate areas in the fusiform gyri, but not in the early visual areas, have been found to exhibit significant enhancement of neural activity during perceptual reversals. When images of a house and a face are presented to different eyes during binocular rivalry, changes in stimulus-selective magnetic resonance signals in the FFA and PPA are differentially accompanied by changes in the person's perceptions. Thus, activity in these object-representation areas seems to reflect the perceived stimulus rather than the actual retinal stimulus.

CONCLUSION

Object recognition is a process wherein retinal input ultimately reactivates distributed neural networks subserving memory of objects in IT cortex. Neural representations in the IT cortex are organized in a columnar fashion and dynamically change their organization even after birth. This dynamic reorganization may be the neural mechanism of memory encoding of objects. Furthermore, the activity of neurons in IT cortex is closely associated with subjective perception. This indicates that conscious percept is mediated by activation of neural representations in the IT cortex.

Although the IT cortex serves as the center for visual recognition of objects in both humans and macaques, the detailed correspondence of anatomical structures between human and monkey remains to be established. One promising approach to clarify this correspondence is the use of fMRI of the monkey brain, enabling us to bridge the gap between data from human fMRI studies and those from monkey single-unit analysis. These comparisons should provide a powerful means of discovering how neural codes are linked to conscious experiences.

Occipital Cortex

Introductory article

Peter De Weerd, University of Arizona, Tucson, Arizona, USA

CONTENTS

The occipital cortex is the thin, 6-layered sheet of gray matter that envelopes the white matter of the most posterior lobe of the brain, and that contains several visual areas involved in the analysis of the retinal image.

INTRODUCTION

The occipital cortex is the gray matter (consisting of neuronal cell bodies) of the occipital lobe, which is the most posterior lobe of the brain. Occipital cortex is strongly involved in visual processing. It contains the primary visual area (V1), which receives retinal information via the lateral geniculate nucleus (LGN) in the thalamus. Depending on the species, it may contain additional visual cortical areas, including the secondary visual area (V2). This article will focus on the anatomy and visual functions of V1 and V2.

In the human brain, V1 is mostly buried in the calcarine sulcus, on the medial side of the brain (Figure 1a and b), whereas in many other species, V1 is largely exposed on the surface of the occipital lobe. The primary visual cortex is often referred to as 'area 17'. This terminology can be traced back to the German anatomist Korbinian Brodmann, who at the beginning of the twentieth century performed detailed anatomical studies to subdivide the human cerebral cortex. Brodmann numbered cortical areas in the order that he studied them, and the 17th area that he delineated is what we now call V1. This region is distinguishable from the immediately surrounding cortex by a prominent stripe of white matter (consisting of myelinated axons) in layer IV, which is called the stria of Gennari. This explains the origin of the name 'striate cortex' – yet another name referring to V1. The area surrounding V1 is V2, or Brodmann's area 18, which performs further cortical analysis of the visual input. In humans, the occipital lobe contains visual territory in addition to areas V1 and V2, which is beyond the scope of this article.

FUNCTIONAL ORGANIZATION OF AREAS V1 AND V2

Properties of Single Neurons

Until the 1950s, light spots had been the most conventional tool for exploring the function of visual neurons. The use of light spots during recordings from ganglion cells in the retina and from LGN cells had revealed a center-surround concentric organization of receptive fields (RFs). However, light spots proved to be an ineffective stimulus for most cortical neurons. The function of the visual cortex remained a mystery until the early 1960s, when Hubel and Wiesel discovered that a straight edge or line was a much more effective stimulus for activating V1 cells. They recorded from single V1 neurons in the anesthetized cat, and stimulated the RFs by back-projecting stimuli on a translucent screen placed in front of the cat's eyes. They made their discovery when they observed that the edge which was projected on the screen while inserting a new stimulus slide in the slide projector was more effective in activating V1 cells than the various dots and disks they had used so far – one more example of the fact that great discoveries are often accidental!

This discovery marked the beginning of an explosive growth in our understanding of the functioning of the visual cortex. Hubel and Wiesel discovered that V1 neurons (except for input-layer IV-C, where RFs have a concentric center-surround organization) were 'tuned' to orientation. The neurons responded optimally to an edge or line of a particular orientation placed in their RF (the 'preferred' orientation), whereas their responses diminished when the stimulus was oriented away from the preferred orientation, until an activity rate was reached that was similar to the rate obtained without a stimulus (Figure 2a). Two main classes of neurons were described, namely simple cells and complex cells (Figure 2b). These

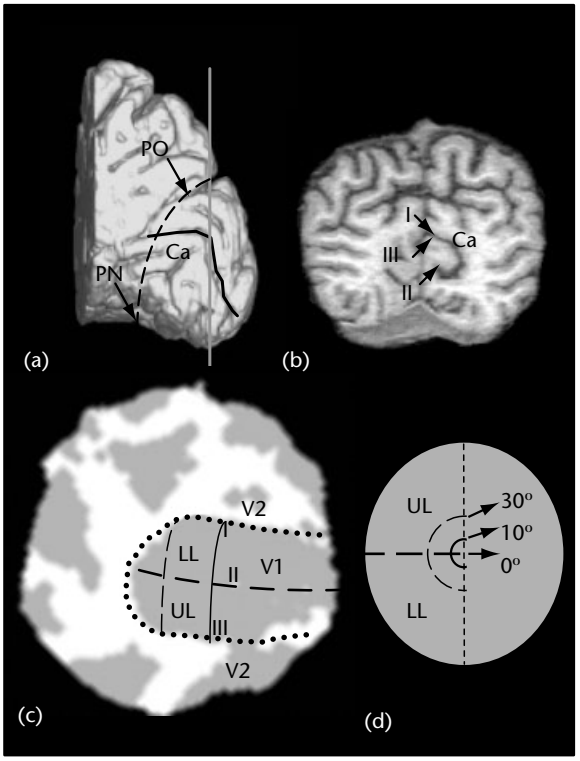

Figure 1. Visual areas in the occipital lobe. (a) Extent of the occipital lobe on a medial view of the right hemisphere. The occipital lobe is located posterior to a line (broken line) connecting the parieto-occipital sulcus (PO) and the pre-occipital notch (PN). The calcarine sulcus (Ca) is indicated by the bold black line. (b) Coronal section through the occipital lobe, at the level of the gray bar in Figure 1a. The right half of the section corresponds to the right hemisphere, and the left half corresponds to the left hemisphere. The view of the calcarine sulcus in Figure 1a corresponds to a view from the left in Figure 1b, after removing the left hemisphere. (c) Flat map of V1 and surrounding cortex (oriented such that posterior aspect is on the right, and dorsal aspect is on top). A flat map is based on an unfolding of cortex, such that cortex inside the sulci becomes exposed. During this process, the upper lip (arrow I in figure 1b) and lower lip (arrow III in Figure 1b) of the calcarine sulcus are pulled apart, such that all of the cortex inside the sulcus becomes exposed, including the fundus of the sulcus (II). In the resulting flat map, cortex that comes from inside a sulcus is shown in gray, and cortex on the surface is shown in white. (d) Representation of the left hemifield and its projection onto flattened cortex in V1 (Figure 1c). The vertical meridian and its representation on the flat map are shown by dotted lines. The horizontal meridian is denoted by a coarse dashed line. The upper left quadrant (UL) of the visual field is projected onto the lower bank of the calcarine sulcus, and the lower left quadrant (LL) is projected onto the upper bank. The upper lip of the calcarine sulcus (I) corresponds to the lower part of the vertical meridian, and the lower lip of the calcarine sulcus (III) corresponds to the upper part of the vertical meridian. The fundus of the calcarine sulcus (II) corresponds to the horizontal meridian. Iso-eccentricity lines in the visual field (fine solid and broken lines in Figure 1d) are projected onto straight lines going across the calcarine sulcus (positions shown in Figure 1c are approximate). A disproportionate amount of cortex is devoted to the central 10° of the visual field (cortical magnification). The vertical meridian forms the border between areas V1 and V2. The projection of the left hemifield onto V2 is mirror-reversed compared with the projection of the left hemifield onto V1 (not shown). The projection of the right hemifield on to visual areas in the left hemisphere is analogous to the projections described here for the left hemifield on to the right hemisphere. The posterior part of the right hemisphere from a human volunteer shown in this figure is a reconstruction based on high-resolution structural MRI scans (3-dimensional Spoiled Gradient Echo Sequence, $512 \times 384 \times 128$ matrix, Echo Time = 5 ms, Reception Time = 24 ms, flip angle 45°) obtained on a 1.5-tesla GE Signa Horizon EchoSpeed system at the Laboratory for Brain and Cognition at the National Institutes of Health. Flattening was done with software from Brian Wandell, enhanced with rendering software by Peter Jezzard.

neurons differ in the specificity of the stimulus that is required to trigger action potentials. To activate simple cells, the edge or line must have a specific contrast polarity in a given RF position. This is due to the fact that simple RFs consist of multiple elongated and juxtaposed subregions with opposite preferences for lightness and darkness (similar to the antagonistic subregions in the RF of LGN neurons). For complex cells, the position and contrast polarity of the stimulus in the RF is irrelevant. Simple cells derive their properties at least in part from excitatory input from LGN RFs aligned along the preferred orientation of the simple cell. Complex cells in turn derive their properties in part from converging input from simple cells with overlapping RFs (Figure 2b). In addition, local inhibitory circuits contribute to the properties of simple and complex cells. Orientation-selective neurons are also present in many extrastriate areas.

Functional Organization of V1 and V2

Columns, retinotopy and cortical magnification

By comparing perpendicular and tangential electrode penetrations in V1, it became clear that neurons with the same orientation preference are grouped together in *orientation columns*, extending

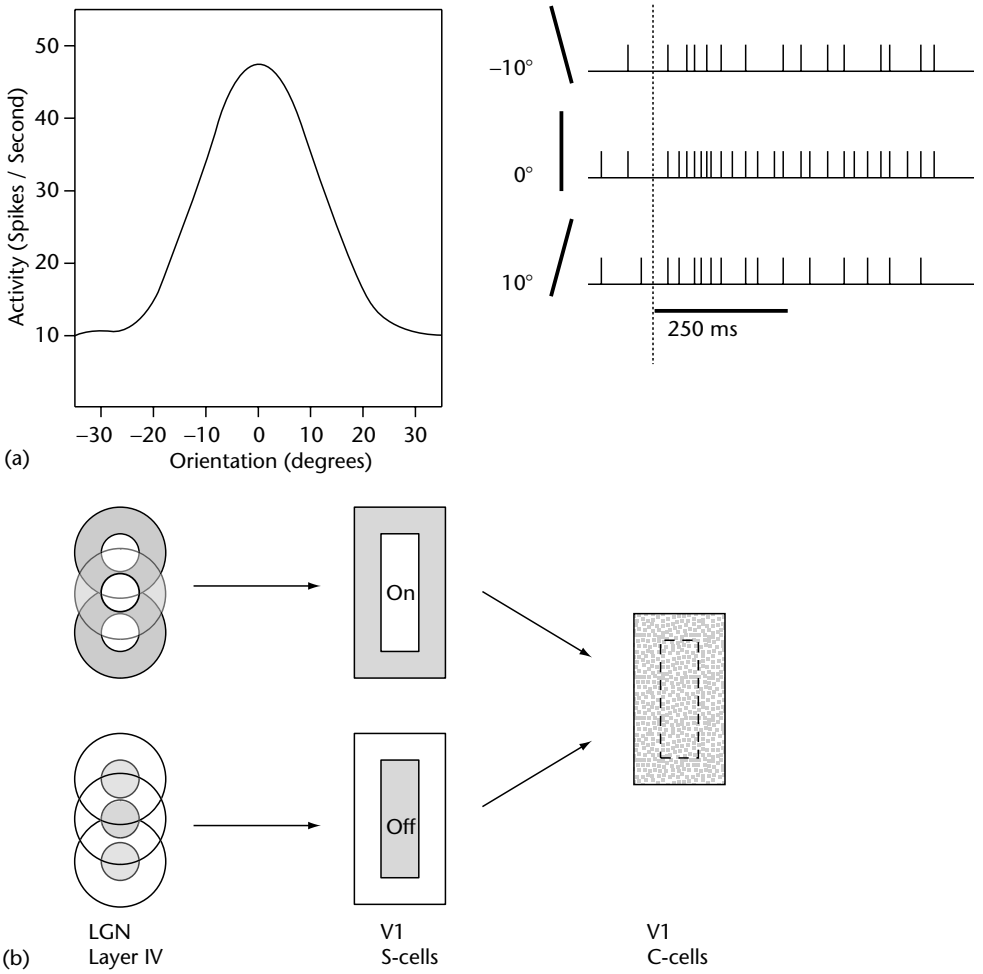

Figure 2. Orientation tuning of visual neurons in the occipital lobe. (a) Idealized graph in which activity of a neuron is plotted against the orientation of a bar stimulus placed in its receptive field. The activity is expressed as spikes (action potentials) per second. On the right-hand side, a single-trial histogram of activity elicited by three different stimuli is shown. Spikes (vertical marks) are shown as a function of time. The vertical stippled line indicates when the stimulus is presented in the receptive field, and the duration of the stimulus (250 ms) is denoted by the solid horizontal bar at the bottom. For each stimulus, the frequency of firing increases after stimulus onset, and then returns to a level similar to that when no stimulus was present (left of the dotted line). While the stimulus is present, a higher firing rate can be observed for the vertical bar (denoted as 0°) compared with bars tilted away from vertical. This indicates that in this example the neuron is 'tuned' to vertical. Orientation tuning curves, such as that shown on the left-hand side, are based on a large number of trials in which the response of the neuron to many different orientations is measured, and expressed in terms of an average number of spikes per second. For the present example, vertical would be referred to as the 'preferred orientation'. (b) Hypothetical scheme proposed by Hubel and Wiesel to explain orientation tuning in V1. White regions in the receptive fields of LGN cells and of V1 simple cells (S-cells) correspond to parts of the receptive field that are activated by bright stimuli on a dark background, and gray regions correspond to regions of the receptive field that are activated by dark stimuli on a bright background. The hatching of the receptive field of the V1 complex cell (C-cell) indicates that the contrast polarity of the stimulus is irrelevant. Orientation tuning properties of S-cells are explained by hierarchical inputs from LGN cells, while the properties of C-cells are explained by hierarchical inputs from S-cells. (For further explanation, see text.)

from the superficial layers (II and III) to the deep layers of cortex (V and VI), interrupted by layer IV. In addition, neurons receive inputs predominantly from one eye or the other, forming ocular dominance columns. Using optical imaging, Blasdel showed that orientation groupings within ocular dominance columns are organized as sectors around a central point (Figure 3). Two ocular dominance columns taken together form a *hyper-column*, which processes all orientation inputs from both

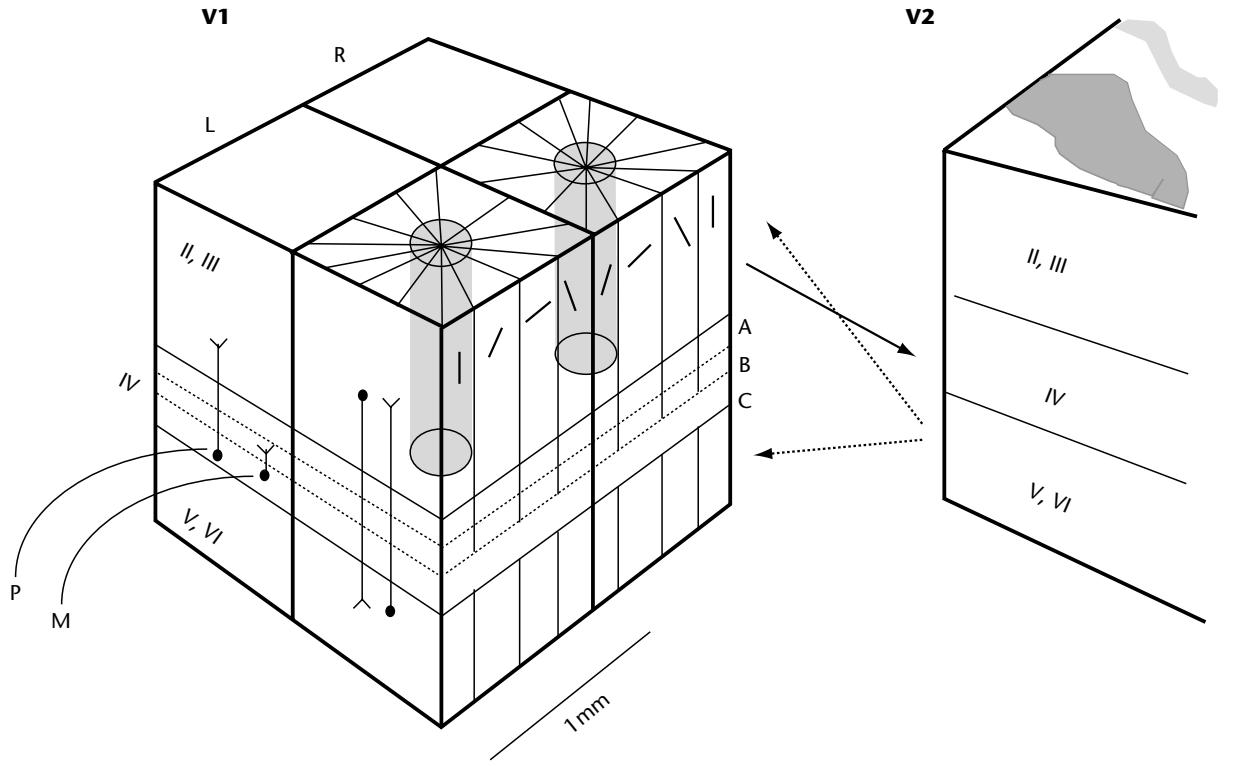

Figure 3. Schematic illustration of elementary processing units in areas V1 and V2, and of their inputs and outputs. The cubes of cortex shown illustrate the anatomical divisions and functional specialization of cortex in V1 and V2. Cortex in V1 and V2 consists of six layers, which are labeled from I to VI. Layers I to III are referred to as superficial layers, and layers V and VI are referred to as deep layers. Layer I is not shown because it contains few or no neurons. In the diagram for V1, further subdivisions of layer IV are shown. Layer IV is subdivided into sub-layers (A–C), and layer IV-C is subdivided into layer IV-Ca (more superficial) and layer IV-Cb (deeper). The latter subdivision is not shown. Layer IV-Cb receives parvocellular (P) input from the LGN, and layer IV-Ca receives magnocellular (M) input. Four symbolic neurons (the dot corresponds to the cell body, and the linear extension corresponds to the axon) show important connections between different cortical layers in area V1. From layer IV, information tends to be sent to superficial layers first, after which interactions between superficial and deep layers occur through vertical connections. Similar communication between layers exists in V2 (not shown). Functional subdivisions shown in V1 include orientation columns (labeled by a bar representing preferred orientation) and ocular dominance columns (labeled by the preferred eye; left 'L' or right 'R'). Other functional subdivisions shown are blobs (gray cylinders) and inter-blobs (the rest of the cortex) in V1, and thick stripes (dark gray), thin stripes (pale gray) and inter-stripes (white) in V2. Arrows show feedforward (solid arrow) and feedback (stippled arrows) connections between areas V1 and V2. (For further explanation, see text.)

eyes. Thus a hyper-column is an elementary processing module with all of the equipment necessary to process elementary information in a small part of the image. V1 uses a juxtaposition of such hyper-columns to process local information from the entire image.

Neighboring hyper-columns in V1 process neighboring points from the retinal image, and this principle is referred to as *retinotopy*. Studies of retinotopy in V1 show that many more neurons are devoted to central vision than to peripheral vision. This reflects the fact that in the fovea of the retina there is a one-to-one relationship between receptors and ganglion cells, and this relationship is preserved in the projections from the fovea to the LGN and V1. The more peripheral vision is, the more convergence there is in the retina from receptors onto ganglion cells, and the sparser are the projections from retina to cortex. The resulting disproportionate representation of central vision in V1 is referred to as *cortical magnification* (Figure 1c and d). The extra processing power allocated to central vision maximizes acuity, and is important for the analysis and recognition of objects.

Area V2 receives projections from V1 that are retinotopically organized, and this area also shows significant, albeit less pronounced cortical magnification. In contrast to V1, area V2 is not organized

into a clear system of hyper-columns, which suggests that it may code image features which are less elementary than the orientation of boundary segments (see below).

Two visual streams in areas V1 and V2

Areas V1 and V2 maintain a relative separation of signals generated by the two main classes of retinal ganglion cells (β and α cells). β cells (with small RFs) are specialized for analyzing object features at high spatial resolution, while α cells (with larger RFs) are specialized for detecting motion. Ultimately, those two different retinal signals form the basis for a subdivision into two cortical systems. One of these systems extends into the temporal lobe and is specialized for object processing, while the other extends into the parietal lobe and is specialized for the processing of motion and the spatial relationships between objects. In non-human primates the occipital lobe is entirely occupied by areas V1 and V2, whereas in humans several additional areas belonging to the two visual processing streams are located within the occipital lobe. In the following paragraphs, the origins of the two visual processing streams in areas V1 and V2 will be discussed (Figure 3).

β cells project to parvocellular (P) cells in the LGN, which in turn project predominantly to layer IV-Cb of area V1, from where inter-neurons send axons to neurons outside layer IV. V1 cortical neurons in layers II and III can be subdivided into two main compartments, namely 'blobs' and 'inter-blobs'. Blobs tend to be more specialized for the coding of wavelength, while the inter-blobs tend to code orientation and disparity (depth) in addition to wavelength. Blobs occupy the center of hyper-columns, whereas inter-blobs occupy the remaining space. Neurons in blobs and inter-blobs strongly project to separate compartments in V2 (thin stripes and inter-stripes, respectively), from where a cascade of anatomical projections starts, directed towards the temporal lobe. This anatomical pathway is specialized for the recognition of objects.

α cells in the retina project to magnocellular (M) cells in the LGN, which in turn project to inter-neurons in layer IV-Ca, which make synapses onto neurons in layer IV-B. Neurons in layer IV-B project to a separate sub-compartment of V2 (thick stripes), and to area MT, from where a cascade of anatomical projections starts, directed towards the parietal lobe. This pathway is specialized for the processing of object- and self-motion, and for spatial aspects of perception.

COMPLEX PERCEPTUAL PROCESSING IN V1 AND V2

The classic view that V1 neurons perform a local analysis of edges and boundaries inside their RF was quickly challenged by unexpected and somewhat paradoxical findings. Indeed, studies conducted during the 1970s showed that responses to stimuli presented inside the RF of V1 cells could be modulated by stimuli *far outside* the classical RF (context sensitivity), while the presentation of those modulatory stimuli by themselves did not result in any effect. Anatomical findings showing lateral (horizontal) connections in V1 running over distances of up to 5 mm provided an anatomical basis for these effects. The context sensitivity of V1 neurons may explain a variety of perceptual phenomena.

For example, surrounding a line segment inside an RF by identical line segments just outside the RF (in the surround) causes a suppression of the response which is smaller than the suppression caused by orthogonal line segments in the surround. This finding provides a neural basis for the perceptual effect of 'pop-out' in texture displays, in which a line segment that is different in orientation from the surrounding elements captures attention, and is detected effortlessly (Figure 4a). Furthermore, the response of V1 neurons to a visual texture covering their RFs is modulated by whether that texture is perceived as a figure or a background, suggesting that V1 neurons contribute to figure–ground segregation. These and many other findings have caused a dramatic shift in views on the function of V1, from an area that contributes to local analysis of edges in the image to an area that contributes to complicated contextual perception, figure–ground segmentation, and even cognitive factors such as attention.

If V1 is doing so much, then what is the function of the other areas? This question is probably put too sharply. Many of the more complex properties of V1 may depend at least in part on feedback from extrastriate cortex, and not just on horizontal connections within V1. Indeed, forward projections from the superficial layers of V1 (mainly layer III) to layer IV of V2 and other extrastriate areas are returned by feedback projections which arrive predominantly in layers II, III and VI (see Figure 3). Thus a fast feedback signal (top-down influence) may influence the information that is sent forward from V1 to extrastriate cortex. Perception may thus depend on several feedforward–feedback loops, and the complex properties of V1 neurons may partly reflect such iterative processing.

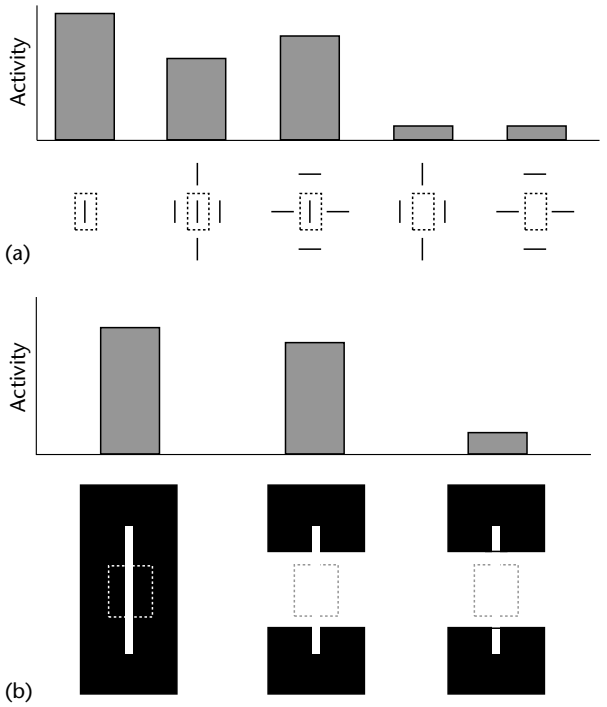

Figure 4. Perceptual effects that have been attributed to functional properties of visual neurons in the occipital lobe. (a) Response of V1 neurons to a single bar in the preferred orientation is suppressed more by lines of the same orientation outside the classical receptive field (dotted outline) than by lines orthogonal to the preferred orientation. This constitutes a possible basis of the perceptual effect of 'pop-out' (see text). Stimuli that are presented outside the receptive field, without any stimulus inside the latter, only have minimal effects on the firing rate of the cell. The drawing summarizes work by Knierim and Van Essen. (b) The activity of many V2 neurons is influenced not only by optimally oriented 'real' bars (left) placed inside the receptive field (dotted outline), but also by 'illusory' bars, whose presence is suggested by the alignment of white cut-outs in the black inducing stimuli. The white bar which seems to be occluding the two black rectangles generates a response in V2, even though no physical stimulation corresponding to the bar is present in the receptive field (middle). When the cut-outs are closed, which is incompatible with the perception of a white bar in the foreground overlying black surfaces in the background, then the response of the V2 neuron to the illusory bar is eliminated. The drawing summarizes work by von der Heydt and Peterhans. (For further explanation, see text.)

Consistent with this idea, neurons in V2 and extrastriate cortex show complex properties that are not present, or that are less pronounced, in V1. The increased complexity of visual processing as one moves from V1 to V2, and to higher-order extrastriate cortex, is referred to as the hierarchical processing of visual information. For example, V2 neurons show responses to illusory contours, which are boundaries perceived in the absence of physical discontinuities in the image. In V1, those responses are far less prevalent. Illusory contours are perceived in two-dimensional displays in which the arrangement of local stimuli suggests a three-dimensional arrangement in which one surface is occluding other surfaces (Figure 4b, middle). The responses of V2 neurons to illusory contours (Figure 4b) therefore suggest that they are involved in completion processes which take place during the processing of objects in the foreground which occlude other objects in the background. Area V2 contributes to a variety of other functions that help to segregate objects from their background. In line with the hierarchical processing of visual information, lesions in V2 cause deficits in grouping and texture segregation, but leave the perception of isolated luminance-defined lines and edges intact. Findings from imaging studies (e.g. functional magnetic resonance imaging) have confirmed that cortical activity related to the perception of illusory and other complex contours is stronger in extrastriate than in striate cortex.

EARLY AND LATE PLASTICITY AND THE EFFECTS OF RETINAL DAMAGE

The modular organization of occipital cortex takes shape during a 'critical period' that extends up to approximately 6 months after birth. During this period, diffuse thalamic inputs to V1 neurons compete with each other such that stronger inputs become strengthened and weaker inputs are suppressed. This competition is molded by the probability of exposure to natural stimuli in the environment. According to this view, orientation selectivity in V1 reflects the abundance of edges in natural visual images. Sensory deprivation experiments during which animals in their critical period are exposed to an impoverished visual environment support this idea. For example, exposure to edges of a single orientation during the critical period leads to an over-representation of neurons tuned to that orientation in V1 and extrastriate cortex.

Many aspects of occipital cortex can also be altered during adult life. Retinal damage, which leads to a scotoma, induces V1 neurons that had RFs within the scotoma to become sensitive to stimuli presented outside the scotoma. Eventually this leads to a permanent remapping of the visual field onto the cortex. Some studies of skill learning suggest that the orientation tuning of V1 neurons, and the extent to which activity of V1 neurons is influenced by stimuli outside the classic RF, can be

altered by experience. These changes in V1, resulting from experience or learning, form the basis of the procedural memory for visual skills. Effects of sensory damage and skill learning on the properties of V1 neurons may reflect changes in the strength of horizontal connections between visual neurons, following the principles of Hebbian learning.

CONCLUSIONS

Areas V1 and V2 in the occipital lobe form the beginning of a cortical network which processes visual input. Although V1 neurons analyze elementary aspects of the visual image, they also contribute to a more complex analysis of surfaces, depth and figure–ground segregation. The more complex properties of V1 depend on lateral connections within V1 and on feedback from extrastriate cortex. The functional organization of V1 and V2 is shaped by the statistics of visual stimulation during a time-limited critical period shortly after birth, but it remains malleable throughout life.

Olfaction and Gustation, Neural Basis of

Introductory article

Peter A Brennan, University of Cambridge, Cambridge, UK

CONTENTS

The senses of taste and smell convey information that is vital for the survival and reproduction of most animals. This information is conveyed by the pattern of activation of receptor cells with different chemical specificities.

INTRODUCTION

Olfaction, by which we mean the sense of smell, and gustation, which is the sense of taste, both provide information about the chemical environment. Taste allows substances entering the mouth to be screened to assess their food qualities and elicit ingestive or rejection behaviors. The olfactory system has the more complex role of detecting and analyzing the vast range of airborne chemicals to provide information about the nature of their source.

ADAPTIVE SIGNIFICANCE OF TASTE AND OLFACTION

As the dietary requirements of different species vary so do their taste systems, but most omnivores such as humans have the ability to sense four classical taste qualities: sweet, salt, bitter, and sour. It has also been acknowledged that some amino acids, especially L-glutamate, give rise to a fifth taste called umami. The purpose of these taste sensations is to provide the body with information about food quality needed to maintain the correct ion balance and energy supply and to avoid potentially harmful foods. (*See* **Hunger, Meals, and Obesity**)

All animals need a supply of energy. Land-dwelling omnivores obtain much of this from carbohydrates, which are digested to yield simple sugars such as sucrose, glucose and fructose. Sensitivity to these sugars in terms of the sweetness of food therefore provides valuable information about its energy content. Maintenance of the body's normal ionic balance depends upon being able to regulate the intake and excretion of sodium ions. Taste plays a vital part in this by identifying the concentration of salt present in food and water. Salt deprivation leads to a craving for salty foods and promotes their ingestion, whereas foods containing high levels of sodium ions are usually rejected, as their consumption would lead to salt overload and dehydration. Sour tastes result from sensitivity to the hydrogen ions found in acids. Although acidity is not necessarily desirable or harmful, it does provide information about the state of food. Unripe fruit has high levels of acidity, as does food that has spoiled owing to bacterial activity. Bitter tastes are frequently caused by toxins that are produced by plants to deter animals from eating them. Animals have evolved the ability to sense these compounds and bitterness is a warning signal that the food may be unsafe to eat. Both sour and bitter tastes elicit rejection behaviors such as spitting and mouth wiping. However, many bitter-tasting substances can in fact be tolerated in the diet in small amounts. Familiarity with these substances can result in an animal acquiring a taste for them, to the extent that they can even become pleasurable.

It should be noted that the terms 'flavor' and 'taste' are often confused. The flavor of a food is a complex sensory perception, most of which is contributed by the smell of the food detected through the olfactory system. More basic information is provided by taste sensation from the taste buds on the tongue, with other receptors providing information about the temperature and texture of the food, and its irritant qualities (such as the burning sensation from chilli peppers). Taste and smell both contribute to the pleasurable qualities of food and the acquisition of food preferences. Animals can also learn to avoid the flavor of foods that cause sickness, especially if they are novel, and

this powerful rejection response may last a lifetime. A further role of the senses of smell and taste is to prepare the body for the digestion of food by stimulating salivation, gut secretions and insulin production from the pancreas.

For many animals, olfaction is the major sensory system through which they are able to sense their environment. Olfaction allows the recognition of food and the fine assessment of its palatability before it encounters the taste receptors. Rats can even learn the smell of a novel food on the breath of other rats, and use it to guide their food preference. Similarly, many young animals develop a preference for the smell of food eaten by their mother, even during their development in the uterus. In addition to food preferences, the olfactory system is involved in prey detection and tracking, as well as predator detection and avoidance. Some animals are able to use odors for navigating their way around their environment. For example, salmon learn the distinctive smell of the stream in which they grew up and use olfactory cues to return there for breeding after spending two years at sea. However, probably the most important use for olfaction is in social communication, especially territorial and sexual behaviors. For instance, male mice use olfactory cues to determine whether a female is sexually receptive and for choosing among potential mates. The sense of smell is much less important for humans than it is for other animals; this is largely because the complexities of human social interactions demand a greater flexibility of behavior than can be governed by chemical cues. Nevertheless, the vast expenditure on perfumes, fragrances and flavorings testifies to the subtle ways in which olfaction can influence human behavior. (*See* **Social Learning in Animals**)

GENETICS OF TASTE AND OLFACTION

Taste and olfaction rely on the interaction of chemicals with receptor proteins or ion channel proteins on the surface of the receptor cells. These sensory proteins are coded by specific genes, and variation in the structure of these genes or their absence can result in differences in the perception of taste and smell among individuals. However, olfaction does not depend solely on genetics, and experience has been shown to have dramatic effects on olfactory sensitivity and discrimination in animals.

Taste Receptor Genes

Chemicals that elicit the sensation of taste are known as 'tastants'. There are a number of different sweet and bitter tastants. However, although they bind to a number of different receptor proteins, they only give rise to the simple sensations of sweetness or bitterness. Several variants of receptors for sweet and bitter tastes have been identified, although they have not yet been associated with the binding of specific tastants. Comparisons of individual sensitivities to a broad array of bitter-tasting substances suggest that at least four types of receptor mediate bitter taste sensation in humans. Individual differences in the genes that are expressed may lead to individual differences in the sensitivity to specific compounds. For example, there are substantial individual differences in sensitivity to the bitter substance *n*-propylthiouracil. The availability of the human genome sequence now makes it possible to identify the genes at specific chromosomal locations, which have been linked with different taste sensitivities, allowing more genes for taste receptors to be identified.

Olfactory Receptor Genes

Airborne chemicals that elicit the sensation of smell are known as odorants. The perception of an odor may occur in response to a single odorant or a complex mixture of odorants. For instance, isobutyric acid on its own has a sweaty odor, whereas a complex mixture of hundreds of individual odorants make up the smell of fresh coffee. The ability of the olfactory system to distinguish between a vast number of odors depends on the binding of odorants to a large array of different receptor proteins. Variability of the amino acid sequence within the odorant binding pocket of a receptor protein causes odorants to be accepted or excluded, based on molecular features such as size, shape and the presence of functional groups. There are about a thousand types of these receptor proteins in rodents such as mice, each binding and responding to a different chemical feature of the odorants. Gene duplication and subsequent mutation have led to the evolution of receptors with different odorant binding specificities, representing the largest superfamily of genes in the genome. However, in contrast to the thousand or so functional receptor types possessed by rodents, humans are only thought to have around 350, which reflects our relatively poor olfactory abilities.

Individual differences in the olfactory receptor repertoire are evident from the existence of specific anosmias, in which individuals may have a greatly reduced sensitivity for certain odorants, such as the sweaty smell of isobutyric acid. There are also individual differences in the perception and naming

of odors. For example, the odorant bangolol is perceived by different individuals as having a pleasant sandalwood odor, an unpleasant urinous odor, or as being odorless.

NEURAL MECHANISMS OF TASTE AND OLFACTION

Taste and olfaction are dependent on the delivery of stimuli to the receptor cells. In the case of taste, saliva and the action of chewing distribute the tastants to taste buds, which contain the taste receptor cells (TRCs). For olfaction, the exploratory behavior of sniffing creates turbulence in the airstream, facilitating the delivery of odorants to the olfactory receptor neurons (ORNs) located in the olfactory epithelium at the top of the nasal cavity. Another important route for odorant access is the retronasal route by which odorants from the mouth and throat reach the olfactory epithelium in exhaled air. This route is particularly important in the perception of the flavor of foods. An additional layer of complexity in odorant delivery is imposed by the layer of mucus that covers the ORNs. Special transport proteins may play an important part in transporting odorants across the mucus layer to the receptors.

Taste Transduction Mechanisms

Taste receptor cells are specialized neuroepithelial cells which are arranged in concentric rings to form a taste bud, similar to the layers of an onion (Figure 1). They are found not only on the tongue but also in the wall of the mouth and throat. Tastants gain access to the receptor proteins on the tip of the TRCs through an opening in the top of the taste bud, called the taste pore. Taste transduction is the process by which the chemical stimulus of a tastant is converted into a change in the electrical potential of the TRC. This activates nerves that contact the TRC and transmit the message to the brain. The sense of taste employs a diversity of transduction mechanisms, reflecting the diversity of taste stimuli. Salt and sour tastants are ions and can affect the electrical potential of the TRC relatively directly. Sodium ions can flow into the TRC through selective ion channels, carrying positive charge into the cell. Hydrogen ions may be able to flow into the TRC through the same channels. In addition, other transduction mechanisms for sour taste appear to exist. One such mechanism may involve an effect of hydrogen ions to block the flow of positively charged potassium ions out of the cell through a selective potassium channel.

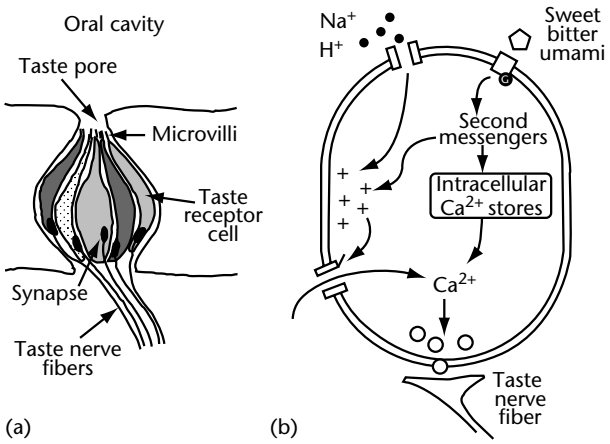

Figure 1. Taste transduction mechanisms. (a) Tastants in the oral cavity gain access to the taste bud via the taste pore. Transduction occurs in microvilli at the apex of the taste receptor cells leading to activation of taste nerve fibers, which contact the basal part of the taste receptor cells. (b) The two main pathways for taste transduction. Ionic stimuli (Na^+, H^+) can enter the receptor cell directly via ion channel proteins to cause a depolarization of the membrane potential. In contrast, complex molecules bind to receptor proteins on the microvilli and activate second messenger systems. These can release calcium ions (Ca^{2+}) from intracellular stores or affect membrane potential by opening or closing ion channels. Flow of positive charge in the taste receptor cell leads to influx of calcium ions via voltage-gated channels and neurotransmitter release, which activates the taste nerve fibers. G, guanine nucleotide binding protein.

Bitter, sweet and amino acid tastants interact with specific receptors in the cell membrane, in a similar manner to odorants in the olfactory system. Binding of a tastant to these receptors activates a cascade of biochemical reactions in the TRC changing the levels of certain chemical messengers, such as cyclic adenosine monophosphate (cAMP) or calcium ions. The identity of these messengers differs among sweet, bitter and umami tastes. However, in each case, changes in the level of the intracellular messenger leads to a change in electrical membrane potential of the TRC and stimulation of the taste nerve fibers. The extent to which combinations of taste transduction pathways are present in individual TRCs is still unclear.

Neural Analysis of Taste Information

Recordings from single nerve fibers show the greatest response to one particular taste sensation but also smaller responses to other tastes. Thus, a fiber that responds best to salt tastants typically

also responds, at a lower level, to sour and sweet tastants. A certain rate of firing in a salt-preferring fiber could therefore be due to a low concentration of salt or to a high concentration of acid. This ambiguity of response means that information about both taste identity and intensity must be represented in the relative rates of activity across a population of taste nerve fibers with different stimulus preferences.

Taste buds are found within papillae, which vary across the tongue in their appearance and the stimulus preferences of their TRCs. The fungiform papillae of the anterior part of the tongue contain taste buds innervated by the chorda tympani branch of the facial nerve. These fibers respond best to pleasant sweet and salt tastants and have little response to bitter tastants. In contrast, taste buds in circumvallate and foliate papillae found on the posterior part of the tongue are innervated by a branch of the glossopharyngeal nerve; they typically respond well to sour and bitter tastants, but have little response to sweet stimuli. Taste buds in the larynx and upper esophagus respond mainly to salt, sour and distilled water stimuli. These taste buds have the role of monitoring the ionic environment of the throat.

The pathway by which taste information travels to the brain is similar in most vertebrates. Taste nerve fibers project primarily to the nucleus of the solitary tract in the brainstem. Many reflexes concerned with the ingestion, digestion or rejection of food are integrated at this level. The response specificity of taste neurons in more central brain regions broadens to include thermal and tactile stimuli. From the nucleus of the solitary tract, there is a projection via the thalamus to the cerebral cortex. It is here that higher-order taste information is linked to olfactory information for the perception of flavors.

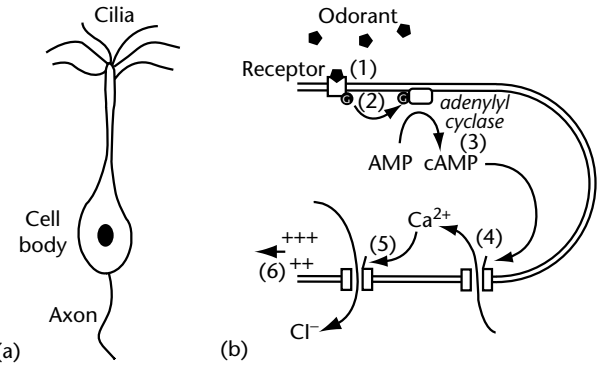

Figure 2. The mechanism of olfactory transduction. (a) Olfactory receptor neurons are bipolar cells. Transduction occurs in the apical cilia leading to the influx of positive charge that spreads passively to the cell body and triggers activity in the olfactory nerve fiber axon. (b) The transduction mechanism in an olfactory cilium. The binding of an odorant to a receptor protein (1) activates a guanine nucleotide binding protein (G) as step (2), which in turn increases cyclic adenosine monophosphate (cAMP) production by adenylyl cyclase (3). Cyclic AMP opens channels that allow positively charged sodium ions (Na^+) and calcium ions (Ca^{2+}) into the cell (4). The increased level of calcium ions in the cilium opens chloride ion (Cl^-) channels allowing negatively charged chloride ions to flow out (5). The influx of Na^+ and Ca^{2+} and the efflux of Cl^- result in net flow of positive charge into the receptor cell, which triggers nerve activity (6).

Olfactory Transduction

Olfactory transduction (Figure 2) is the mechanism by which the binding of an odorant to receptor proteins produces a change in the electrical potential of the ORN. In vertebrates, binding of an odorant to a receptor protein activates a cascade of biochemical reactions resulting in an increase in the level of the intracellular messenger cAMP. This cAMP directly opens an ion channel that allows both sodium and calcium ions to flow into the ORN. In addition to carrying positive charge into the cell themselves, they open a chloride ion channel that causes negatively charged chloride ions to flow out of the ORN. This change in electrical potential triggers activity in the olfactory nerve fibers, which transmit the information to the brain. Mice that have been genetically manipulated to lack these cAMP-activated ion channels have no sense of smell. An increase in the level of calcium ions in the ORN also reduces its activity in response to sustained stimulation. This important feature of olfaction reduces the sensitivity to the background odors to which an animal is constantly exposed, enhancing the response to important odors.

Coding of Olfactory Information

Each ORN expresses only a single type of receptor protein. However, the receptors are not thought to be highly tuned to respond to only a single molecule. Instead, they appear to respond to a particular chemical feature of a range of related odorants, such as the number of carbon atoms in a chain, or the presence of a functional group such as —OH. It may seem surprising that olfactory receptors are not specific in their response to odorants, but this feature allows the olfactory system to respond to an enormous range of chemical stimuli. In the case of

humans, if each of the 350 or so olfactory receptors responded specifically to a single odorant, the olfactory system would only be sensitive to 350 odorants. Instead, the olfactory system analyzes the pattern of responses generated by an odorant across the whole receptor array. It is this overall pattern that is specific for a particular odorant, rather than the ambiguous response of an individual ORN, and the olfactory system can thus respond to many thousands of different odorants. In general, similar molecular structures will tend to fall within a broad odor class, such as 'fruity' or 'minty'. However, there are exceptions, and similar structures can have very different odors. For example, (*R*)- and (*S*)-carvone have the same molecular formula but are mirror images of each other, and they have different smells. Moreover, molecules with quite different structures can smell remarkably similar. Not only will a particular olfactory receptor respond to a range of similar odorants (known as the molecular receptive range), but a single odorant will also activate a number of different olfactory receptor proteins, which have different affinities. Therefore, different concentrations of an odorant may activate different populations of ORNs. This means that the olfactory system must be able to generalize these slight differences in the patterns of receptor activity to give consistent odor perception across a range of odor intensities.

Neural Analysis of Olfactory Information

The ORNs send their odor information to a region of the brain called the olfactory bulb. Here they provide input to mitral cell neurons in specialized spherical structures called glomeruli. Although ORNs that express a particular type of receptor protein are scattered across large areas of the olfactory epithelium, they send their axons to only one or two glomeruli in the olfactory bulb. As each glomerulus receives information from only one receptor type, it may be thought of as a fundamental unit of odor processing. The task of identifying the pattern of receptors that are activated by an odor is therefore reduced to that of identifying the pattern of activated glomeruli in the olfactory bulb.

The initial stage of odor analysis is performed in the olfactory bulb (Figure 3). Mitral cells collect information from a single glomerulus and have inhibitory interactions with neighboring mitral cells via inhibitory interneurons. This lateral inhibition integrates the information about glomerular activity into a pattern of mitral cell activity that represents that odor. Most natural odors are complex mixtures of different odorants and it is often the subtle differences in the minor components that are biologically important. Learning plays an important role in associating the components of a complex odor to form a distinct odor representation that can be distinguished from similar odors with different meanings. This learning involves substantial neural changes at the level of the olfactory bulb. Odor information also has to be linked with other sensory information and appropriate behavioral responses. This aspect of learning occurs in more central brain areas. (*See* **Neural Inhibition**)

The main output of the olfactory bulb is to the piriform cortex. This simple cortical structure has extensive interconnections with the rest of the brain and may have a role similar to higher-order association areas in other sensory systems. From here, odor information reaches the orbitofrontal cortex. This region is probably important for attributing meaning to odors and flavors. Medial temporal lobe structures such as the hippocampus are thought to be important for flexibly learning relationships among odor stimuli and among stimuli from other senses. The large olfactory projection to the amygdala is important for learning the emotional response elicited by meaningful odors. There is also a large olfactory input to a region of the brain called the hypothalamus that is involved with feeding and reproductive behaviors.

DISORDERS OF TASTE AND OLFACTION

Many people who complain of a lack of taste in their food actually have an olfactory deficit. True taste disorders are uncommon. There may be a loss of the ability to detect salt, sweet, sour and bitter tastes, or abnormal tastes may be present in the mouth. The most common cause of a loss of taste sensation is damage to the nerve supply resulting from surgery, dental treatment or the presence of a tumor.

The complete absence of a sense of smell is known as 'anosmia'. This condition can be congenital and have a genetic basis. However, this is rare. Anosmia usually arises from injury or illness that results in damage to the ORNs or their nerves, or blockage of the nasal passages. Physical trauma such as a blow to the head can shear the olfactory nerves, disrupting transmission of olfactory information. Being exposed to the environment, ORNs can also be damaged by noxious chemical vapors,

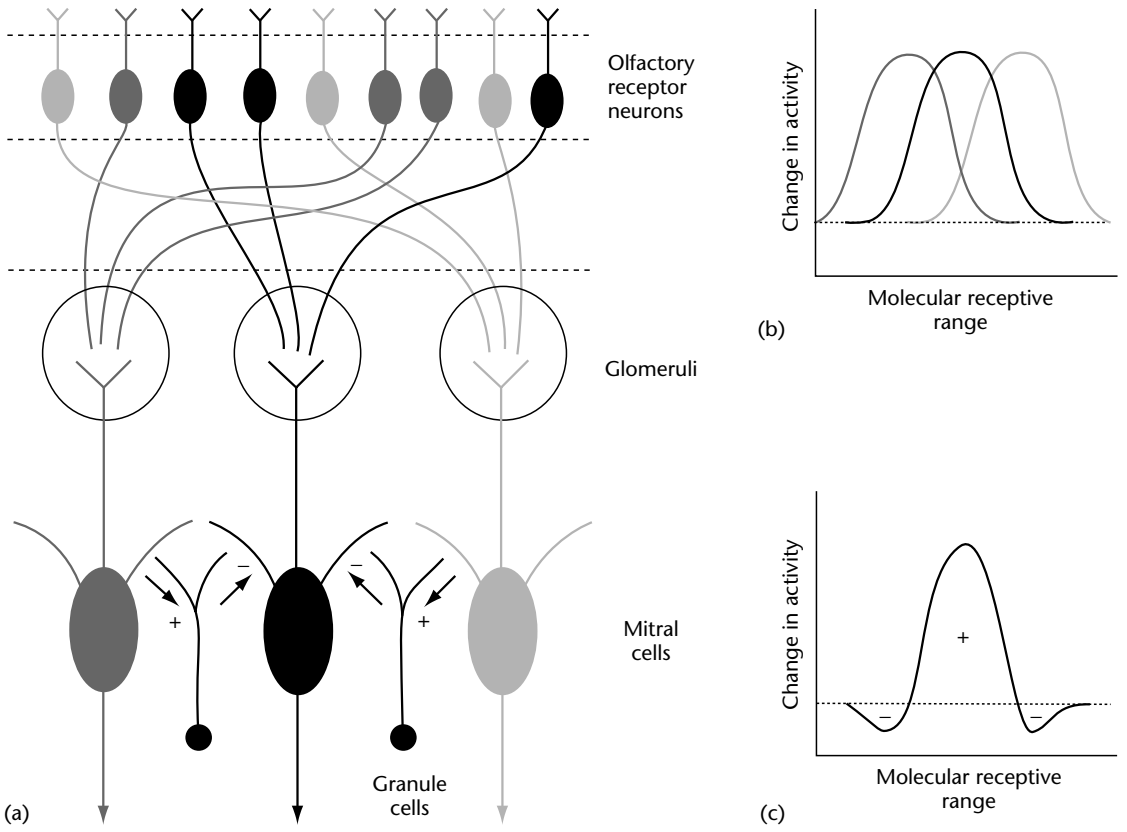

Figure 3. The initial stages of odor processing in the olfactory bulb. (a) Olfactory receptor neurons expressing a single receptor type are randomly distributed in the olfactory epithelium but their axons converge onto one glomerulus in the olfactory bulb. Mitral cells receive information from a single glomerulus and therefore from a single receptor type. The first stage of comparison of the activity across receptor types occurs in the olfactory bulb, by lateral inhibition from neighboring mitral cells, via granule cell inhibitory interneurons. (b) Olfactory receptors respond to a variety of similar odorants and the molecular receptive ranges for individual olfactory receptor neurons overlap. (c) Lateral inhibition acting on the central mitral cell from neighboring mitral cells that respond less well to the same stimuli, sharpens its molecular receptive range. The mitral cell is excited by a narrower range of similar odorants and is inhibited by odorants just outside that range, which stimulate neighboring mitral cells more effectively. This increases the contrast in the pattern of mitral cell activity compared with that of the olfactory glomeruli.

especially caustic ones such as ammonia. The receptor neurons are also vulnerable to infection, particularly by viruses, which can lead to a total loss of function. However, probably the most frequent cause of anosmia is a physical obstruction of the nasal passages that prevents odorant access to the olfactory epithelium. This can be caused by a displaced nasal septum, nasal polyps, or swelling due to infection or irritation of the nasal passages. Many people with anosmia do not complain about the condition and live quite normally, although they are unaware of their body odor, which can be a cause of anxiety. However, such people are subject to serious risks due to the lack of the warning function provided by the olfactory system. They need to install smoke protectors to warn of fire and take precautions when using gas appliances. Additionally, without a sense of smell to elicit an aversive reaction, they need to be careful not to eat food that has gone bad.

Hyposmia is a less severe olfactory deficit, in which the sensitivity to odorants is reduced. It is commonly associated with smoking and with allergies such as hay fever. The incidence of hyposmia increases after the age of 60 years, and olfactory sensitivity drops severely after the age of 70 years. This can have adverse consequences for the diet of elderly people, as most of the flavor of food and the pleasure derived from eating it relies on olfactory sensation. The loss of odor sensitivity in elderly patients can lead to a loss of appetite, which contributes to slow recovery from illness. However, to some extent this can be overcome by adding extra flavoring to food. A more distressing olfactory

disorder is that of parosmia in which the identification of odors is distorted; for example, coffee may be perceived as having an unpleasant chemical or rotting odor. Rarely, people may suffer from phantosmias, in which a persistent perception of a (usually unpleasant) odour is continually present in the absence of odor stimuli, and pervades their life.

Olfactory function may be disrupted in various diseases and can even be used in their diagnosis: for example, 42% of people with Parkinson disease are reported to be anosmic. Moreover, olfactory deficits show up at an early stage of Parkinson disease and are so distinctive that they can be used to differentiate the condition from related motor disorders. Olfactory function also appears to be abnormal in depression and Alzheimer disease, although in these cases the disorder may reflect abnormal functioning of central brain systems rather than solely an olfactory deficit. They may have problems naming odors, although this is generally difficult to test satisfactorily owing to their limited attention span. People with depressive disorders show a lower arousal to pleasant odors and a greater arousal to unpleasant odors than normal. Liver or kidney disease and some metabolic disorders result in the accumulation of toxins in the bloodstream, which can affect olfaction. Endocrine disorders can also be associated with reductions in olfactory sensitivity: 75% of people with diabetes are reported to be hyposmic or anosmic. As ORNs are exposed to damage from the environment, they are continually replaced by new receptor cells. This can lead to the restoration of olfactory sensitivity in cases of damage to the mature receptors. However, conditions that affect this replacement can result in olfactory deficits. Hypothyroidism impairs the maturation of olfactory receptors, resulting in reductions in ORN density in the olfactory epithelium. This is associated with hyposmia. Chemotherapy or radiotherapy in the head region may also disrupt the replacement of the receptor neurons and is likely to lead to hyposmia. However, in most cases the deleterious effect of the primary disorder on quality of life is far greater than that caused by olfactory dysfunction. Pain and Analgesia, Neural Basis of

Introductory article

AD Craig, Barrow Neurological Institute, Phoenix, Arizona, USA

CONTENTS

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage. Analgesia is the alleviation or the absence of pain.

INTRODUCTION

Pain is a multidimensional sensory experience that is essential for survival. It is a somatic distress signal that indicates unhealthy physiologic conditions in the body, warns of the danger of physical harm, or alerts to injury. Although subjective, pain is a specific, discriminative sensation that can be cognitively evaluated, localized, scaled, timed, and qualitatively described. Pain has a defining, affective unpleasantness that motivates behavior, which can lead to the long-term psychological experience of 'suffering'. The unpleasantness can be graded and qualitatively differentiated, ranging from the discomfort of fatigued muscles or a small cut to the agony of a toothache or gallstone.

Pain was once regarded as an exteroceptive somatosensory modality (like touch), but pain signals the condition of the body itself, not the features of an impinging external object or the movements of the body, and skin is but one organ from which pain can originate. Like hunger, thirst, itch, and other 'feelings' from the body, the affective drive (or motivation) that is an essential characteristic of pain reveals an evolutionary origin in the process of homeostasis (the regulatory mechanisms that maintain the body and generate basic drives). This is evidenced by the reflex autonomic responses and interactions that pain generates and by the integration with emotion that is inherent in pain. The neuroanatomy of pain in humans substantiates the concept that pain is a specific aspect of interoception, the sense of the physiologic condition of the body itself. A direct interoceptive representation in the cerebral cortex incorporates pain, temperature, itch, and other feelings from the body; thus, pain is part of a system that provides an important basis for awareness of the material self. This cortical representation is essentially unique to primates, and it is well developed only in humans. Conceptual recognition that pain is an emergent sensation based on the homeostatic and motivational systems of the central nervous system provides a fundamental framework for understanding the psychological interactions between pain and general health, as well as a sound reason for treating pain clinically with an integrated, multidisciplinary approach.

QUALITIES OF PAIN

Psychophysical studies of cutaneous pain indicate that mechanical or thermal pain can be localized nearly as well as touch (within 4–10 mm on the hand and arm). Perceptual thresholds for pain vary with body region, time of day, and perhaps gender. The mean force threshold for mechanical cutaneous pain is approximately 10 g per mm circumference of a flat probe; the mean cutaneous pain thresholds to heat and cold are about 45°C and 15°C, respectively. Different levels of painful heat can be discriminated at steps of about 1°C, and paired forced-choice trials indicate that differences of about 0.4°C can be detected on the face and the hand. Whereas differences much smaller than 1°C can be detected at innocuous cool temperatures, steps of over 4°C are required for discrimination in the noxious cold range.

Qualitatively different feelings are associated with pain caused by different cutaneous stimulus modalities (mechanical, hot, cold, or chemical stimuli) or with pain from different tissues (muscle or viscera), indicating different neural mechanisms.

Sudden noxious stimuli (whether by electrical or natural means) elicit two distinct pain sensations: an immediate sharp, pricking sensation, and about 1 s later an unpleasant burning sensation. These 'first' and 'second' pain sensations are associated with fast-conducting A fibers and slow-conducting C fibers respectively in peripheral nerves, and different sets of spinal neurons. Activity of C fibers from deep (noncutaneous) tissues produces a dull aching or cramping sensation.

Brief (less than 1 s) noxious heat stimuli repeated at short intervals (3 s) cause an augmenting second pain sensation but only a weak first pain sensation. This temporal summation occurs centrally (in the spinal cord and brain). In normal people it shows a striking reset phenomenon; that is, the summation caused by one series of repeated stimuli vanishes after 4–8 s and begins again from baseline in a subsequent series. Dysfunction of the mechanism underlying the rapid inhibition of this central augmentation may be critical in people with chronic pain. Noxious mechanical stimuli (e.g. pressure from a thin point) generate a first pain sensation that also augments if maintained for minutes, which similarly results from central summation.

A surprising sensation of burning pain can be elicited by the thermal grille illusion displayed in many science museums. Innocuous (nonpainful) warm and cool bars that are spatially interlaced produce a painful, ice-like feeling that mimics the burn of noxious cold. This unmasking (or disinhibitory) phenomenon demonstrates that there is a central mechanism for the inhibition of pain by cooling that is reduced by simultaneous warming; this mechanism reflects the importance of the integration of pain and temperature sensibilities for homeostasis (i.e. thermoregulation). The burning pain felt when lukewarm water is applied to feet that are numb from cold is a similar phenomenon. Painful cold evoked by the cold pressor test, in which the hand is held in circulating water at 4°C, is often used to test the effect of drugs on pain tolerance.

Pathologic activity from visceral tissues can produce referred pain localized to a cutaneous zone represented in the same spinal segments. Many pain conditions produce hyperesthesia, or increased sensitivity to any stimuli in a cutaneous zone. For example, pain from cardiac tissue is referred to the left shoulder in angina pectoris, and cutaneous facial hypersensitivity often accompanies a toothache. A zone of hyperalgesia, or increased pain from noxious stimuli, usually surrounds an injury site. Pain evoked by normally nonpainful mechanical or thermal stimuli, called allodynia, may also occur.

In general, pain is influenced by many physiological processes of homeostasis, not only by coolness and warmth, but also by exercise, food ingestion and cardiovascular hypertension, as well as by attention and cultural factors. Pain is also modulated by hormones, particularly those released by stressors, including corticosteroids, catecholamines, androgens, and immune-related cytokines, for which pain-processing neurons have specific receptors.

EFFECTS OF INJURY

Damage or infection elicits a local tissue injury response (inflammation). This includes the production of eicosanoids (metabolites of arachidonic acid from cell membranes) including prostaglandins, bradykinin (from plasma), lactic acid, and superoxide free radicals (from leukocytes and mast cells), as well as serotonin, histamine, and proinflammatory cytokines. These antimicrobial mediators activate or sensitize A and C fiber endings. Activated C fibers contribute a neurogenic component to inflammation by peripheral release of glutamate, peptides, and adenosine triphosphate (ATP), which further enhance vasodilatation and plasma extravasation (increased permeability between capillary endothelial cells), activate mast cells, and influence release from sympathetic nerve fibers. This increases tissue infiltration with blood cells, plasma, and cytokines, which in small quantities results in erythema (redness or flare), and in larger quantities in edema (swelling). The spread of this inflammatory cascade is restricted by systemic corticosteroids (released by activation of the hypothalamo–pituitary–adrenal axis). Trophic agents, such as nerve growth factor, are also induced and may play a part in neuropathic pain, in addition to their role in healing.

Sensitization of nociceptors produces the condition of primary hyperalgesia; for example, following sunburn, even light touch or warmth hurts (lowered threshold) and a hot shower is more painful than normal (increased activation). Inflammatory hyperalgesia is important in many diseases, such as arthritis. A zone of secondary hyperalgesia also surrounds an injury, due to increased spinal neural excitability (central sensitization). Preventing C-fiber activity during an injury from reaching the spinal cord can avoid this; this is the rationale for prophylactic use of analgesic agents prior to surgery (preemptive analgesia). Central sensitization depends on a chemical

cascade elicited by immune-competent glial cells that release cytokines in the spinal cord.

Unhealthy physiologic tissue conditions such as ischemia, hypoglycemia, or excessive muscular activity also cause pain. Loud noises that threaten eardrum rupture cause pain (due to excessive middle ear muscle contraction). These situations cannot be rectified by homeostatic mechanisms alone and require behavioral compensations for survival. Thus, hyperalgesia produces protective behavior that allows tissue healing without disturbance. Children or animals born lacking peripheral C fibers have congenital pain insensitivity and generally do not survive into adulthood.

NEURAL MECHANISMS OF PAIN

Peripheral sensory fibers that innervate all tissues of the body are sensitive to chemical or metabolic stimuli (low pH, hypoxia, hypoglycemia, ATP, bradykinin, and lactic acid), and to strong mechanical or thermal stimuli. These include nociceptors that respond selectively to noxious (or potentially damaging) stimuli. These have thinly myelinated (A) or unmyelinated (C) fibers and small cell bodies in the dorsal root ganglia. The receptor terminals are free nerve endings. Some A-fiber nociceptors respond specifically to noxious mechanical stimuli, noxious heat stimuli, or both. Most C-fiber nociceptors are polymodal (sensitive to noxious mechanical, thermal, and chemical stimulation). Some C fibers are unresponsive unless sensitized by inflammatory agents. The discharge rate of nociceptors is low (C fibers rarely fire faster than 20 Hz), and central summation is required for the perception of pain. Above the perceptual threshold, the intensity of pain directly correlates with the number of action potentials fired.

The small-diameter primary afferents develop in a second wave of neurogenesis after the large-diameter fibers (the mechanoreceptors). They enter the spinal cord through the medial division of the dorsal roots, arborize over one to three spinal segments, and terminate in laminae I and II of the superficial dorsal horn. Collaterals terminate also in lamina V (the neck of the dorsal horn) and lamina X (near the central canal).

Spinal nociceptive neurons in lamina I and lamina V send ascending axons to the brain; these provide specific and integrative activity, respectively. In lamina I, there are distinct types of neurons that respond to specific stimuli within small receptive fields (in skin, muscle, joint, or viscera). Nociceptive-specific (fusiform) lamina I cells dominated by A-fiber input correlate with first pain; polymodal nociceptive (multipolar) lamina I cells dominated by C-fiber input correlate with second pain. Lamina I cells that respond specifically to innocuous cooling, to warming, or to histamine correspond directly with thermal or itch sensations, respectively. The nociceptive neurons in lamina V have large receptive fields and considerable background activity, and they respond both to nonnoxious and noxious mechanical stimuli (over a wide dynamic range). They integrate afferent activity from all somatic tissues; as a population, their activity is related to the cumulative intensity of stimulation. Nociceptive cells that respond to visceral stimulation can have an additional cutaneous receptive field, which is probably the basis for referred pain. The substantia gelatinosa (lamina II) was once considered to be the pain relay, but it contains only small inhibitory interneurons that arborize locally; the functional organization of this modulatory region is a mystery.

The modality-specific lamina I neurons project to hierarchically organized homeostatic regions, including sympathetic spinal neurons and homeostatic brainstem areas. These projections provide the basis for somatoautonomic reflex adjustments of cardiorespiratory function in response to noxious, thermal, or metabolic stimuli (including exercise). Accordingly, lamina I receives descending controls from brainstem homeostatic areas and from the master autonomic control center, the hypothalamus. The integrative lamina V neurons project to spinal motoric regions and to the brainstem reticular core, where they affect somatomotor integration and behavioral state. (*See* **Autonomic Nervous System**)

Thus, the parabrachial nucleus, the major homeostatic integration site in the brainstem, is involved in pain processing; it receives both lamina I (sympathetic) and vagal (parasympathetic) afferent input. It is interconnected with most other homeostatic sites in the brainstem and forebrain, including the periaqueductal gray matter, and it projects pain-related activity to the hypothalamus and amygdala. The amygdala is involved in fear conditioning and in opiate-induced analgesia. The periaqueductal gray matter is the major brainstem site controlling homeostasis, vocalization, facial expression, and emotional, sexual and defensive behavior, and it drives descending antinociceptive control of spinal neurons. Finally, indirect nociceptive inputs to the hypothalamus from the parabrachial nucleus and catecholamine neurons in the medulla affect basic emotional drives, neuroendocrine responses, and thermoregulatory, osmoregulatory, and immune system control. (*See* **Amygdala**)

ROLE OF THE CEREBRAL CORTEX

The main pathway for pain sensation is the lateral spinothalamic tract (STT), which crosses the midline to ascend contralaterally in the middle of the lateral funiculus and consists primarily of lamina I axons. Human cordotomy cases indicate that this pathway is clinically and behaviorally critical for pain, temperature, itch, and other feelings from the body. Lamina I STT axons terminate in a specific relay nucleus in the posterior thalamus (VMpo), in a portion of medial dorsal thalamus (MDvc) that projects to the anterior cingulate cortex (ACC), and in a part of the main somatosensory nucleus of thalamus (VP), which relays mechanoreceptive lemniscal activity from the dorsal column nuclei to somatosensory cortex. (Lamina V axons ascend in the anterior STT in the ventrolateral funiculus and terminate in patches within the VP.) Ancillary multisynaptic pathways (e.g. the parabrachial nucleus) provide pain information to the forebrain. Nociceptive projections in subprimates are fundamentally different. (*See* **Somesthesis, Neural Basis of**)

The specific pain and temperature relay nucleus VMpo in turn projects topographically to a distinct portion of the mid/posterior insular cortex (and to Brodmann's area 3a near the central sulcus). This insular cortical field, which is well developed only in humans, constitutes a limbic sensory area that is interconnected with the amygdala and hypothalamus, and it represents the physiologic condition of the entire body. In turn, this area projects to more anterior insular and orbitofrontal cortical areas on the right (nondominant) side that are neurologically associated with emotional evaluation of the physical self, which is consistent with the 'somatic marker' hypothesis of consciousness and the James–Lange theory of emotion. (*See* **Neural Correlates of Consciousness as State and Trait**)

Pain sensation clearly involves the cerebral cortex. The long-held (incorrect) view that pain is sensed in the thalamus was based on the failure of lesions of the somatosensory cortex (which did not damage the insular cortex) to produce analgesia. Analysis of cortical activity during pain is a vigorous field of study. Functional neuroimaging and evoked potential studies indicate that mid/posterior insular cortex and the ACC are coactivated by painful stimuli (Figure 1). Somatosensory cortical activation is seen only in some studies, perhaps because noxious stimuli inhibit the primary somatosensory area 3b as they activate the adjacent area 3a. Other regions activated include dorsolateral prefrontal cortex, striatum, cerebellum, hypothalamus,

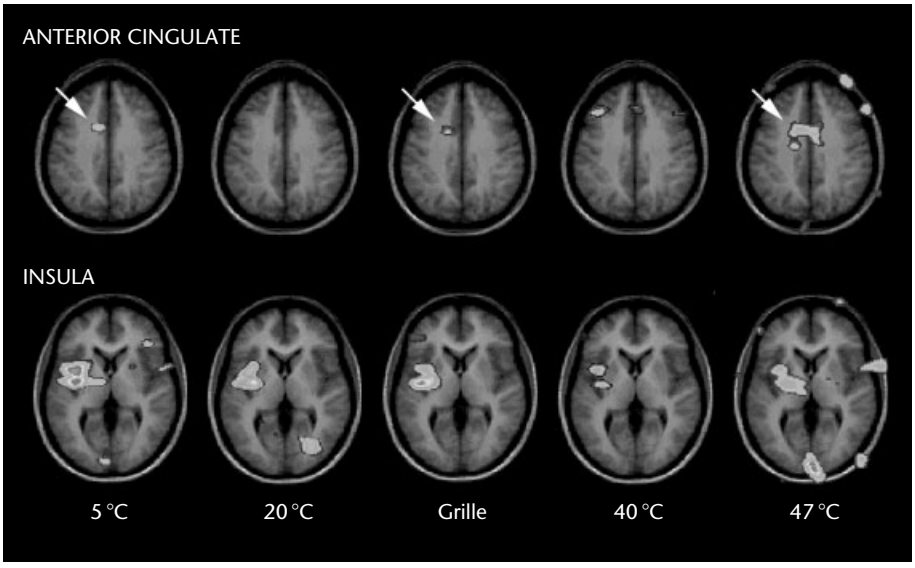

Figure 1. Functional imaging by positron emission tomography of activation in the human brain due to application of noxious heat, noxious cold, innocuous warmth, innocuous cool, and the thermal grille (an illusion of pain) to the right hand. Activation occurred in the left insular cortex with all stimuli, but activation was observed in the anterior cingulate cortex only with the noxious stimuli and the grille stimulus (in which interlaced innocuous warm and cool bars elicit a feeling of ice-like burning pain). This experiment showed that the thermal grille elicits a pattern of brain activation indistinguishable from that produced by noxious cold, validating the psychophysical inference that the illusory feeling it unmasks is like the burn of noxious cold. These images demonstrate the two main regions of the brain activated by painful stimuli in all imaging studies. From Craig *et al*. (1996) *Nature* **384**: 258–260.

amygdala, and periaqueductal gray matter. Many of these areas are interconnected, and the experience of pain clearly involves multiple forebrain regions that interact within a complex network; yet, associations of particular regions with different roles are likely. The VMpo projection field in insular cortex seems to serve as a primary sensory field for pain, temperature, itch, muscle and visceral sensations, and be associated with sensory identification, memory and homeostasis; abnormal activation of this region has been observed in people with chronic pain. The ACC appears particularly important for motivation (urgency), attention and response guidance; its activation is selectively correlated with the perception of thermal pain and with hypnotic modulation of pain unpleasantness. Expectation of pain activates more rostral areas in the ACC and the insula, reflecting further processing stages. Lesions involving VMpo or insular cortex can severely impair pain and temperature sensation, but they can also result in a paradoxical central pain syndrome. Lesions of ACC may blunt the emotional (but not the sensory) aspect of pain, but the great anatomical variability between human brains in this region presents a serious confound. (*See* **Neuroimaging**)

NEURAL MECHANISMS OF ANALGESIA

The classic examples of endogenous neural pain control are soldiers with massive wounds who do not complain of pain, and the placebo analgesia that can be elicited in patients with organic causes of pain. Antinociceptive (analgesic) circuits probably evolved because they enhance survival (by enabling defense behaviors), and because they facilitate recuperative illness responses. Central control of pain makes sense because healing requires considerable time. Several mechanisms are recognized.

Fast inhibition of second (C-fiber) pain is initiated by low-threshold A-fiber activity (e.g. rubbing, vibration) and by A-nociceptor activity (counterirritation). These effects can be demonstrated during a progressive pressure block of peripheral nerve conduction and occur at spinal and cortical levels, but they are still poorly understood. They suggested the heuristic gate control theory of pain integration. Dysfunction of these mechanisms could underlie touch-evoked neuropathic pain (mechanical allodynia). These mechanisms may be engaged by transcutaneous electrical nerve stimulation (TENS) and by dorsal column stimulation, procedures used by some clinicians for pain control.

Innocuous thermal stimuli inhibit C-fiber evoked pain. Cooling has a peripheral palliative effect on inflammation and on sensitized nociceptors, and it inhibits pain processing in the forebrain. This interaction is demonstrated by the thermal grille illusion of pain, in which simultaneous cooling and warming of the skin minimizes ascending thermosensory activity; this unmasks (disinhibits) the cold-evoked burning sensation associated with noxious cold that is normally inhibited by ongoing thermosensory activity. Accordingly, the thermal grille produces the same pattern of forebrain activation as noxious cold, which differs from the insular cortical activation produced by innocuous thermal stimuli because it also produces activation of the ACC (Figure 1). Thermosensory inhibition of pain processing may occur by direct and indirect interactions between these two cortical areas.

Electrical or chemical stimulation of descending and ascending pathways from the periaqueductal gray matter can cause stimulation-produced analgesia. These pathways activate serotonergic, enkephalinergic and catecholaminergic cells in homeostatic control regions that modulate nociceptive processing in the spinal dorsal horn. Descending bulbospinal projections also include pronociceptive (facilitatory) components, which may be imbalanced in neuropathic pain. These projections have direct actions on sympathetic neurons, but in certain conditions deep brain stimulation can alleviate chronic pain without autonomic changes or emotional experiences.

The endogenous pain control systems are activated by environmental stressors (stress-induced analgesia) or danger signals, which can be classically conditioned or learned. Meditation or biofeedback training may access these systems. Conversely, endogenous antianalgesia (pronociceptive) circuits are activated by learned safety signals that indicate when danger will not occur. Such circuits are distinguishable from the analgesia circuits and oppose or reverse their effects at the spinal level by the spinal release of peptides (particularly cholecystokinin) which can block analgesia produced by stress or even morphine. Such antianalgesia mechanisms may play a key part in chronic pain and in the development of morphine tolerance.

ROLE OF OPIATES AND ASPIRIN IN PAIN

The main analgesic drugs used today are nonsteroidal antiinflammatory drugs (NSAIDs) and the opiates. These agents are useful for acute, organic

pain, yet development of better methods for the alleviation of both acute and chronic pain is urgently needed, because pain has enormous costs for both individuals and society.

The prototypical NSAID is acetylsalicylic acid (aspirin), originally derived from willow tree bark. Aspirin permanently blocks cyclooxygenases (COX), which catalyze the production of prostaglandins from arachidonic acid (a cell membrane lipid). Prostaglandins produced during tissue inflammation sensitize nociceptors to other metabolites (ATP, lactic acid, bradykinin) and decrease their thresholds to mechanical and thermal stimuli. Thus, blocking the peripheral production of prostaglandins reduces ongoing pain and hyperalgesia. Corticosteroids have a similar effect by preventing the induction of COX and proinflammatory cytokines (which also sensitize nociceptors).

The NSAIDs inhibit both the COX-1 (constitutive) and COX-2 (inducible) isozymes, which produce different prostaglandins and are localized in different tissues. The constitutive form COX-1 is essential for the health of the stomach and kidney, where chronic high doses of aspirin cause damage. The prostaglandins made by COX-2 are involved in inflammation, sensitization and fever, and thus selective COX-2 inhibitors ('superaspirins') have been developed to minimize the gastrointestinal effects of aspirin.

These analgesics also have central effects. Prolonged activity in C-nociceptors causes production of prostaglandins and proinflammatory cytokines by astrocytes and microglia in the spinal cord, which sensitizes spinal nociceptive neurons and increases neurotransmitter release from primary afferents. Spinal (intrathecal) administration of small amounts of NSAIDs (or cytokine antagonists) reduces pain behavior and neurogenic inflammation (caused by antidromic activity in nociceptive fibers and the peripheral release of peptides). In addition, systemic NSAIDs act synergistically with endogenous opiate-mediated pain control mechanisms in the spinal cord and in the brainstem.

The opioids (which include classic opiate drugs such as morphine and also peptides with similar actions) are still the most potent analgesics available. They have both peripheral and central actions. Peripheral opioid injections affect immune cell activity and reduce inflammatory sensitization of nociceptive primary afferents. In the spinal cord, opioids inhibit nociceptive afferents and the postsynaptic nociceptive spinal neurons. In contrast to NSAIDs, both sensitized and normal pain transmission are reduced by opiates. All three types of opiate receptors (mu, delta, and kappa) are involved, but lumbar epidural injections of fast-acting μ-selective opiates (e.g. fentanyl) are clinically most effective. Such injections usually include the adjuvant bupivacaine, a long-lasting local anesthetic agent that blocks small-diameter fibers, reducing the dosage of opiate needed and the danger of respiratory depression due to rostral spread. Kappa opioids seem to be effective for deep pain selectively in women.

Systemically administered opiates engage endogenous pain control mechanisms in the spinal cord and the forebrain, particularly in the brainstem periaqueductal gray matter and the amygdala. Mu-selective agonists activate the descending pathways involving serotonergic and noradrenergic fibers that are activated by stimulation-produced analgesia. Another antinociceptive pathway normally activated by endogenous β-endorphin in the periaqueductal gray matter is not engaged by morphine.

Nociceptive primary afferent fibers activate dorsal horn cells with the same neurotransmitters (glutamate or aspartate) used by most neurons, and agents that act at these receptors (e.g., dextromethorphan) can affect pain. They also release other substances (e.g. ATP), including the peptides substance P and calcitonin gene-related peptide (CGRP), which have long-lasting postsynaptic actions. Spinal substance-P receptive neurons are located almost exclusively in lamina I, and their abolition reduces chronic pain behavior in animal models. The inhibitory transmitters in the spinal cord include γ-aminobutyric acid (GABA), glycine, enkephalin, dynorphin, and adenosine, which are used by lamina II interneurons that modulate nociceptive processing.

MANAGEMENT OF CLINICAL PAIN

Effective relief from clinical pain of organic origin should be managed according to the 'three-step ladder' of the World Health Organization. Medications with the fewest side effects and the least addictive potential – NSAIDs – are offered first, in addition to treating the organic cause. Their efficacy is limited by a 'ceiling' dose beyond which they are no longer therapeutic, and their potential for gastrointestinal and renal injury. The second step is the combined use of NSAIDs and weak opioids such as codeine. This achieves a synergistic effect which decreases the doses needed; compounded preparations are used that limit the doses, based on NSAID toxicity. The third step is the administration of strong opioids such as morphine orally, rectally, intravenously, or transdermally. Significant side

effects include respiratory depression, pruritus, sedation, and constipation. Opiates have traditionally been underused for acute pain relief, because of dependency fears. However, opioids are now strongly recommended in order to restore patients' function and minimize the deleterious homeostatic effects of pain, based on studies showing improved recovery and an addiction risk of less than 1%. Coadministration of adjuvants that reduce the development of tolerance (the pharmacological need for larger doses) has enabled opiate usage in bedside pumps for patient-controlled analgesia. Nonetheless, regular outpatient administration must still be carefully monitored because of dependency, tolerance, and potential abuse.

Pain interacts with many aspects of homeostasis, including immune system function. Illness and immune challenges induce hyperalgesia. Proinflammatory cytokines have direct effects on nociceptors and central neurons. Increased headache and migraine incidence occurs during systemic immune responses. An exaggerated pain state can be regarded as a natural concomitant of neurally organized, immune-activated illness behavior (which includes fever, decreased activity, decreased food and water intake, and increased sleep), consistent with the role of C fibers and pain processing in metabo-reception and homeostasis.

However, pain itself can have strong negative effects on health. Incessant pain, like stress or surgery, inhibits immune function, enhances tumor growth, and increases morbidity and mortality by sleep deprivation, loss of appetite, immobilization, cardiovascular stress, severe impairment of general health, and even suicide. Pain *can* kill. Unrelieved pain can produce a neural pain 'memory' that persists even when the organic cause is removed. Management of patients with intractable chronic pain presents a great challenge. Appropriate multidisciplinary and behavioral therapy for pain is an important aspect of clinical team management, including techniques of biofeedback, visualization, and relaxation, and if pain is complicated by anxiety or depression, psychiatric treatment. Pain reports can be influenced by psychological factors such as culture, context, emotional status, experience, social support, and beliefs. Attention and expectation have strong effects on pain; in the laboratory, anticipation of a noxious stimulus can cause a warm stimulus to feel painfully hot. Neural blocks, deep brain stimulation, and neurosurgical lesions may be used in particular patients if pharmacologic and behavioral therapies prove insufficient.

Chronic, pathological pain can also occur through damage to the nervous system itself. The brain itself is insensate, but injury to peripheral nerves can result in neuropathic pain. Peripheral nerve damage (e.g. carpal tunnel syndrome) or pathogenic processes (e.g. diabetic neuropathy, postherpetic neuralgia) can produce abnormal neural activity, molecular phenotype changes, or anatomical sprouting. For example, novel sensitivity of nociceptors to circulating adrenaline (epinephrine) and sympathetic efferent activity may underlie reflex sympathetic dystrophy; i.e. complex regional pain syndrome or causalgia. Sympatholysis, systemic lignocaine (lidocaine) or orally administered gabapentin may relieve neuropathic pain by interfering with these mechanisms. Deafferentation pain occurring with a brachial plexus root evulsion can be effectively treated by a lesion of the dorsal root entry zone that eliminates hyperactivity in the spinal cord. Phantom limb pain following amputation, particularly if there was significant preoperative pain, may involve changes in both peripheral nerve and brain function.

Intractable pain can also result from damage to the brain. In Wallenberg syndrome (anesthesia dolorosa), an infarct in the caudal medulla produces loss of pain and temperature sensations in the ipsilateral face (due to damage to the trigeminal dorsal horn) and the contralateral body (due to interruption of the spinothalamic tract), and paradoxical burning pain arises in these regions. Similarly, a spinal lesion (e.g. in multiple sclerosis) or stroke-induced damage in the posterolateral thalamus or the insular cortex can result in a central pain syndrome, if normal temperature and pain sensation is eliminated in the contralateral body, in which paradoxical ongoing burning pain arises which is exacerbated by cooling or touch. Both syndromes may result from imbalanced homeostatic integration in the brain, due to the loss of sensation and disruption of endogenous analgesia mechanisms. These syndromes are unresponsive to opiates, but tricyclic antidepressant (amitriptyline) or antiepileptic (carbamazepine) agents can be efficacious.

Parietal Cortex

Introductory article

Jody C Culham, University of Western Ontario, London, Ontario, Canada

CONTENTS

Parietal cortex consists of the cortical surface of the parietal lobes. It contains numerous specialized subregions involved in encoding bodily sensations and integrating sensory information to perform motor actions.

INTRODUCTION

Parietal cortex forms approximately 20% of the cerebral cortex, the crumpled outer layer of the mammalian brain that performs higher intellectual functions. The parietal lobes form the top, back region of each of the two cerebral hemispheres (Figure 1). Parietal cortex can be divided into two main regions: the somatosensory cortex and posterior parietal cortex (PPC). The somatosensory cortex, in the frontward section of parietal cortex, receives input about touch from the opposite side of the body. Posterior parietal cortex, behind the somatosensory area, is 'association cortex' which integrates information from many sensory inputs and performs higher-level processing. The posterior parietal cortex is well situated to take input from sensory regions (including visual areas in the occipital lobe, auditory areas in the temporal lobe and tactile areas in parietal somatosensory cortex) and to provide output to premotor and motor regions within the frontal lobe. (*See* **Somesthesis, Neural Basis of**; **Motor Areas of the Cerebral Cortex**; **Frontal Cortex**)

To review the functions of parietal cortex, consider the stages necessary in using sensory input to guide motor output in everyday tasks such as taking a sip of coffee from a cup. The cluttered spatial environment, such as an office desk, must be encoded and whittled down to focus on the target object, the cup in this example. Once the cup has been located, the eyes are directed to look at it and the hand reaches towards it with the wrist oriented vertically and the fingers opened to an appropriate size. The initial visual processing codes the cup with respect to its location on the retina, but the motor output requires that the hand move relative to its location on the body. When the hand contacts the cup, touch receptors on the fingers send sensory information that is used to determine the cup's shape, size, orientation, weight and material. Sensory feedback is also used to optimize the grip on the cup and guide it to the mouth using the appropriate force, more for a full cup than an empty one. This seemingly simple everyday task suggests the range of functions the parietal cortex performs in sensorimotor processing – spatial coding, attention, visuomotor control, coordinate transformation and tactile exploration.

ANATOMY

Figure 1 shows the boundaries of the parietal lobes in the human brain. The parietal lobes are divided from the frontal lobe by the central sulcus, from the occipital lobes by the parietooccipital fissure (and its extrapolation to the lateral side), and from the temporal lobes by an arbitrary boundary. Between the central sulcus and the postcentral sulcus, within the postcentral gyrus, lies primary somatosensory cortex (S I). The somatosensory strip in each hemisphere receives information about touch sensations from the opposite side of the body. Below S I lies the secondary somatosensory cortex (S II). The posterior parietal cortex lies behind somatosensory cortex and is divided by the intraparietal sulcus (IPS) into the superior parietal lobule (SPL) and inferior parietal lobule (IPL). The IPL consists of two main subregions, the supramarginal gyrus and the angular gyrus. The continuation of the SPL onto the medial side is called the precuneus.

During the course of evolution parietal cortex first emerged in mammals, in conjunction with their greater reliance on visual and auditory information than on the sense of smell that predominates in lower animals. Parietal regions are limited in animals that use their limbs for locomotion (e.g.

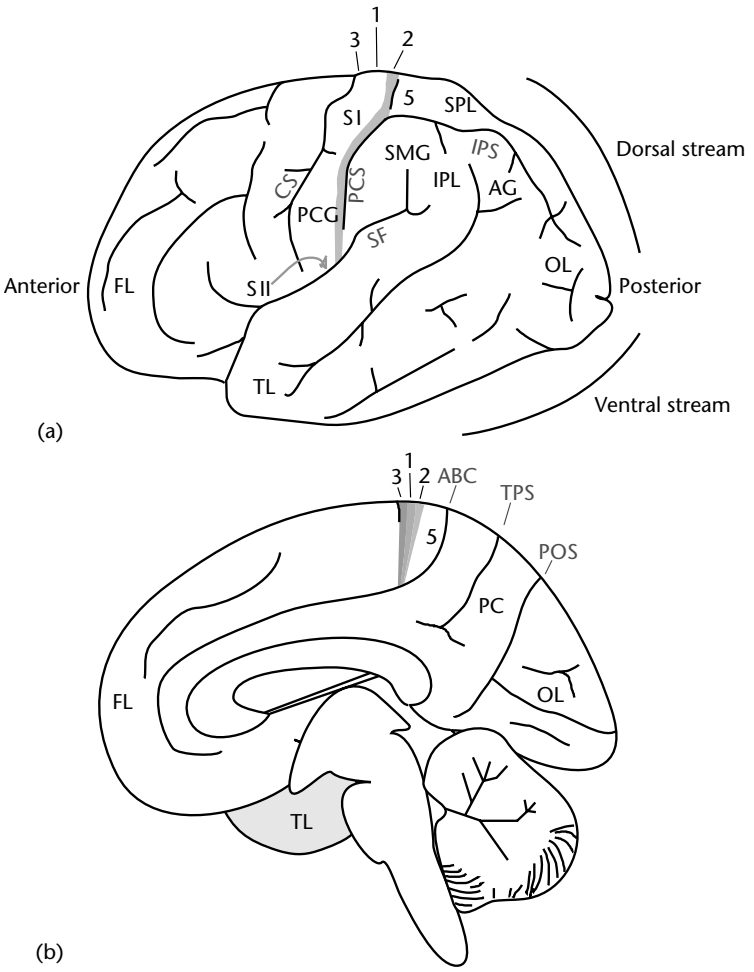

Figure 1. Regions and boundaries of human parietal cortex seen from (a) lateral and (b) medial views. Primary somatosensory cortex (S I, Brodmann's areas 3, 1 and 2) is shown between the central sulcus (CS) and postcentral sulcus (PCS) in the postcentral gyrus (PCG). Secondary somatosensory cortex (S II) is buried within the parietal operculum above the sylvian fissure (SF), as indicated by the arrow. The posterior parietal cortex is divided by the intraparietal sulcus (IPS) into the superior parietal lobule (SPL) and inferior parietal lobule (IPL). The IPL is composed of the supramarginal gyrus (SMG) and angular gyrus (AG). The continuation of the SPL on the medial side is called the precuneus (PC), which lies between the parietooccipital sulcus (POS) and the ascending band of the cingulate sulcus (ABC), and contains the transverse parietal sulcus (TPS). FL, frontal lobe; OL, occipital lobe; TL, temporal lobe.

bears), but are more conspicuous in arboreal mammals (e.g. tree shrews and lemurs), probably related to the additional sensorimotor processing required for locomotion through the trees. Parietal cortex is larger in primates (especially monkeys and chimpanzees) than in lower mammals and larger still in early hominins and modern humans. The surface area of parietal cortex is 20 times larger in the human than in the macaque monkey (in contrast to visual cortex which is twice as large, or temporal cortex which is nine times as large). One suggestion is that the evolutionary growth of parietal cortex (particularly PPC) occurred in conjunction with increased use of the forelimbs (or other limbs such as the monkey's tail or elephant's trunk) for action and interaction with objects, including in humans the increased use of tools. (*See* **Human Evolution**; **Human Brain, Evolution of the**)

Although human parietal cortex has not been extensively mapped, much has been learned from the study of closely related species, particularly monkeys. The best-studied nonhuman species to date has been the macaque monkey (Figure 2). However, it can sometimes be difficult to determine which regions of the monkey brain, if any, are comparable to those in the human. Interspecies comparisons are made difficult by the differences in techniques available for studying monkeys and

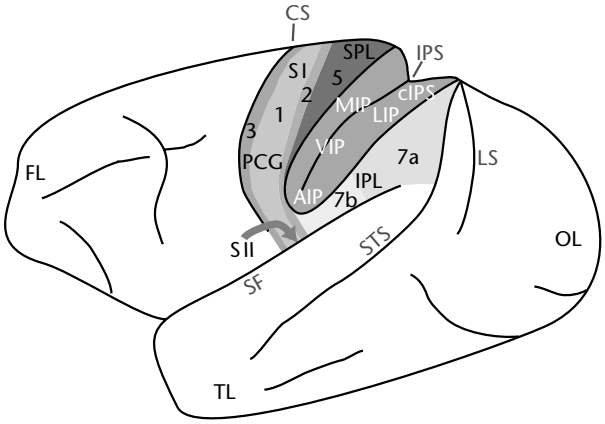

Figure 2. Regions and boundaries of parietal cortex in the macaque monkey, the most intensively studied non-human primate species, seen from a lateral view. As in the human, somatosensory areas 3, 1 and 2, forming SI, lie behind the central sulcus (CS). Although macaques also have superior parietal lobule (SPL) and inferior parietal lobule (IPL) regions, their comparability to human SPL and IPL remains questionable. Monkey SPL contains only area 5, whereas the IPL comprises areas 7a and 7b. Numerous highly specialized areas exist within the macaque intraparietal sulcus (IPS), which is indicated here by gray shading to indicate that the sulcus has been opened up to expose the areas lining its banks. These areas include the caudal IPS (cIPS), the lateral intraparietal area (LIP), the medial intraparietal area (MIP), the ventral intraparietal area (VIP) and the anterior intraparietal area (AIP). The sylvian fissure (SF), superior temporal sulcus (STS) and lunate sulcus (LS) are also shown. FL, frontal lobe; OL, occipital lobe; TL, temporal lobe.

humans. In the monkey, neurophysiologists have used electrode recordings of single neurons to study the function of numerous highly specialized parietal regions, particularly within the IPS (Figure 2). Data from humans has historically come from studies of neuropsychological patients with lesions to regions of parietal cortex. The introduction of brain imaging techniques such as functional magnetic resonance imaging (fMRI) has made possible the detailed study of parietal function in normal humans. More recently scientists have begun to perform fMRI experiments on monkeys, facilitating the possibility of comparing brain activation patterns between the two species. To date, many of the comparisons are based on cytoarchitectonic mapping, using microscopic examinations of the layers of cortex to distinguish subregions. One of the more popular cytoarchitecture schemes was proposed by Brodmann in 1905 for both the human and the monkey. Primary somatosensory cortex includes Brodmann's areas 3, 1 and 2 which appear comparable between the two species. However, in PPC the correspondence between Brodmann's areas (e.g. area 7) in the two species is less clear and is somewhat controversial. (*See* **Neuroimaging**; **Single Neuron Recording**)

FUNCTIONS OF POSTERIOR PARIETAL CORTEX

Theorists have suggested that the processing of visual information proceeds through two distinct pathways, a dorsal stream from early stages of visual processing in visual cortex to PPC and a ventral stream from visual to temporal cortex. Although there is general agreement that the ventral stream is involved in the processing of visual information for the purpose of object recognition, the function of the dorsal stream has been debated. In 1982, Ungerleider and Mishkin suggested that the overarching function of the dorsal stream, including PPC, was the processing of spatial locations. They suggested that the PPC analyzes 'where' objects are in the world, in contrast to the ventral stream, including regions of temporal cortex, which analyzes 'what' the objects are in order to recognize and remember them. However, in 1992 Goodale and Milner argued that the PPC might instead analyze 'how' actions can be accomplished. They suggested that one reason for the division of labor between the two visual systems arose from the necessity of coding space in different frameworks. The ventral or temporal stream represents the world in object-centered coordinates regardless of its location or orientation. For example, a coffee cup must be recognizable regardless of whether the handle is on the left or right or whether it is 20 cm or 200 cm away. In contrast, the dorsal or parietal stream represents the world in egocentric, or person-centered, coordinates. To grasp the coffee cup requires a computation of how to guide the hand from where it is to the location of the handle and how to orient and shape the hand appropriately to hold the handle. Although the majority of theory and research on dorsal versus ventral streams has focused on the processing of visual information, there are suggestions that a similar dichotomy may also exist for the other spatial senses – hearing and touch. (*See* **What and Where/How Systems**)

The profound deficits of patients with parietal damage suggest the fundamental role these functions have in everyday behavior. For example, people with extensive damage to both parietal lobes often demonstrate the phenomena characteristic of Balint syndrome, including an inability to

notice more than one object at a time (simultanagnosia); 'sticky fixation', where the eyes do not normally explore space (gaze apraxia); highly inaccurate movements towards objects (optic ataxia), such as pouring water from a jug but missing the glass; and spatial disorientation, such as being unable to find one's bedroom or to find the bed within the room.

Spatial Processing

One of the fundamental functions of parietal cortex is the processing of information about where things are in the world. Following damage to parietal cortex, humans or monkeys demonstrate gross deficits in the perception of space. For example, monkeys with PPC lesions fail at a task that requires them to discriminate locations, although they succeed at tasks that require them to discriminate objects. Humans with parietal lesions also show profound difficulties in conceptualizing space: for example, patients with right hemisphere parietal damage demonstrate great difficulty in copying two-dimensional drawings or three-dimensional block arrangements (constructional apraxia). Neuroimaging studies have also found enhanced brain activity in the parietal lobes when normal participants perform a task that requires spatial judgment (versus an object recognition task).

The 'space' represented in PPC may not be limited to the real world. Parietal cortex also plays a part in spatial mental imagery (e.g. imagining the locations of shops on a street) and mental rotation (e.g. imagining whether, when rotated to another orientation, a piece will fit into a slot on a piece of furniture you are trying to assemble). People with parietal damage may show deficits in these functions, and neuroimaging studies have reported increased parietal activation for such tasks. Parietal 'space' may be even more abstract, as with numerical representations in mathematics that appear to be encoded in the angular gyrus. (*See* **Mental Rotation**; **Acalculia**)

Spatial Attention

Parietal processing of information at a particular spatial location depends on the observer's attention. In any visual scene, certain regions of space or objects within them may be particularly important. For example, one might be searching for a particular object, be it the coffee cup or the children's book character Waldo. The posterior parietal cortex is essential for directing attention to relevant items so that they can be processed more effectively. Damage to this area can lead to severe problems in the way people process space, particularly when they must attend to a particular region or objects within it. (*See* **Attention**; **Attention, Neural Basis of**; **Spatial Attention, Neural Basis of**)

People with unilateral PPC lesions can develop a bias to attend to one side. In one syndrome, extinction, the patient fails to notice a stimulus on the side opposite to the lesion when it is presented at the same time as another stimulus. In the classic clinical test for this condition the doctor faces the patient with both arms extended horizontally and asks the patient to report whether the doctor is moving the fingers of one hand or of both. A patient with extinction arising from right hemisphere damage would correctly report when the doctor moved the fingers of either the left hand or the right hand alone. However, when both fingers were moved simultaneously, the patient would report seeing only the movement of the doctor's left fingers (on the patient's right side), oblivious that the fingers of the doctor's right hand (on the patient's left side) had also moved. Unilateral neglect is a related but dissociable syndrome that is even more striking. It occurs most often in patients with damage to the right hemisphere. These patients show an inability to attend to the left side of space: they may ignore the left side of the world, the left side of objects, and even the left side of their own bodies or the left side of an imagined object or scene. Neglect has traditionally been attributed to damage to the right inferior parietal lobule (supramarginal and angular gyri); however, more recent evidence suggests that the focus may instead be in the right superior temporal cortex.

People with PPC damage may show problems in switching attention from one location to another. In one task, participants are given a cue that a target will appear to one side of where they are looking. If the cue is valid and the target appears on the cued side, people with parietal damage are nearly as fast as normal participants. However, if the cue is invalid and the target appears on the opposite side, they are much slower to respond. Thus it is thought that damage to the parietal cortex leads to problems in disengaging and shifting attention from an expected location. People with such damage may also show problems in attending to more than one item at a time (simultanagnosia). For example, when looking at an array of objects on a desk, a patient might report seeing only the pencil, then only the stapler. In such cases, attention becomes locked on one item to the exclusion of others.

Visual attention can lead to enhanced firing of neurons in PPC. Higher firing rates in monkey area

7 neurons are found when the monkey keeps its eyes fixed straight ahead but must pay attention to a target in another (peripheral) location regardless of whether or not an eye movement is then made to the target. One unresolved debate concerns whether attention and eye movements are separable mechanisms. Certainly, one can pay attention to something without making an eye movement towards it, but does that simply involve planning an eye movement that is never executed? Neurophysiological studies of parietal cortex suggest that the processing of a target may depend not so much on attention towards it as the 'intention' to interact with the target via the eyes (by a saccadic eye movement) or the hand (by a reaching movement).

Human neuroimaging studies have reported robust PPC activation (in the IPS, SPL and temporoparietal junction, as well as frontal and subcortical structures) during the performance of attentional tasks. A similar network of areas is activated during eye movements (saccades). The PPC is thought to be the source of where attention is directed. Once attention has been directed to a particular location, the relevant features of that item (e.g. its shape, motion or color) can be processed by sites in the temporal lobe that are specialized for that feature. Although the majority of attention studies have focused on vision, other varieties of attention also rely on parietal lobe function, including auditory attention, tactile attention, and motor attention.

Sensorimotor Control

The PPC as a whole has a key role in using sensory information to guide motor actions. Furthermore, sensorimotor control is specialized within PPC in that numerous subregions are each tuned to a particular action such as moving the eyes towards a target, reaching towards it, or grasping it. Given that the inputs to PPC association cortex originate in different coordinates (retina-centered for vision, body-centered for touch, head-centered for hearing), the guidance of action requires the computation and transformation of a variety of coordinate frames. For example, by combining what the retina sees with information about where the eyes are looking allows the system to calculate where an object is with respect to the head. (*See* **Action**)

Eye movements

The eyes are reflexively drawn towards a target that suddenly appears – such as the flashing lights of an ambulance appearing in a rear-view mirror. Similarly, when the attentional system flags a potential item that one is seeking, such as the red and white stripes on the shirt worn by Waldo, the eyes are then directed to it so that it can be processed fully to determine whether it is indeed Waldo or simply a distractor. The PPC plays a crucial role in guiding not only attention, as described above, but also eye movements. (*See* **Eye Movements**)

Bilateral PPC lesions can cause problems with movements of the eyes. Although people with these lesions can move their eyes to a target that suddenly appears, if they are asked to look voluntarily at a target or to move their eyes to search for a target, they show pronounced problems including slow and abnormal eye movements (gaze apraxia or 'sticky fixation'). Other eye movement problems are also reported with parietal damage, including deficits in keeping the eyes fixated on a target, tracking a smoothly moving target with the eyes (smooth pursuit), or focusing the eyes at the appropriate depth (accommodation and convergence). Even unilateral parietal lesions can lead to a slowness in making eye movements towards the opposite visual field.

One PPC area in particular, within the lateral intraparietal sulcus (area LIP), represents space as it is explored by the eyes. Neurons in this area respond when a monkey makes an eye movement to a visual target. These cells also respond without an eye movement if the monkey pays attention to a visual target or remembers its location after it disappears. Although LIP neurons code space in an eye-centered (retinotopic) framework, their responses are more complex than those in simple visual areas. Neuroimaging studies in humans have also found activation for eye movements in an IPS area that probably corresponds to LIP.

Arm and hand movements

When one goes to pick up an object, such as a coffee cup, the hand must be transported to the location of the cup and then the wrist and fingers must be oriented appropriately to grasp it. The process of reaching to a target location, and then grasping it by preshaping the hand, depends critically on regions within the PPC. Lesions in these regions, particularly in the anterior IPS and area 5, cause problems with movements of the hands towards visible targets in actions such as reaching and grasping (optic ataxia). People with parietal lesions may show problems in reaching towards visible objects even though movements without visual guidance are made normally. For example, people with ataxia can quickly and accurately touch parts of their own bodies. This suggests the problem is

not purely a motor one, but a visuomotor one. Although misreaching (optic ataxia) and eye movement disorders (gaze apraxia) both occur in Balint syndrome, there are cases of patients who can guide their eyes but not their hands to a target, indicating the misreaching is not merely a symptom of more general spatial disorientation.

An area in the medial IPS (area MIP) responds when monkeys make reaching movements, particularly those guided by vision. Cells in this area respond best to nearby stimuli, close enough to be reached with the arms. Interestingly, these cells respond not only to the space which the arm can reach, but when a tool is used, also to the space around the tool.

In some ataxic patients, the deficit can be specific to grasping with intact reaching movements. People with grasping deficits can guide their hand to the location of a target, but are unable to process object shape and orientation to preshape the hand appropriately. They will fail to pick up an object correctly because they do not open the hand to the right size or place the fingers on the most stable points for grasping, as is normally done. The site of damage in patients with grasping disorders is the anterior IPS, a region that is activated in brain imaging experiments during grasping. The anterior IPS region in humans appears to correspond to an anterior intraparietal (AIP) region in monkeys which has a key role in using vision to guide grasping. Monkey AIP contains neurons that respond when the monkey sees an object and grasps it. Some cells respond to sight of the object alone, others respond to the act of grasping alone (even in the dark), and many respond to the combination of seeing the object and grasping it. If this area is inactivated by injection of an inhibitory drug, the monkey can still reach towards an object, but loses the ability to shape the hand to grasp the object correctly, behaving much like the human patients with lesions to the anterior IPS. The AIP receives input from the caudal intraparietal sulcus (cIPS), which contains neurons that encode object properties such as surface orientation.

Parietal arm movement disorders are not limited to direct actions on real objects. Apraxia is the inability to make skilled motor movements in the absence of pure sensory, motor or cognitive deficits. It typically results from IPL damage opposite to the dominant hand, and can take several forms. The deficits can be relatively stronger for pantomiming actions (ideomotor apraxia), imitating actions (conduction apraxia), using tools (conceptual apraxia), or performing a sequence of movements (ideational apraxia). (*See* **Apraxia**)

Head-centered motion

The ventral part of the monkey IPS contains a region (area VIP) that responds well to motion in the visual, tactile or auditory domains. This area codes motion towards the head, regardless of where the eyes are looking, and has neurons that responds to touch to a particular part of the face or to motion towards that part. This region represents space centered around the head, especially the mouth, and is particularly responsive to motion in ultra-near space. Many VIP neurons respond to optic flow (mainly expansion but also contraction) like the motion one would experience when moving through the world. Brain imaging experiments have identified a human IPS area with similar properties: it responds to motion in different modalities (visual, auditory, tactile) and it responds both to motion towards the head and touching of the face. The VIP area may play an important part in head movement and perhaps in guiding the hand towards the head in actions such as feeding or grooming.

FUNCTIONS OF SOMATOSENSORY REGIONS

Primary somatosensory cortex (SI, Brodmann's areas 3, 1 and 2) lies along the postcentral gyrus and contains neurons tuned to somatosensory (touch) stimulation on the opposite side of the body. SI contains a tactile representation of the human body, first discovered by Wilder Penfield and colleagues during surgery on conscious epilepsy patients. When SI was electrically stimulated in one hemisphere, patients reported tactile sensations such as numbness, tingling or pressure on a specific body part on the other side of the body. This enabled Penfield to determine maps of the somatosensory homunculus – the 'little man' represented on the somatosensory strip along the postcentral gyrus. The somatosensory representation is distorted. First, it is largely upside down: the foot is represented at the top of the strip, with the legs, torso, arm, hand and head subsequently below it. Second, the amount of cortex devoted to each body part differs based on the resolution of that part – the hands and face have relatively large representations compared with the torso, for example. The representation in SI is quite plastic. For example, following amputation, the representation of the amputated limb is taken over by adjacent body part representations. Output from SI goes to the secondary somatosensory cortex (SII, in the upper bank of the sylvian fissure) and PPC association areas (5 and 7 in the monkey), which elaborate

further on complex properties such as direction selectivity and are more susceptible to cognitive factors such as attention. Vestibular input from the inner ear provides information about head movement to several regions of parietal cortex. (*See* **Penfield, Wilder**)

People with damage to somatosensory regions (postcentral gyrus) lose the sense of touch, temperature, pain and muscle sense (proprioception) from the opposite side of the body (hemianesthesia). Their finger movements may be clumsy because of the loss of feedback regarding finger position. Even when the sense of touch itself is intact, these people may be unable to recognize objects felt by touch, even though they can recognize them visually (astereognosis). Damage to secondary somatosensory cortex can lead to somatosensory extinction, an inability to register two simultaneous touches even though either one alone would be perceived.

Some of the more unusual parietal lesion disorders are disturbances in the way people represent the knowledge of their bodies and the relationship of their bodies to the environment. These asomatognosias can include denial of or indifference to bodily illnesses (anosognosia and anosodiaphoria, respectively, typically on the left side of the body following right PPC lesions), a lack of aversion to pain (asymbolia to pain, possibly resulting from a disconnection between parietal sensation regions and emotional centers of the brain), or an inability to localize and name body parts (autotopagnosia, usually resulting from left parietal damage). In one form of autotopagnosia known as finger agnosia, patients are unable to identify or distinguish their own fingers or those of another person. Patients with right–left disorientation cannot differentiate between left and right on their own bodies or others' bodies. (*See* **Anosognosia**)

CONCLUSION

The parietal cortex is a somewhat arbitrary territory with few clear-cut boundaries, making it difficult to attribute a common function to the region. However, the continuity of parietal cortex with adjacent cortex in the other lobes is consistent with its associative sensorimotor role. That is, parietal cortex receives sensory input from somatosensory parietal cortex, occipital visual cortex and temporal auditory cortex; it encodes spatial locations in a variety of coordinates, particularly for attended targets that are behaviorally relevant; it generates specific instructions to interact with the world using the eye, arm, hand, mouth and body that are then sent to the frontal premotor cortex for motor programming; and it uses somatosensory information about the resulting tactile responses and proprioceptive feedback about the positions of the joints, along with visual feedback, to fine-tune motor actions during visually guided actions and exploratory movements.

CONTENTS

Parkinson disease is a neurodegenerative disorder resulting in the loss of dopamine-producing neurons and disruption of basal ganglia-dependent motor and cognitive function.

INTRODUCTION

The study of Parkinson disease (PD) provides a unique opportunity to investigate functional aspects of dopamine regulation and cortical–basal ganglia–thalamic anatomy. The disease is associated with a variety of cognitive changes; in a large proportion of people, these are quite subtle. In addition, a subset of sufferers develop a dementia that differs from that seen in Alzheimer disease.

To date, cognitive research in PD has focused on three issues. First, what types of dementia are associated with PD? Second, what specific cognitive changes are found in nondemented patients? Third, how can the cognitive deficits be related to the affected neurotransmitter and anatomical systems? These questions are considered following a description of the disease and its pathology.

DEFINITION, DIAGNOSIS, AND FREQUENCY

A cluster of motor signs known as parkinsonism characterizes Parkinson disease. The three primary signs of parkinsonism are tremor, rigidity, and akinesia (Agid, 1991). The tremor is seen at rest, has an approximate rate of 9 cycles per second, and is most evident in the distal portion of the limbs as a 'pill-rolling' motion of the thumb and forefinger. Rigidity refers to stiffening of the limbs evident during external manipulation. Akinesia is difficulty in initiating movements, sustaining repetitive movements, and performing simultaneous movements, as well as a general paucity of movement ranging from slight to complete immobility. This difficulty is most evident when patients attempt to avoid obstacles or change directions, and is often described as 'freezing'. Akinesia can be attenuated in the presence of external stimulation. In some classification schemes the third primary symptom is bradykinesia, or slowness in the execution of movements, and freezing is considered a secondary symptom (Fahn, 1995).

One common set of criteria for the diagnosis of PD requires the presence of either resting tremor or bradykinesia in addition to one other feature such as rigidity, flexed posture, loss of postural reflexes, or freezing (Fahn, 1995). A major difficulty in diagnosis is distinguishing between PD and other parkinsonian syndromes. These syndromes are divided into four classes according to their etiology (Fahn, 1995). Parkinson disease is classified as idiopathic parkinsonism, an allusion to the absence of a firmly established cause, either genetic or environmental. The other classes are symptomatic parkinsonism, Parkinson-plus syndromes, and heterodegenerative disorders. Nonresponsiveness to levodopa usually excludes a diagnosis of PD, but responsiveness is not sufficient to rule out certain non-PD syndromes: symptomatic syndromes related to methylphenyl tetrahydropyridine (MPTP) toxicity and encephalitis, and early-stage Parkinson-plus syndromes like striatonigral degeneration and olivopontocerebellar atrophy, will also respond to levodopa. Differential diagnosis therefore relies on additional features, such as a syndrome presenting with a known cause (i.e. symptomatic syndromes) or with unique symptoms (e.g. the eye-movement difficulty associated with progressive supranuclear palsy).

The prevalence of PD is approximately 160 cases per 100 000 individuals. The incidence rate is about 20 per 100 000. Because PD is an age-related neurodegenerative disorder, both prevalence and incidence increase with age. Thus, at 70 years of age the prevalence is 550 per 100 000 and the incidence is 120 per 100 000. The mean age of onset is 55 years

with a range of 20–80 years. The disease is somewhat more common in men, with a male to female ratio of 3 : 2.

NEUROPATHOLOGY

The principal neuropathological change in PD is degeneration of neurons in the substantia nigra pars compacta (SNc), a pigmented midbrain nucleus that is the principal source of dopamine in the striatum. This results in dopamine depletion of the striatum (Agid, 1991; Fahn, 1995) and large alterations to the normal patterns of connectivity within the rest of the basal ganglia (Delong, 1990). Reduced striatal output downregulates the 'direct' pathway between the striatum and the internal segment of the globus pallidus, reducing inhibition of the latter structure. Reduced striatal output also upregulates the 'indirect' pathway that includes the external segment of the globus pallidus and the subthalamic nucleus, resulting in increased excitation of the globus pallidus. The net result is an increase in activity of inhibitory projections from the globus pallidus to the central medial, ventral lateral and ventral anterior thalamic nuclei, and a corresponding decrease in activity of excitatory thalamocortical projections. Since the globus pallidus projects in large part to cortical areas that have direct input to the striatum, the ultimate effect of reduced nigral dopamine output is reduced activity of the thalamocortical–basal ganglionic circuitry.

By the time the first signs of PD appear, as many as 70% of the dopamine-producing neurons are already dead (Agid *et al*., 1989; Agid, 1991; Fahn, 1995). This suggests that normal motor function of the basal ganglia can persist until a threshold is surpassed. This extensive cell death is associated with uneven dopamine depletion through the striatum. The putamen evidences extensive depletion early in disease progression. This portion of the striatum forms a circuit via the thalamus with the motor cortices, explaining the relatively early expression of motor symptoms in the disease course. Dopamine depletion then extends to the dorsal regions of the caudate nucleus, which has principal connections with the dorsal–lateral prefrontal cortex. This presumably leads to the expression of cognitive changes (see below), although certain cognitive symptoms are apparent early in the disease course as well.

Standard treatment with dopamine replacement therapy consisting of levodopa has dramatic effects on the motor symptoms of PD and leads to vast improvements in the quality of life of patients (Fahn, 1999). Long-term treatment of PD with levodopa often results in the appearance of new symptoms, however, including dyskinesias, involuntary spastic movements of the limbs and neck, and the on-off effect – increasingly rapid fluctuations in the efficacy of dopamine replacement therapy. Both dyskinesia and the on-off effect are thought to result from hypersensitization of striatal neurons.

While dopamine depletion is the most pervasive and evident cause of PD symptoms, other neurotransmitter systems are also affected (Agid *et al*., 1989). The locus ceruleus, the pigmented midbrain source of noradrenaline (norepinephrine), and the nucleus basalis of Meynert, a principal basal forebrain source of acetylcholine, both show extensive loss of neurotransmitter-producing neurons early in the disease course. This pattern of multiple system involvement may underlie the varied efficacy of dopamine replacement therapy in treatment of the numerous symptoms of PD. It also belies the notion that PD is a perfect model of SNc lesions, and thus limits attribution of cognitive deficits to the dopaminergic systems.

There are three major hypotheses concerning PD pathogenesis (Agid, 1991). The first is that cell death results from increased oxidative stress. Oxidative stress stems from three sources: first, lipid peroxidation is increased, resulting in an increase in free radicals apparently from an increase in detoxifying enzymes in the SNc; second, neuromelanin production in pigmented neurons results in free radical production; and third, dopamine degradation by monoamine oxidase B results in free radical production that may accelerate in remaining neurons as cell death proceeds. This is a particularly important aspect of the free radical hypothesis since dopamine replacement therapy drives dopamine production in remaining cells, potentially exacerbating free radical production.

The second hypothesis is that cell death results from impairment of cellular metabolism. Some reports indicate that complex I mitochondrial metabolism is impaired in the platelets of PD patients. This is an important but unconfirmed observation since methylphenyl pyridinium (MPP+), a metabolite of the MPTP toxin that produces a parkinsonian syndrome, impairs complex I activity.

The third hypothesis involves the role of Lewy bodies. These structures are found with greatest frequency in the dopamine-producing neurons of the SNc. While clearly pathological, the degree to which Lewy bodies are associated with cell death and dopamine depletion is in question owing to the fact that the Lewy bodies consist of normal cellular components. In PD, Lewy bodies are

characteristically found in subcortical areas. However, cortical Lewy bodies are found in PD patients with dementia with greater frequency than in nondemented patients, suggesting that they may play a part in the pathogenesis of that aspect of PD.

DEMENTIA

While PD has been traditionally considered the archetypal extrapyramidal motor disorder, it has long been evident that PD patients exhibit pervasive cognitive deficits. Some PD patients exhibit dementia, but most do not. Those who are not demented have patterns of cognitive impairment that suggest specific problems with implicit learning and memory, executive function, and interval timing.

Dementia is more prevalent in patients with PD than in control populations. Estimates of the frequency of dementia in PD range from 10% to 50%. Variation in these estimates stems at least in part from differences in assessment methods, criteria for labeling an individual as demented, control populations and other methodological issues. One major predictor of the incidence of PD dementia is the age of the patient, and age at onset of disease. Beyond this, a prospective incidence study found that the raw frequency of incident dementia in PD patients (about 19%) over a 3.5-year period was greater than that found in control subjects (about 15%) after accounting for differences in age, education and gender (Marder *et al*., 1995). Major predictors of dementia in PD patients included a high score on the Hamilton Rating Scale for Depression and more severe extrapyramidal motor signs.

The question naturally arises as to whether dementia in PD is due to concomitant Alzheimer disease (AD). Postmortem studies suggest that AD pathological change is indeed present in a proportion of PD dementia cases. However, the cognitive profiles of the dementia in these two diseases differ. One informative study compared demented and nondemented patients with PD to individuals with AD who were matched to the PD patients' overall level of intellectual function (Stern *et al*., 1993). Demented patients with PD performed worse than their matched AD controls on measures of verbal fluency and visuospatial tasks, whereas the AD patients performed worse on a memory task after delay. A similar study also found differences between probable AD and PD patients matched for moderate dementia. Patients with PD showed large number of intrusion errors, but not as many as the AD patients, and derived a much larger benefit from cues given during recall. It was therefore concluded that the explicit memory deficits in PD dementia are associated primarily with retrieval of previously stored items. These studies indicating that PD dementia differs from AD dementia suggest that, while some PD patients with dementia have comorbid AD, most are probably demented for other reasons. Likely candidates include damage to the cholinergic basal forebrain nuclei and spread of Lewy bodies into the cortex.

COGNITIVE DEFICITS IN PATIENTS WITHOUT DEMENTIA

Nondemented patients with PD exhibit a variety of cognitive changes that are evident on standard neuropsychological tests, as well as on more focused tests of specific cognitive functions. Neuropsychological tests consistently show PD-related changes such as reduced verbal fluency, increased perseverative errors on the Wisconsin Card Sorting Test and the Odd Man Out Set Shifting Test, slowed responses on the Trail-making Test (particularly, slow responses on Trails B, which requires set shifting), increased interference on the Stroop Test, impaired block construction and picture assembly (such as those used in the Weschler Adult Intelligence Scale version III-Revised: WAIS III-R), among many others. Overall, the neuropsychological profile of PD patients is one of impairment in executive function, or in the executive component of working memory. Memory changes have also been noted in nondemented patients with PD; such patients recall fewer items in list-learning tasks than do matched control subjects, but recognition memory remains intact. Studies of MPTP-induced parkinsonism, which primarily affects the dopamine system, suggest that at least some of these observed cognitive changes are related to loss of dopamine (Stern *et al*., 1990).

Many studies have investigated the degree to which procedural learning is impaired in PD. Patients show abnormally slow learning of sensorimotor tasks including serial reaction time, pursuit rotor, and mirror reading. The serial reaction time task has been particularly informative. Patients fail to show the typical speeding of reaction time when several repetitions of a sequence of targets are surreptitiously introduced into a spatial choice reaction time task (Ferraro *et al*., 1993). This effect persists even after those who could explicitly report part of the sequence are removed from the analysis. In addition, ability to explicitly report part of the sequence does not differ between PD patients and controls. It thus appears that implicit procedural

learning is especially impaired in PD and may be dependent on intact striatal function.

Another line of research has sought to elaborate the nature of PD executive dysfunction, exemplified by findings of increased perseverative errors on the Wisconsin Card Sorting Test. One possibility is that executive dysfunction in PD is primarily a deficit of set-switching, or the remapping of responses to stimuli within an experimental session. This hypothesis is supported by the observation that reaction times increase when set changes occur. For example, in one experiment (Hayes *et al*., 1998) the signal 'AA' indicated the key sequence 1-2-3-1-2-3 and 'BA' indicated 3-1-2-1-2-3. The reaction time to press the '1' key in the fourth position was longer following 'BA' than 'AA', indicating slowed processing when moving between two different sequences of three elements. Reaction times are similarly slow when PD patients switch from mapping color to keys to mapping shape to keys, compared with two sequential mappings of the same type. Importantly, the appearance and magnitude of both set-switching effects depended on the degree of motor impairment evident in the patient immediately before testing. More severely akinetic patients had the slowest set-switching reaction times. Since the motor symptoms of PD stem from dopamine depletion, these results suggest that set-switching is a dopamine-mediated cognitive function, and is dependent on intact basal ganglia.

The timing abilities of PD patients are abnormal in several ways. In one study, a single PD patient performed a repetitive tapping task with both hands. As with many PD patients, one hand was more impaired than the other. The inter-tap intervals produced by the more impaired hand were more variable. This was attributed to increased variability in a central pattern generator rather than to peripheral motor sources (Wing *et al*., 1984). Increased timing variability was attenuated by dopamine replacement therapy, suggesting that the deficit is related to dopamine depletion (O'Boyle *et al*., 1996). Similar deficits were evident when patients compared the duration of two tones, but not when loudness or pitch were compared, suggesting that the problem is specific to timing rather than with some cognitive process related only to motor control.

Two additional dopamine-dependent deficits are evident when patients with PD are asked to reproduce an interval by delaying a key-press for a period of time equal to a previously demonstrated standard (Malapani *et al*., 2001). When PD patients are tested on these tasks while on dopamine replacement therapy, performance is equal to or better than age-matched controls. Off medication, the same patients overestimate the shorter of two intervals (6 or 8 s in duration) and underestimate the longer of the two (17 or 21 s), a pattern referred to as the 'migration effect'. Patients show a second deficit if they learn either one or two intervals while off medication, but are tested on medication.

CONCLUSION

Parkinson disease is a complex and variable condition. Its signs and symptoms can vary widely from person to person, and its cause is still unknown. The variability in the expression of symptoms stems at least in part from the fact that many brain systems are affected by the disease, giving rise to a wide variety of motor and cognitive manifestations. Nonetheless, PD is one of the best naturally occurring opportunities for understanding the cognitive neuroscience of the basal ganglia and other dopamine-dependent brain structures.

Not all cognitive functions that have been identified as impaired in PD patients can be directly attributed to dopaminergic and basal ganglia dysfunction. Among those that can are timing and set switching. Uncertainty in attributing the neural origins of cognitive deficits in PD can be reduced by considering three major issues. First, many diseases other than idiopathic PD present the parkinsonian syndrome, so patients must be carefully screened to insure that a homogeneous sample is tested. Second, dementia is prevalent in PD, and probably represents the effects of additional neuropathology beyond that found in nondemented patients. Experiments aimed at investigation of specific cognitive function should carefully screen out demented PD patients. Third, many neurotransmitter systems are involved in PD. To insure that a cognitive deficit stems from dopamine depletion, patients should be compared on and off dopamine replacement therapy, or in different states of dopamine replacement efficacy.

CONTENTS

From the retina to the cerebral cortex, the early stages of the visual system decompose the visual scene into a number of relevant features, while discarding redundant information. Successive stages of the visual system perform an increasingly complex analysis of the visual scene.

INTRODUCTION

The visual system analyzes the two-dimensional images projected on the retinas, and from these images extracts informative features. These features allow the perception of form and texture, and enable the observer to distinguish and recognize objects and ultimately construct an internal three-dimensional representation of the world. The computations that extract the informative features constitute 'pattern vision'.

Pattern vision is achieved by a succession of neural operations performed by the early stages of the visual pathway. These operations have been studied extensively by recording the activity of individual neurons in cats and in primates such as macaque monkeys. Studies in these animals have revealed principles that probably apply to humans as well. Indeed, recent studies employing functional magnetic resonance imaging (fMRI) in humans have confirmed a tight relationship between neural activity and the perceptual aspects of pattern vision. (*See* **Single Neuron Recording**; **Vision: Early Psychological Processes**)

Anatomy of the Visual System

The early stages of visual processing are illustrated in Figure 1. The optics of the eye focus images onto the retina. Through a network of retinal cells, electrical signals generated by photoreceptors are transmitted to retinal ganglion cells. These cells

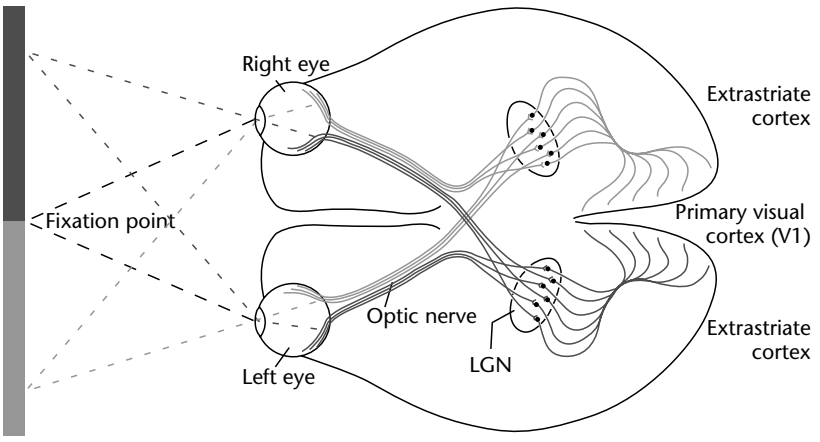

Figure 1. [*Figure is also reproduced in color section*.] Basic organization of the visual pathways. Images originating in the left and right visual hemifields are projected onto opposite parts of each retina. Retinal ganglion cells connect through the optic nerve to the lateral geniculate nucleus (LGN). Neurons in the LGN then project to the primary visual cortex. The visual information is further analyzed in an array of subsequent visual areas. Note that the left visual hemifield is analyzed in the right cerebral hemisphere, and vice versa.

produce spikes of electrical activity, which are carried by the optic nerve to the lateral geniculate nucleus (LGN). The neurons of the LGN in turn send their own spikes to the cerebral cortex, in a large area called the primary visual cortex, or area V1. Area V1 is a key center of visual processing, whose outputs are sent to numerous other visual cortical areas and to the rest of the cortex. (*See* **Vision: Early Psychological Processes**; **Occipital Cortex**; **What and Where/How Systems**)

PATTERN VISION AS IMAGE FILTERING

Neurons in the visual system respond to the distribution of light presented in a particular region of the visual field – the neuron's 'receptive field'. The study of the receptive fields of visual neurons is fundamental to our understanding of visual function, and provides the basis for the current knowledge about pattern vision. In particular, receptive fields can be seen as filters through which cells view the visual scenes; filtering is a well-known concept in engineering and computer science. Image filtering by the receptive fields in the early stages of the visual system is illustrated in Figure 2. Starting with a visual stimulus (a), this follows the operation of successive stages in the retina (b, c) and in the primary visual cortex (d, e). The operation of each stage is illustrated through a 'neural image', a map of the responses that would be obtained if an array of identical cells were looking at the physical image in all possible positions. In a neural image, gray indicates no response, whereas white and black indicate higher and lower responses. (*See* **Vision: Early Psychological Processes**)

Image Filtering in the Retina

Photoreceptors in the retina have small receptive fields (Figure 2(b), lower panel), and transform light into electricity. The gain of this transformation depends on the prevalent light conditions, a phenomenon known as 'light adaptation'. Thanks to light adaptation, rather than signaling absolute light intensity, photoreceptors encode the strength of light relative to the average in the recent past in that local region of the retina. This relative measure of light is called 'contrast', and it entails discarding information about absolute light levels. The advantage of computing contrast is illustrated in the

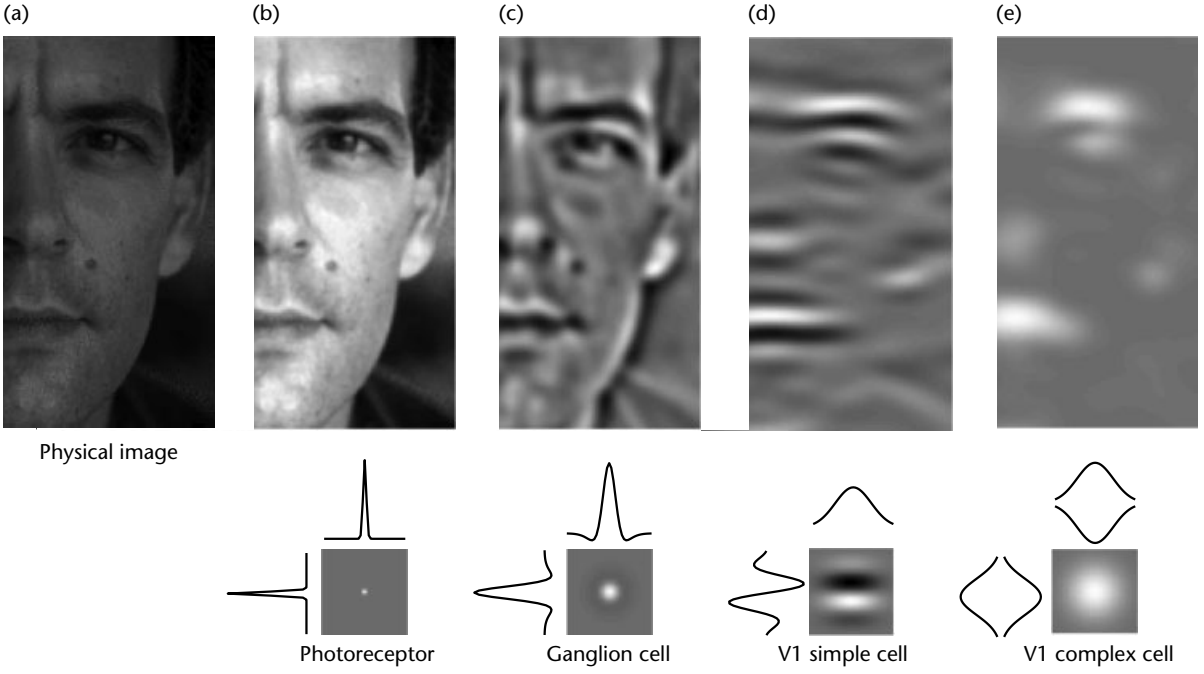

Figure 2. Receptive fields and neural images in the retina and primary visual cortex (V1). (a) A physical image obtained in conditions of dim illumination. (b–e, top row) Receptive fields of a photoreceptor, an on-center ganglion cell, a horizontally tuned V1 simple cell, and a horizontally tuned complex cell. (b–e, bottom row) Neural images corresponding to the cell types above. A neural image is a map of the responses of a given cell as it scans the whole image. White indicates a positive response, black indicates a negative response, and gray means no response.

neural image given by the responses of the whole array of photoreceptors (Figure 2(b), top). This neural image uses the full available range of responses (represented as white to black), even though the visual stimulus was illuminated by dim light (Figure 2(a)). We are mostly oblivious to light adaptation, but can become briefly aware of it by stepping from a dark room into bright daylight or vice versa.

Retinal ganglion cells have receptive fields organized in a center–surround fashion, and respond to the difference between the intensity of light in the center and in the surround. Cells in our example are on-center (Figure 2(c), lower panel), so they are optimally stimulated by a light spot on a dark background: they thus give a negative response to the mole just to the right of the person's nose, which is darker than the surrounding skin (Figure 2(c), top). Center–surround receptive fields enhance contours such as those at the edges of the face, the mouth, and the eyes. By extracting these features, they discard information about light intensity in uniform regions. Uniform regions, such as the cheek or the dark area behind the face in our example, stimulate both the center and the surround, whose contributions average out (resulting in gray regions in the neural image, Figure 2(c), top).

Image Filtering in Primary Visual Cortex

While the receptive fields of LGN neurons are similar to those of retinal ganglion cells, the receptive fields of neurons of cortical area V1 are radically different. Most V1 cells show receptive field properties that are absent at earlier stages, including selectivity for stimulus orientation and direction of motion. In particular, because of their orientation selectivity, V1 cells respond strongly to bars and edges of the appropriate orientation. (*See* **Vision: Early Psychological Processes**; **Occipital Cortex**; **Motion Perception, Neural Basis of**)

The receptive field of 'simple' V1 neurons is composed of separate 'on' and 'off' elongated regions (Figure 2(d), lower panel). The optimal stimulus to obtain a positive response is one that stimulates the 'on' regions with positive intensity while stimulating the 'off' regions with negative intensity. In our example, this happens near the mouth, the eye, and the eyebrow (Figure 2(d), top). In contrast, the edge of the face is mostly vertical, so it stimulates the 'on' regions and the 'off' regions at the same time. The inputs from these regions cancel out, and the resulting response of the cell is zero (gray in the neural image). The eyebrow is mostly horizontal, and evokes a negative response flanked by two positive responses, evoked by the regions above it and below it. Indeed, just like cells in earlier stages of the visual pathway, simple cells are sensitive to the precise location of a stimulus within their receptive field, and to the 'polarity' of a stimulus; i.e., whether the stimulus is brighter or darker than the background. This dependence on stimulus location and polarity is overcome by V1 'complex' cells. Complex cells have receptive fields where 'on' and 'off' regions overlap. For example, the 'on' region of our model complex cell takes up the whole receptive field (Figure 2(e), lower panel). As a result, the cell gives roughly the same positive response to a bar presented anywhere within its receptive field, whether it is lighter or darker than the background.

The neural image produced by complex cells (Figure 2(e), top) shows responses corresponding to the location of horizontal features such as the mouth, eye, and eyebrow. Complex cells such as the one in Figure 2(e) can be thought of as summing the positive outputs of many simple cells such as that in Figure 2(d), whose receptive fields are elongated in the same direction, and whose spatial location is displaced. By summing positive outputs from displaced simple cells, complex cells would overcome the dependence on stimulus location and polarity shown by simple cells. Invariance for location and polarity might be useful to maintain continuous responses in spite of small eye movements.

The neural images in Figure 2(d) and (e) illustrate only two of the many concurrent representations that are formed in our primary visual cortex when we look at a stimulus such as that in Figure 2(a). Indeed, the primary visual cortex contains cells selective for the full range of orientations and for a variety of spatial scales. (*See* **Occipital Cortex**; **Cortical Columns**)

An example of this variety is illustrated in Figure 3 for four simple cells selective for different combinations of orientation and spatial scale. The two cells in the left quadrants are selective for horizontal orientations, whereas the two cells in the right quadrants are selective for vertical orientations. The two cells in the top quadrants are selective for lower spatial scales than the two cells at the bottom. These cells respond to very different features in the visual stimulus (Figure 3(c)). The cell in the top right quadrant gives a negative response to the edge of the face, where the 'on' region is strongly stimulated by the dark background, and the lighter skin stimulates the 'off' region. None of the other cells responds well to these features. In contrast, the cell in the lower right quadrant responds strongly

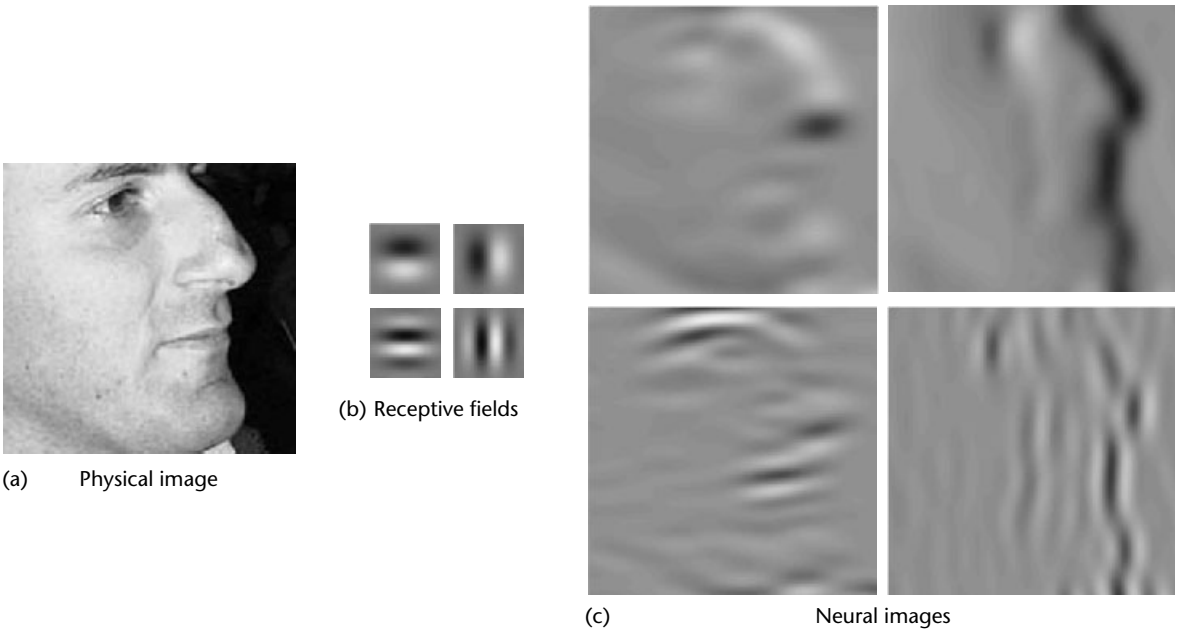

Figure 3. Neural images in V1. (a) Physical image. (b) The two-dimensional receptive fields of four simple cells, each sensitive to vertical, horizontal, or oblique orientations. The top set encodes orientations at a lower spatial scale than the bottom set. (c) The neural images resulting from the analysis of the image shown in (a) by the two sets of cells shown in (b). Each cell extracts one particular orientation at a given spatial scale. Adding together the four images in (c) would result in a coarse but faithful representation of the physical image (a).

to features such as the mouth and eyebrows, which are missed by the other cells.

In summary, cells in the primary visual cortex extract relevant elements of the visual image such as contours, lines and edges, at a variety of spatial scales. For the image in Figure 3(a), simple and complex cells stimulated by the edges of the face will give a strong response. Those centered on the background or on uniform parts of the face will remain mostly silent. Thus, the primary visual cortex extracts the face's edges and the contours of the face's various features. Simple cells provide an accurate description of the location of these features, as well as the indication of their polarity. For example, they indicate that the face is brighter than the background. The combined activity of simple and complex cells can yield a stable, faithful representation of the objects present in the environment.

CONTEXTUAL EFFECTS ON PATTERN VISION

We have described responses of visual neurons as entirely determined by the instantaneous distribution of light on their receptive field. In fact, these responses also depend on factors such as the previous history of stimulation, the overall contrast within the receptive field, and the distribution of contrast in the surrounding regions. These factors mostly affect the responses of neurons in the visual cortex.

Pattern Adaptation

Prolonged exposure to a visual pattern perturbs visual perception, reducing the perceived contrast and altering the appearance of subsequently viewed patterns. A classic example of this alteration can be experienced by looking at a pattern made of oblique bars for 30s or so and then looking at a pattern made of vertical bars. The vertical pattern will appear briefly as if it were tilted in the opposite direction to the preceding pattern. Effects of this kind are termed 'pattern adaptation'. A simple explanation for the perceptual effects of pattern adaptation states that, first, perception is the result of a weighted sum of the outputs of sensory neurons, and second, that pattern adaptation fatigues the neurons that respond most strongly. By causing these neurons to respond less strongly than they normally would, adaptation biases perception away from the adapting pattern.

The physiological substrate of pattern adaptation appears to lie in the primary visual cortex and in subsequent cortical areas. The responses of V1

neurons are sharply reduced after only a few seconds of stimulation, in a manner that could account for the perceptual effects. In contrast, the responses of neurons in the LGN and in the retina are essentially unaffected.

Pattern adaptation reflects a self-calibration mechanism in the visual cortex. This mechanism is continuously at work to adapt the responses according to the prevailing statistics in the stimulus. Its goal might be to increase the independence of subsequent neuronal responses, so that the response at a given time cannot be predicted by an earlier response. This makes maximal use of the resources, as it uses neuronal responses to encode the information that is not redundant over time. We tend to notice this calibration mechanism only when it misbehaves: when a prolonged stimulus is turned off, the calibration mechanism is caught off-guard, and visual perception is then briefly perturbed.

Interactions Between Superimposed Patterns

In addition to interacting in the time domain, different patterns interact when they are presented simultaneously. An example of this kind of interaction can be seen by superimposing two oriented patterns: for example, superimposing an orthogonal mask on an oriented test pattern impairs the perception of the test pattern. This phenomenon is known as 'masking', and reduces the apparent contrast of the test pattern.

The physiological correlate of masking appears to lie in mechanisms present in the retina and especially in the primary visual cortex. These mechanisms control the responsiveness of neurons and depend on overall contrast in a visual region centered on the receptive field. When two patterns are superimposed, overall contrast is increased, and neuronal responsiveness is reduced. This reduction in responsiveness has been observed in visual neurons of cats and monkeys, as well as in the electroencephalogram (EEG) obtained from visual cortex of humans. (*See* **Electroencephalography (EEG)**)

The current interpretation of masking effects involves inhibition between V1 neurons that have overlapping receptive fields but are selective for different orientations. Two superimposed patterns differing in orientation stimulate two sets of neurons, which inhibit each other and thus respond less than to a single pattern. This explanation, however, is being challenged and may not be entirely correct.

Interactions Between Spatially Displaced Patterns

Patterns do not have to be spatially superimposed to interact with each other. Strong interactions can also be observed between patterns that are spatially segregated. Perceptually, these interactions can be suppressive or enhancing, depending on stimulus configuration.

The physiological substrate of these interactions between spatially separate visual patterns seems to lie in area V1 and in the successive cortical areas. The responses of V1 neurons are influenced by stimuli presented in the regions surrounding their receptive field. This influence is commonly considered to originate in 'lateral inhibition', reciprocal inhibitory connections between pools of V1 neurons with displaced receptive fields.

Among the phenomena that would be explained by lateral inhibition is 'surround suppression'. Oriented patterns situated in the region surrounding the receptive field of a V1 neuron can substantially reduce the responses of the neuron, especially if their orientation is similar to that preferred by the neuron. For example, the responses of a V1 neuron to an optimally oriented bar can decrease if the bar is made to extend beyond the receptive field of the neuron. Cells showing this property are often called 'end-stopped'. One of the roles of surround suppression might be to enhance the independence of V1 neurons. The statistics of images commonly encountered by the visual system are such that contours and edges tend to be surrounded by other contours and edges. For example, in Figure 3 the horizontal contour given by the mouth is close to the vertical contour given by the edge of the face. Without surround suppression, knowing that a V1 neuron is strongly activated would also say something about the nearby neurons: they would be more likely to be active than other neurons. This lack of independence between neurons would be wasteful, as it would encode redundant information.

In addition to suppression, interactions between different regions of the receptive field can in some conditions involve enhancement. This enhancement may result from a sort of double inhibition: if one reduces the activity of a population of neurons that normally inhibits another population, the activity of the second population may be enhanced.

Anatomically, the interactions between different regions are thought to be mediated by local circuits as well as by long fibers running parallel to the cortical surface, which connect V1 cells over

distances of several millimeters. Long-range connections tend to link cells that share the same preferred orientation. Moreover, they preferentially connect cells along an axis that corresponds to the cells' preferred orientation.

SPATIAL REPRESENTATION OF VISUAL PATTERNS

Area V1 contains a full representation of the visual field, with nearby regions in the visual field corresponding to nearby regions in area V1. This kind of representation is called 'retinotopic'. Retinotopy is derived by a similar organization in the retina, optic nerve, and LGN; it coexists with other organizational principles that group cells according to characteristics such as orientation preference and ocular dominance. (*See* **Cortical Columns**)

Retinotopy can be observed in Figure 4(a), which illustrates an idealized visual stimulus resembling a bull's-eye, and the corresponding map of responses across area V1 in one hemisphere (Figure 4(b)). This representation of the visual stimulus is heavily distorted: just like the retina and the LGN, area V1 devotes most of its cells to the center of fixation (fovea). Indeed, while the portion of the bull's-eye that is inside the first solid ring takes up a tiny portion of the surface of the stimulus, the region that represents it occupies about half of area V1. Another major difference between the stimulus and the corresponding map of activity is the geometrical arrangement of the features. Concentric circles and radial lines in the stimulus become vertical and horizontal stripes of activity in the cortical map. This geometrical distortion could be important to help the rest of the brain recognize objects regardless of their distance and of their orientation. Indeed, as we move closer to an object, its size on the retina is scaled up. If we tilt our head (or the object), the object's image on the retina rotates around the fovea. Thanks to the transformation operated by the cortex, such scalings and rotations become simple translations, which may be easier to analyze for the subsequent stages of visual processing.

A striking example of the consequences of cortical magnification is illustrated in Figure 5. In this simulation, a mathematical model was fed a photograph of a room (a) and generated a prediction of the distribution of responses across the primary visual cortex in one hemisphere (b). The model simulates an observer who focuses her eyes on the letter 'O' on an eye chart (see detail) located at the back of the room. The representation in V1 is amazingly distorted. Most of the cortical surface devoted to the stimulus is taken up by the eye chart, and particularly by the letter 'O' and by the nearby letters. Barely any cortical space is given to the rest of the room, even though it occupies by far the largest portion of the visual stimulus.

PATTERN VISION BEYOND PRIMARY VISUAL CORTEX

Area V1 is by no means the only visual area in the cerebral cortex: in primates there are tens of visual areas, each containing a full representation of the visual field. These areas receive input directly or indirectly from V1. From what we understand, different areas emphasize the analysis of different aspects of the visual world. In particular, areas V2, V4, and IT appear to be closely related to the perception of visual patterns. (*See* **Occipital Cortex**; **What and Where/How Systems**)

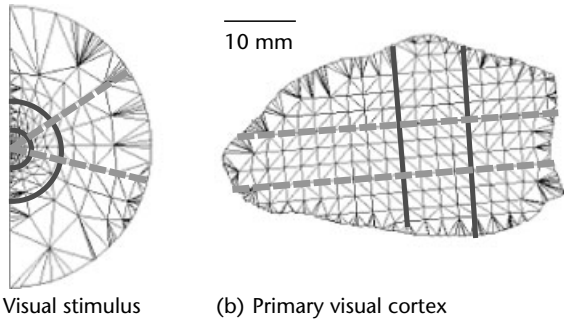

Figure 4. Retinotopy in primary visual cortex. Mathematical model of the transformation between a visual stimulus (a) and area V1 in one hemisphere (b). Solid and dashed lines indicate the transformation of concentric and radial features in the visual stimulus into vertical and horizontal lines of activity in V1. From Frederick C and Schwartz EL (1990) Conformal image warping. *IEEE Computer Graphics and Applications* (March): 54–61.

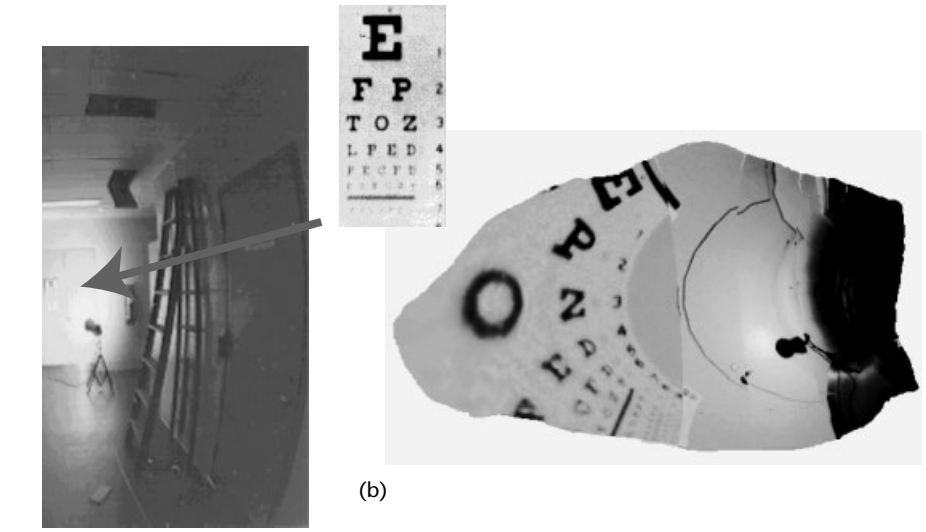

Figure 5. Application of the model in Figure 4 to simulate the representation in area V1 of the image of a room. In the back of the room is an eye chart (see detail), and the retina is centered on the letter O. The representation in cortex greatly magnifies the letters in the eye chart at the expense of the rest. From Schwartz EL, Merker B, *et al*. (1988) Applications of computer graphics and image processing to 2D and 3D modeling of the functional architecture of visual cortex. *IEEE Computer Graphics and Applications* (July): 13–23.

Cortical Area V2

The next stage of visual processing after V1 is performed in the secondary visual area, V2. The precise role of V2 is unknown; some differences between the responses of V2 and of V1 have been found, but most receptive field properties are similar in both visual areas. At equivalent positions in the visual field, the receptive fields of V2 cells are slightly larger than in V1. A functional property that has been demonstrated for V2 cells is their ability to respond to illusory contours, contours that are defined by figural clues rather than by lines or edges. Such contours could result from partially occluded objects, and the capacity to interpolate them is necessary to segment the visual scene into various objects. On the other hand, there are suggestions that also V1 cells can respond to such contours, so it is not clear that this property is specific to V2.

Cortical Area V4

The properties of V4 cells are even less well understood than those at earlier stages, but several results suggest that V4 cells have an important role in pattern vision. First, receptive fields in V4 are considerably larger than in V1 or V2, making V4 cells suitable for the analysis of large areas of the visual field. Large receptive fields could set the stage for the detection and identification of whole objects. (*See* **What and Where/How Systems**)

Second, V4 transmits information to the inferior temporal (IT) cortex, a cortical region that is known to be crucial for object recognition (see below). Third, a number of studies have shown that the activity of V4 cells is strongly modulated by attention. The response of a V4 cell to a given stimulus is high if the stimulus has a behavioral relevance (i.e., if the observer is paying attention to it), and low otherwise. Fourth, the foveal representation is even more enhanced in V4 than it is in either V1 or V2. This would seem reasonable if V4 were to be concerned with pattern vision rather than with attributes of the whole visual field.

Finally, recent physiological results, although controversial, add further support to a role of V4 in pattern vision. Although most V4 neurons, like those of V1 and V2, are selective for the orientation of a visual stimulus, a number show a preference for stimuli that differ from the bars and edges that seemed optimal to stimulate cells at earlier levels. For example, some V4 neurons respond better to stimuli made of concentric rings, or of radially oriented line segments, than to simpler bar and edge stimuli.

Thus, individual V4 cells seem able to encode visual patterns more complex than those encoded by individual cells at earlier levels. Taken together,

these facts strongly suggest that V4 is important for pattern vision.

Inferotemporal Cortex

In the cortical areas of the inferior temporal lobe, neurons prefer stimuli even more complex than those described in area V4. These cells often produce their highest activity for stimuli that have complex, irregular shapes, or for stimuli made of numerous features arranged in complex patterns. There are, for example, neurons in the anterior IT cortex that respond selectively to faces, or to other body parts. The responses of IT neurons are often invariant relative to stimulus position within their receptive field. For familiar objects, they can even be invariant relative to the angle of view. A given neuron could thus respond to an object regardless of the object's rotation, even though the object's two-dimensional projection on the retinas varies considerably in these conditions. These neurons are therefore important for the perception of complex patterns, a function necessary to achieve object identification. (*See* **Face Cells**)

The role of IT cortex in complex pattern perception and object perception is supported by lesion studies. Humans and monkeys with IT cortex lesions are severely impaired in object recognition tasks. They fail to recognize familiar objects, and are incapable of learning new ones. A particular example of such a loss is the incapacity to recognize faces, a condition called 'prosopagnosia'. This condition is thought to result from lesions to the parts of IT cortex specialized in the analysis of faces. Studies of the neurons' receptive fields and those of cortical lesions thus converge to indicate that IT cortex has an important role in pattern vision.

THE PERCEPTION OF PATTERNS

We have seen that visual stimulation activates neurons at numerous stages in the visual pathway. In the responses of these neurons we have also found counterparts for perceptual effects such as pattern adaptation, masking, and the interactions between spatially displaced patterns. These results suggest a link between the responses of cortical neurons and the perception of visual patterns.

Neural Activity and Pattern Vision

Other links between the responses of cortical neurons and the perception of visual patterns have been demonstrated by lesion studies and by stimulation experiments. Studies have been made of people with lesions of the visual cortex due to disease or to accident, for example patients with gunshot wounds after World War I. These studies established that the absence of a part of visual cortex yielded some deficit in visual perception. Stimulation experiments employ localized injections of current to stimulate small groups of cortical neurons, and have been mostly performed on surgical patients or on blind volunteers. Electrical stimulation of the visual cortex leads to the perception of illusory visual stimuli.

More recently, a strong link between neural activity and pattern vision has been demonstrated using fMRI. This imaging technique is not invasive, and allows the experimenter to measure brain activity in people who are awake, while they make perceptual decisions on the presence or absence of a visual stimulus. Using this method it has been shown that the detection of visual patterns relies on neurons in V1 and in subsequent areas of the visual cortex. The activity of these neurons predicts the performance of the participants and even correlates with perceptual decisions on a trial-by-trial basis. When making a difficult perceptual judgment, participants make a number of mistakes, such as indicating that a pattern is present when it is absent (false alarms), or that it is absent when it is present (misses). The responses of visual cortical neurons correlate with the perceptual decision of the participant rather than with the physical stimulus. Responses in visual cortex determine whether the person will perceive the stimulus.

The Binding Problem

Most of the theoretical and experimental work described above implies that the early stages of the visual system decompose an image into features, or components. Our visual perception, however, is one of unity and coherence, not a juxtaposition of independent elements. This suggests that at some stage of the visual pathways the image components must be bound together to form a coherent perception. To date, the solution to this problem is largely unknown. (*See* **Decoding Single Neuron Activity**)

In an attempt to provide an answer to this question, it was proposed that the neuronal substrate that glues different features together is found in the temporal pattern of neuronal activity. In that view, two cells coding for features belonging to the same object would synchronize their activity. The synchronicity of cell firing would thus serve as a tag for a given object, which is propagated through the various stages of visual processing. The so-called 'binding by synchrony' hypothesis received some

experimental support with the discovery of cells in the visual cortex of cats and monkeys that, for example, synchronize their activity when they are simultaneously activated by a single bar, and not when activated by two distinctly separate bars. Whether this synchronization reflects the process of 'binding' is the subject of intense debate and experimental scrutiny and there is, to date, no consensus on its validity.

Perceptual Systems: The Visual Model

Introductory article

Brian J Stankiewicz, University of Texas, Austin, Texas, USA

CONTENTS

Perception is the interpretation of specific sensation from the visual, auditory, somatosensory and olfactory sensation systems. Computational models of perceptual systems attempt to understand the connection between the input (sensation) and the output (perception) of these systems.

INTRODUCTION

Humans are equipped with a series of sensing systems that give us information about the environment around us. Ranging from tactile sensors that allow us to grasp and feel an object, to our visual system that allows us to recognize family and friends across a crowded room, our senses provide us with vital information about our immediate and distant environment. One of the goals of cognitive scientists is to understand how the human brain converts the raw data from each of these sensing systems into a coherent and meaningful interpretation of the outside world. One of the approaches to understanding how this is done is to develop computational models of perception that use either real or simulated sensory data, which provide a meaningful interpretation of the data.

Because our cognitive system is designed to interpret sensory data with such remarkable speed and accuracy, it is often difficult to appreciate some of the computations that are involved in a common event. For example, imagine that you are walking down the sidewalk and you suddenly hear a loud sound behind you. This sound would produce a significant startle response, causing you to turn your head immediately to observe the event. Your visual system would then provide you with distal information about the scene (*See* **Visual Scene Perception**). Seeing a bicycle careening out of control in your general direction, you might decide to jump off the sidewalk on to the grass lawn. Wanting to ensure that you would not hurt yourself too badly during this move, you might hold your arms out to 'break' the impact of your fall. On feeling the grass touching your hands, you would gently collapse the muscles in your arms so that you landed safely on the grass.

The above example demonstrates how we use our senses every day with little thought. In this example your auditory system received a series of sound pressure waves indicating a loud sound. Your perceptual system processed the sound waves in order to localize the source as being behind you. Your visual system then received visual information about a moving object and quickly calculated the motion vector of the object to determine that it was heading in your general direction. Finally, your tactile system allowed you to determine the time of contact so as to break your fall safely after jumping out of the way of the careening cyclist.

Each and every day we perform thousands of processes on the sensations that our body and brain receive. These senses provide the fundamental input to our cognitive system that enables us to interpret the world around us. Whether they are determining whether Stilton cheese and walnuts taste good together or they are avoiding an out-of-control cyclist, our senses are providing our cognitive system with vitally important information about our environment.

PROCESSING SENSORY INFORMATION

Our senses provide us with a wealth of information. However, in its raw form this data is not very informative. Somehow the cognitive system must utilize the raw sensory data and interpret it informatively. In the above example, the visual system provided the pedestrian with essential information about the direction of travel of the cyclist. If the cyclist had been traveling in the

opposite direction, it would not have been necessary to jump out of the way. Using the raw images that are projected on to the retina is insufficient for estimating the direction of an object. In order to calculate the heading direction of the cyclist accurately, the visual system must make multiple computations across time to calculate the object's heading precisely.

Research scientists who are interested in understanding human perception often attempt to model the input–output relationship between sensation and perception. That is, using the information that is available to the human visual system (e.g. a series of raw images), these researchers will postulate how the raw information is processed and develop computational models that make explicit calculations about the external environment (e.g. the heading of an object, given a sequence of images). These models then make predictions about how other stimuli will be processed by the human observer, and if they model human perception accurately, these predictions will be supported by empirical (behavioral) data.

INFLUENCE OF NEURAL CODING STRATEGIES

Although perceptual models are mainly influenced by behavioral data, these models are also strongly influenced by knowledge from neuroscience. Neuroscientists are interested in understanding how specific types of information are processed and encoded in the brain. To do this, they use a technique called single-cell recording. Single-cell recordings are made by inserting an electrode into a neuron (or a group of neurons) and measuring the neural responses of these neurons to specific stimuli (e.g. an image or a sound). From an understanding of the properties of a group of neurons in a specific area of the brain, neuroscientists try to deduce the computations completed by this group of neurons.

Understanding how specific neurons in the brain respond to specific stimuli has greatly influenced our understanding of visual perception. The human eye serves as the initial sensing device for the visual perceptual system. The eye is equipped with an array of light-sensitive neurons that convert light energy into neural responses. Research scientists have presented carefully controlled stimuli to a visual system while making recordings from different areas of the eye and/or brain. These studies have revealed a number of important facts about the neural processing of visual stimuli. Although the details of these studies are beyond the scope of this article, the following sections provide an introduction to some of the properties elucidated by the use of this technique.

Receptive Fields

An important concept in the subject area of perception and neuroscience is that of a receptive field (*See* **Amygdala**). Most sensing systems have some type of receptive field coding. However, the concept of a receptive field is perhaps most intuitive with regard to the visual system. To understand the concept of a receptive field fully, one needs to understand the initial input into the visual system. The retina is located at the back of the human eye and is composed of approximately 130 million individual cells called photoreceptors that measure the light from a very small part of the visual field. These cells convert that light energy into neural responses. The retina is similar to the charge-coupled device (CCD) on a digital camera or digital video camera that converts light energy into electrical signals that can be recorded on to a digital medium. However, instead of recording these light intensities, the visual system subjects them to a series of online processing to convert them into meaningful pieces of information about the external world. In fact, there is major information processing of the image within the eye itself.

Each photoreceptor in the eye has a specific receptive field. That is, each cell is responding to light that is projected from a specific area of the visual field. If one was to shine a light on a specific photoreceptor, the neuron would become active, but shining the light anywhere else on the retina would produce no response. One can infer the receptive field of a photoreceptor by recording where the light is when the cell fires. The cells that leave the eye are called ganglion cells. The latter have dramatically different receptive fields to those of the photoreceptors. Ganglion cells take input from multiple photoreceptor cells that try to excite or inhibit the response of a given ganglion cell. Figure 1 illustrates the influence of photoreceptors on ganglion cell responses.

Using single-cell recording techniques, researchers have determined that there are two types of ganglion cells, both of which have a 'center–surround' receptive field (see Figure 1). One type of ganglion cell has an 'on-center–off-surround' receptive field. These cells respond maximally to an image that has a bright center with a dark ring surrounding it. The 'off-center–on-surround' cells have the opposite configuration.

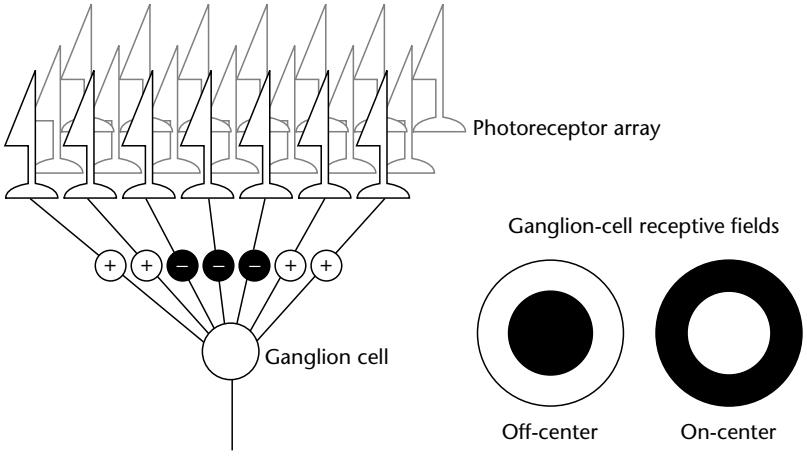

Figure 1. Two types of center–surround ganglion cell receptive fields ('off-center–on-surround' and 'on-center–off-surround'). The diagram on the left demonstrates the relationship between ganglion cells and photoreceptors. Activation of some photoreceptors will excite a ganglion cell ('+' connection), while other cells when activated (i.e. shown light) will inhibit the response of the ganglion cell ('−' connection). This type of relationship between photoreceptor and ganglion cell would produce an 'off-center' ganglion cell receptive field. The two diagrams on the right illustrate the optimal stimulus (i.e. the stimulus that gives the largest response) for the two types of ganglion cell. One responds best to a stimulus with a dark center and a bright surround, while the other responds best to a stimulus with a bright center and a dark surround.

Perceptual Influence of Ganglion Cells

The famous Hermann illusion is shown in Figure 2. This can be explained by the output of the ganglion cells from the eye. Almost immediately upon viewing the image in Figure 2 you will observe a series of gray areas between the white intersections. If you inspect the image closely (perhaps by covering up any four squares with your fingers while leaving the four-way intersection visible), you will see that these gray areas are not in fact part of the image. That is, the areas are solid white. This graying is an illusion produced by our visual system.

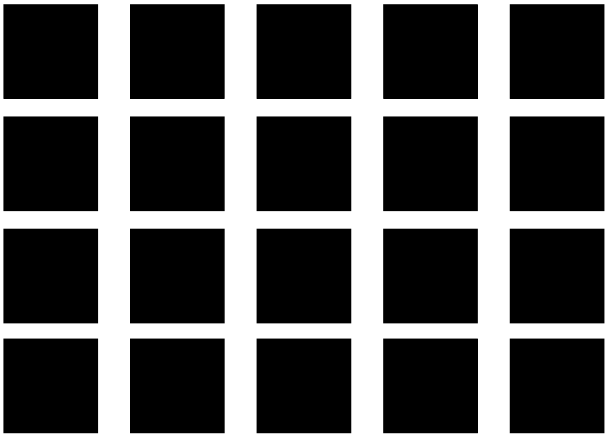

Figure 2. The Hermann illusion. Note the perception of gray dots at the intersection of each white '+' symbol. These gray dots are a perceptual illusion that can be explained by the output of visual ganglion cells.

In order to understand the illusion, we can refer back to the center–surround receptive fields of the ganglion cells. Figure 3 provides an explanation as to why we perceive the stripes as being brighter than the four-way intersections. The explanation relies on the output of the center-surround receptive fields found in the ganglion cells of the eye (see Figure 1). The on-center–off-surround cells have different levels of activation on the stripes to those that they have on the intersections. The ganglion cells that are spatially centered on the stripes will receive positive input from the white bar, and will receive a small amount of negative input from the white bar. By contrast, the ganglion cells that are spatially centered on the intersections will receive the same positive input as the cells on the stripes, but they will receive much more negative input from the two sets of stripes (the two white stripes; see right-hand side of Figure 3). This increase in negative input into a ganglion cell will cause the ganglion cells on the stripes to be more active (indicating a higher contrast) than the cells on the intersections. The brain then interprets this difference in ganglion cell output activation as the stripes being brighter than the intersections.

The Hermann grid illusion provides a good illustration of the basic principles underlying perceptual

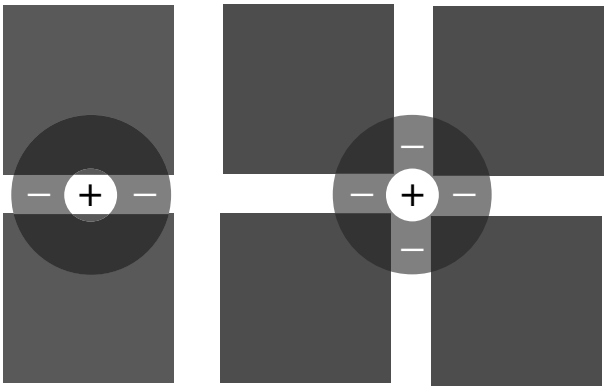

Figure 3. Application of the center–surround receptive fields to the Hermann grid illusion. The ganglion cells that are 'on-center' receive more negative input at the four-way white intersections than at the white stripes. This increase in negative input to the 'on-center' ganglion cells produces a smaller response for ganglion cells at the intersections than for those on the stripes. This reduced response translates into an interpretation by the visual system that the area is not as 'bright', thus producing the illusion observed in Figure 2.

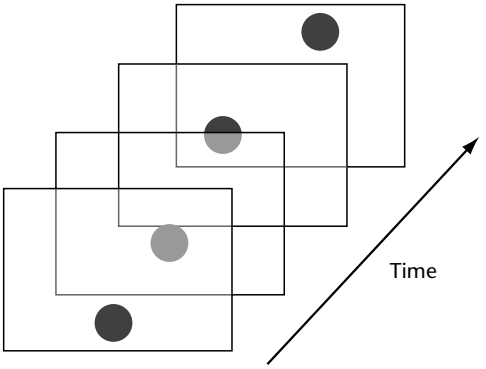

Figure 4. Illustration of apparent motion. A circle moves from the lower part of the image in frame 1 (the foremost frame) to the top of the image (the last frame). If these four images are viewed in succession with a fraction of a second presented between each frame, the human visual system perceives the circle to be moving from the bottom of the image to the top of the image.

modeling. The endeavor typically begins with a perceptual observation – in this case the dark spots in the Hermann grid. This is then followed by an observation in neuroscience or a hypothesis about how the neural substrate may be processing visual information to produce the behavior. In this example, the explanation started with a neuronal observation, namely the center–surround receptive fields of the ganglion cells. Following the observation or hypothesis, a model is developed. In this case, the model is a rather simple one in which the excitatory and inhibitory responses from the retina are simply added together to obtain a ganglion response. Although this is a simple example, it illustrates how all perceptual modeling is typically completed.

MOTION PERCEPTION

The Hermann grid illusion provides an important illustration of modeling perceptual processing for static images (*See* **Vision: Early Psychological Processes**). However, most of the time we do not process static images, but rather we need to deal with our highly dynamic environment in which objects move relative to one another, producing the perception of motion. As was illustrated by the example of the out-of-control cyclist, it is often important to judge the motion direction of other objects relative to one's own body. At other times, perhaps while driving, one needs to adjust one's heading or speed in relation to other objects. Both of these tasks rely on the visual system providing an accurate cue of how objects in the environment are actually moving. To make these computations, one needs to analyze more than one image (unlike analysis of the Hermann grid illusion). Figure 4 illustrates a motion effect. The figure contains a series of four images. If the sequence of images was to be presented rapidly, one's visual system would interpret the scene as a circle moving from the bottom to the top of the page. One can observe this motion phenomenon with 'flip-books', which are composed of several hundred images in which the objects are moved slightly from one page to the next in the book. By rapidly 'flipping' the pages (typically with one's thumb) one perceives apparent motion of the objects in the images. This technique of apparent motion is the basis of cartoons and motion picture production. By drawing a series of images, or taking a series of pictures across time and then presenting them in rapid succession, the objects in the movie are perceived to be actually moving.

Computing Motion

Unlike our earlier analysis of the ganglion system that could be understood by modeling a single image, motion computations rely on computations from multiple frames (*See* **Motion Perception, Psychology of)**. There are two important parameters that define the movement of an object in space, namely the direction in which the object is moving and the speed at which the object is moving. Computational models of motion attempt to calculate both of these properties of motion from a sequence of images presented to the retina.

Measuring motion direction

Figure 5 shows a simple model of motion estimation using a delayed-circuit approach. There is a series of receptors that respond to changes in luminance. When there is a change in luminance (either from light to dark or from dark to light), these cells try to activate the cells to which they are connected. If the cell is connected to a 'delay' unit, the latter waits a certain period of time before sending the activation to the direction-selective cells to which it is connected. In Figure 5 the direction-selective cells have to receive activation from two cells simultaneously in order to be active. If we assume that the delay is one time slice, then the second receptor from the top will receive a change in luminance on time slice 3, and will send that activation instantaneously to the delay unit. On time slice 4, the uppermost receptor will receive a change in luminance, and will send that activation to the vertical direction-selective unit. At the same time, the delay unit will also send its stored activation (from time slice 3) to the vertical motion-selective cell. In this case, the vertical direction-selective cell will receive activation from two units simultaneously (from the delay unit and from the uppermost receptor).

If we analyze the downward direction-selective cell, we find that it does not receive activation from two cells at the same time. On time slice 1, the unit receives activation from the lowest receptor. On time slice 2, the second lowest receptor receives a change in luminance and sends its activation to the delay circuit. After a delay of one time slice (on time slice 3), the delayed activation is sent to the downward direction-selective cell. The latter receives activation on time slice 1 and time slice 3, thus not satisfying the requirement for receiving activation from two sources simultaneously in order to become active.

Measuring motion speed

As was mentioned earlier, there are two important components to the perception of motion, namely direction and speed. Figure 5 illustrates how motion direction is computed, but it does not specify how the speed of the motion is computed. To measure the speed of the motion in addition to its direction, one simply needs to modify the amount of delay. In the above example the delay was set to one time slice. If we add another unit that receives direct input and input that is delayed by three time slices, then we have one unit that is sensitive to upward motion which is fast (a delay of one time slice) and a second unit that is sensitive to slow upward motion (a delay of three time slices). Using this model can probe the motion-direction cells to determine the direction of motion in a particular location in the visual field, as well as estimating the speed of the motion.

VISUAL OBJECT RECOGNITION

An impressive component of human perception is our ability to recognize three-dimensional objects from their two-dimensional retinal projections (*See* **Vision: Object Recognition**). We are so proficient at human object recognition that it can be difficult to understand completely some of the difficulties faced by our human object recognition

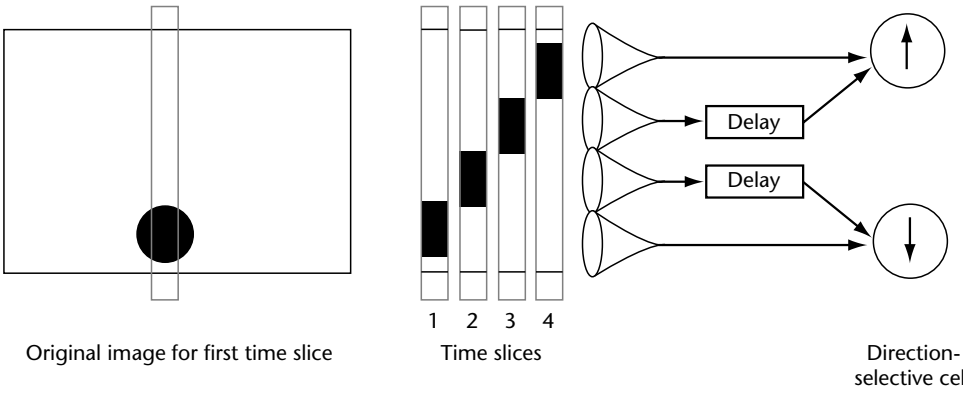

Figure 5. A simple motion-detection model. The image on the left-hand side is the original image for the first time slice shown in Figure 4. The black box is selecting a single column of pixels for the analysis. The right-hand side shows the same column of pixels for time slices 1 to 4 from Figure 4. The far right-hand part of the figure shows a method for detecting upward motion and downward motion using a delay circuit. When the circle moves from one receptor to the next at the appropriate delay, the responses from the upper two cells activate the vertical-motion detector simultaneously. This simultaneous activation indicates that there was vertical motion at a specific rate. The lower two receptors are wired to detect downward motion.

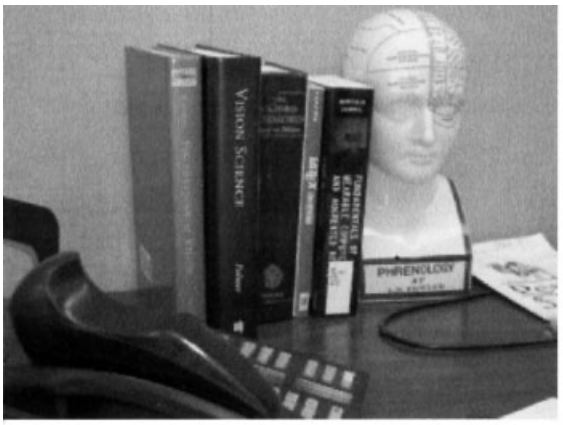

Image 1

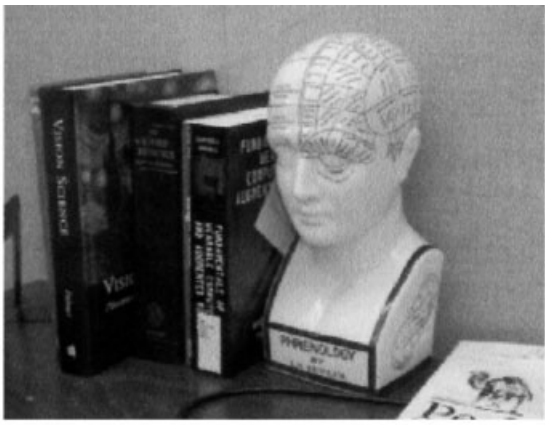

Image 2

Image 1 – Image 2

Figure 6. Example of object recognition performance. The upper two images are two views of the same scene. Immediately upon viewing these images one is able to determine that the two images are projections of the same set of objects. However, the sets of images are dramatically different, as is illustrated by the lower image that is the difference between the two upper images. If the images were identical, the lower image would be black.

system. Perhaps one of the most amazing aspects of human object recognition is that we are able to classify an image as a projection of a known object despite the fact that we will never see the same image projection twice. Figure 6 illustrates this. The two images are projections of the same three-dimensional object from two different viewpoints. Almost immediately upon viewing the two images you were probably able to determine that the two objects were the same. However, closer inspection shows that the two images are dramatically different. To illustrate just how different these two images are, we can simply take a difference in the image intensities at each image pixel. Figure 6 illustrates this difference. As you can see, these two images differ quite substantially.

Figure 6 illustrates one of the fundamental challenges faced by the human visual system, namely recognizing objects from different images when a certain imaging variable is changed. In this illustration the imaging variable that has been changed is viewpoint, but you can achieve a similar effect by changing the lighting direction, or by occluding part of an object by placing one object in front of another. However, to illustrate the modeling components of visual object recognition I shall mainly consider issues associated with viewpoint.

Feature Models of Human Object Recognition

One approach to modeling human object recognition is to propose that the visual system does not store in memory the precise pixel array to match new views of an object, but instead stores a collection of features in memory. The features might consist of extracted edges, color and/or vertices. For each object stored in memory, there would be a feature vector that would specify the set of features for a particular object. According to this

approach, the location of the features in the image is not important. Simply having the same set of features would be sufficient to enable the object's identity to be determined.

Limitations of feature models

Because feature models do not store the locations of the features, these models can recognize new views of an object if the same set of features is present in the image. However, this has a consequence. Simply specifying the set of features without specifying their spatial relationships in the image produces some strange behavior. For example, a feature model would treat the two images shown in Figure 7 as equivalent (the features are all present – they have just been rearranged from one image to the other). Although we might classify the image on the right as a mug, our perception of the objects in the two figures are not equivalent. Feature models would classify these two images as containing an identical object. A second limitation of feature models is that as an object is rotated in depth, the set of image features in one view becomes occluded (unobservable) in another view (for example, in Figure 6 the left ear of the phrenology head in Image 2 is not visible in Image 1). This makes the correspondence problem difficult for these models.

Alignment Models

More sophisticated versions of the feature models are alignment models (*See* **Mental Rotation**; **Vision: Object Recognition**). Unlike the feature models, alignment models utilize the spatial arrangements of the features in the image. However, in order to compensate for viewpoint changes, these models allow for specific types of image transformation on all of the collection of image features and their locations. For example, some simple image transformations that can be achieved include changing the size of the image (scale), changing the position of the image (translation) and rotating the object around the line of sight. By applying these image transformations from one view of an image to another, we can recognize new views of an object by applying these transformations to the set of features stored in memory and seeing whether they can be aligned with the locations of the features in the viewed image.

Limitations of alignment models

Alignment models are capable of aligning one view of an object with another if the change in viewpoint is due to a change in the object's size (scale) or location in the image (translation), or to rotation in the picture plane. However, these models encounter problems with rotations in depth when features become occluded (e.g. the left ear of the phrenology head in Figure 6). Because these models use features and align the positions of those features from one view to another, it is usually necessary to solve the correspondence problem (i.e. to determine which feature in one image corresponds to a feature in another image). When objects are rotated in depth, new features can appear while other features become occluded (*See* **Vision: Occlusion, Illusory Contours and 'Filling-in'**). Under these conditions, aligning the set of features from one view to another can be a very difficult task.

Part-Based Models

Another way to model human object recognition is by using a part-based approach. Part-based models begin by decomposing an object into a set of simple

Figure 7. A challenge faced by feature models of human object recognition. The features of the object on the left-hand side remain present when the image is scrambled. According to the feature approach, the two images are the same.

volumetric primitives. After the object has been decomposed into its constituent parts, the model then uses the image features to make shape estimations of the parts. For example, the cup part of the mug might be described as having a 'curved cross-section' and a primary axis that is 'straight'. The handle might also be described as having a 'curved cross-section', but with a primary axis that is 'curved'. In addition to describing the parts, these models also specify the relationships between the parts. For example, the simple volume describing the handle might be described as being 'beside' the cup portion of the mug. In these models the inter-part relationship can either be specified with respect to the viewer (e.g. 'beside' is specified as being to the left or the right of another part) or relative to the object as a whole (e.g. 'beside' is specified as being to the left or the right of the global primary axis of the object).

Limitations of part-based models

One of the primary limitations faced by these part-based models is segmenting the object from the background and then decomposing an object into its constituent parts. Although to most people it is obvious which parts of the image shown in Figure 6 are the object and which areas are the background, making these distinctions from the gray-level image can be difficult. A second limitation of these models is the ability to make the appropriate shape inferences from the gray-level image. That is, although there are image cues that may provide clues as to whether the cross-section is curved or straight, these cues can be very subtle in the image, and extracting them can prove challenging.

SUMMARY AND CONCLUSIONS

Perception plays an important role in our ability to interpret our environment. Whether we are watching a child ride a bicycle or listening to an old friend's voice on the telephone, perception is at work trying to convert the raw sensory data into a meaningful interpretation of the world around us. Because perception plays a vital role in our knowledge of the world in which we live, cognitive scientists are interested in understanding how the human mind converts these raw sensory patterns into meaningful interpretations. In order to understand better how a perceptual system might interpret raw sensory patterns, perceptual scientists will develop computational models of a specific perceptual process. These models will try to account for the current body of behavioral data as well as making novel predictions about human perception that can be tested.

Phonology, Neural Basis of

Intermediate article

KG Munhall, Queen's University, Kingston, Ontario, Canada

CONTENTS

The phonology of a language includes a representation of the set of sounds used in the language and a representation of the rules for producing and perceiving the sounds in sequences. Clinical evidence from aphasic patients indicates that phonological impairment on language perception and production results from both anterior and posterior cortical lesions. Functional imaging research has confirmed this pattern and using these techniques a more detailed neural mapping of the neural basis of phonology is beginning.

INTRODUCTION

At the heart of natural human language is an oral-, aural-based sound system called a phonological representation. To be a native speaker of a language means that you have learned to say and hear a set of sounds (the phonetic inventory) that is unique to that language and have learned a set of rules for ordering these sounds (phonotactic rules) and producing them in contexts (allophonic rules). The more than 5000 living languages exhibit a diverse set of phonetic inventories ranging in size from 11 sounds in languages such as Rotokas and Mura to more than 140 sounds in languages such as !Xu (see Maddieson, 1984). Languages also have quite different phonotactic and allophonic rule systems. So, for example, the vowel in the English word 'cat' does not occur in the Japanese phonetic inventory, nor do Japanese phonotactics permit a syllable final /t/. English voiceless stops such as /p/ have aspirated and unaspirated allophones whereas in other languages such as Bengali, Korean, and Sesotho aspiration is used contrastively. Words beginning with the aspirated versus unaspirated versions of /p/ will differ in meaning in these languages.

When you speak, listen to, and read your native language you access this sound representation or phonology and this processing is carried out by dedicated neural systems. Phonetics and phonology are two aspects of the same sound system. Traditionally phonetics refers to the physical realization of the more abstract phonological categories. While there is considerable overlap in the domains of these two components of language, this review will primarily focus on the the more abstract phonological representation and its use in spoken language processing. The localization of this phonological function has been at the heart of neurolinguistics since Broca and Wernicke first described patients with language production and perception disorders. In this article, the neural basis of phonological representation will be summarized and the contributions from recent imaging studies will be reviewed.

CLINICAL EVIDENCE

One of the earliest ideas about neurolinguistics was that separate components of the language system could be selectively impaired. While this selectivity is rare or perhaps nonexistent, it is clear that there are disproportionate deficits associated with particular lesions. There is abundant evidence that phonology is affected in this manner by neurological damage. Although it is difficult to distinguish the representation of phonology from processes that use this knowledge, lesions in a few areas have long been known to impair phonological aspects of language use. These include the left inferior frontal gyrus and the left superior temporal gyrus, extending into the supramarginal and angular gyri. Lesions in these areas are associated with well-known aphasic syndromes (Broca's aphasia, Wernicke's aphasia, conduction aphasia) that include phonological impairment as part of their spectrum of deficit.

Traditionally, anterior aphasias with frontal lobe lesions in Brodmann's areas (BA) 44 and 45 have been described as having a deficit in phonological output. Language output by these patients is slow and labored with many sound errors. Posterior lesions in the superior posterior temporal regions

have been characterized as producing problems with receptive phonology. Language output by these patients is generally fluent, but there are severe deficits in comprehension. This anterior–posterior typology, however, has been questioned on a number of grounds.

Both anterior and posterior aphasias show disturbances in phonological aspects of language input and output (Caplan, 1992). In experimental speech perception tasks, both anterior and posterior aphasias show deficits in judging phonological contrasts such as the first consonant in 'bear' vs. 'pear' (e.g. Blumstein *et al*., 1977). In experimental production tasks, all aphasias show difficulties in producing the correct phonological forms of words. These difficulties include problems selecting and ordering the sounds in words (e.g. Blumstein, 1973) with both anterior and posterior aphasias having a large number of sound substitution errors (Blumstein, 1998). While anterior and posterior aphasias are certainly distinguishable on the basis of patterns and types of phonetic and phonological errors, there is significant phonological involvement in both of these diagnostic categories of aphasia.

At first glance this broad cortical involvement suggests that phonological processing must involve a complex and distributed neural network. However, it has become clear in recent years that language processing, including phonological processing, is subtly sensitive to the requirements of experimental and clinical tasks. Tasks such as silent noun generation, rhyme judgments, visual object naming, and spontaneous speech all involve phonological processes but differ in what aspects of phonology are involved, how the phonological representation is accessed, and in the number of other language processes involved (see, for example, the task analysis in Indefrey and Levelt, 2000). Because of this complexity, the boundaries of the phonetic, phonological, lexical, and semantic components of language are difficult to distinguish in the tasks that are commonly used to test phonological processing. These difficulties have played a significant role in modern functional neuroimaging.

RECENT CONTRIBUTIONS FROM FUNCTIONAL IMAGING

Since the onset of positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) of language (Petersen *et al*., 1988, 1989), the comparison of neural activation patterns between two tasks has been at the heart of experimental designs. Regional cerebral blood flow measures during a baseline task are commonly subtracted from or compared to the regional blood flow estimates during a target activation task. Baseline conditions are selected with the assumption that they differ from the activation condition only in the processing component that is being tested. The validity of this assumption has been questioned for the study of phonology (e.g. Price and Friston, 1997) and other linguistic activities (e.g. Jennings *et al*., 1997). Further, the experimental tasks utilized in various imaging studies differ on many dimensions and thus potentially involve different aspects of phonology. These task factors have created controversy about the exact localization of the neurological substrates of phonological processing (Démonet *et al*., 1996; Poeppel, 1996).

In spite of these methodological problems, functional imaging has yielded some consistent patterns for phonological activity. The posterior region of the superior temporal gyrus is one of the most common cortical areas associated with phonological tasks. Studies that focus on auditory speech processing have consistently shown posterior temporal lobe activations (e.g. Petersen *et al*., 1988; Démonet *et al*., 1992; Zatorre *et al*., 1992; Fiez *et al*., 1995; Price and Friston, 1997; Binder *et al*., 2000; Scott *et al*., 2000; Wise *et al*., 2001).

Binder and colleagues (e.g. Binder *et al*., 1996; Binder 1999) have proposed that speech processing follows a dorsal to ventral pattern in the temporal lobe. The preliminary auditory processing takes place in the primary auditory area in the superior temporal lobe. Further processing takes place in more ventral areas within the superior temporal sulcus (STS) where phonemic pattern recognition takes place. Activations of the STS have also been observed for lipreading and audiovisual speech perception (e.g. Calvert *et al*., 1997, 2000). More ventrally in the medial and inferior temporal lobe lexical and semantic processing are thought to take place. Others have confirmed this dorsal to ventral pattern (e.g. Scott *et al*., 2000; Wise *et al*., 2001) but also have suggested that the anterior–posterior axis in the temporal lobe differentiates different phonological functions. In Scott *et al*.'s study the anterior STS only showed activation for intelligible speech while the posterior STS showed activation for auditory phonetic cues independent of the intelligibility of the utterance.

Studies that focus on speech production and reading also show activity near the posterior temporal region. Indefrey and Levelt (2000) concluded from their review of 58 word production studies that the posterior superior temporal gyrus is involved in retrieving phonological structure during

word production. Further, there are a number of studies showing evidence of temporal lobe processing of auditory feedback during speech (see Munhall, 2001 for a review). Studies of reading show posterior temporal activations during phonological tasks as well (Fiez and Petersen, 1998) and also in areas slightly posterior to this (e.g., BA 40; Price, 1998).

As suggested by the lesion data, the inferior frontal cortex plays a significant role in reading and spoken language. There is good evidence that the frontal cortex can be subdivided into areas involved in semantic processing (anterior inferior frontal/prefrontal areas) and phonological processing (posterior inferior frontal cortex; Fiez, 1997; Fiez and Petersen, 1998). In this latter region, Broca's area and the surrounding inferior frontal lobe show activation during a range of different speech and phonological tasks (e.g., Petersen *et al*., 1988, 1989; Sergent *et al*., 1992; Zatorre *et al*., 1992, 1996; Démonet *et al*., 1992, 1994; Paulesu *et al*., 1993; Price and Friston, 1997; Fiez and Petersen, 1998; Poldrack *et al*., 1999, 2001; Burton *et al*., 2000).

Meta-analyses of these studies have led to proposals for further subdivisions of the posterior inferior frontal gyrus for different types of phonological processing. For example, Burton (2001) suggests that auditory speech processing involving segmentation shows activation in superior and posterior parts of the inferior frontal gyrus while visual phonological judgments (mostly rhyme decisions) activate areas slightly inferior and anterior to those areas involved in auditory speech processing (Fiez and Petersen, 1998). Speech production is strongly associated with the frontal operculum and anterior insula (Wise *et al*., 1999), but similar areas have been implicated in the translation of semantic information to a phonological form (Price, 1998) and the translation of orthography to phonology (Fiez and Petersen, 1998).

CONCLUSION

Considerable progress has been made in the last 10 years in understanding the anterior and posterior cortical regions involved in phonological activity; however, a range of problems is still unresolved. First, the roles played by the right hemisphere and subcortical structures in phonological processing are not well understood. Clinical studies show that lesions in the left hemisphere produce significantly more phonological disorders than right hemisphere lesions, but the functional imaging work has frequently shown bilateral activation for phonological tasks (Hickok and Poeppel, 2000). Subcortical structures are a significant part of the language network including phonological processing (Nadeau and Crosson, 1997), but much remains to be learned about their role. Clearly, for both the right hemisphere and subcortical structures further work will be necessary to understand their full contribution to phonological processing. Second, functional imaging experimental designs use many different baseline and activation tasks. A complete understanding of the neural basis of phonology awaits a more comprehensive description of what actually is involved in phonological processing during these tasks. Finally, much of the work that has been done has focused on the English language. Recent work by Paulesu *et al*. (2000) demonstrates different patterns of activation for reading and naming tasks in Italian and English speakers. These results suggest that not only must we understand what is involved in phonological tasks but we must understand tasks within the context of a specific language system.

Place Cells

Intermediate article

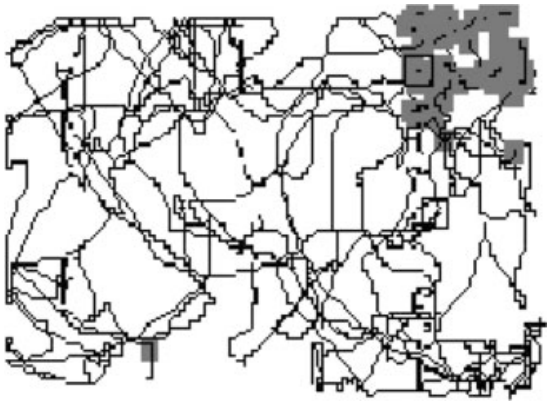
John O'Keefe, University College London, London, UK

CONTENTS

Research in the 1970s first suggested that neurons in the rat hippocampus signaled the animal's location in its environment. This prominent correlation with the animal's spatial location has led to these cells being termed place cells.

THE ROLE OF HIPPOCAMPAL PYRAMIDAL CELLS

In the early 1970s, O'Keefe and Dostrovsky reported that neurons in the rat hippocampus signaled the animal's location in its environment, and they suggested that these place-coded cells might provide the animal with a spatial map of its environment (O'Keefe and Dostrovsky, 1971). As the animal moves around a familiar environment, the typical hippocampal pyramidal cell will be silent for most of the time, only springing into activity each time the animal enters a delimited area. This prominent correlation with the animal's spatial location has led these cells to be called *place cells*, and the location where each cell fires is called its *place field*. An example is shown in Figure 1. The activity of this hippocampal unit was recorded as the animal searched for random pieces of food in a familiar rectangular-shaped environment. Place cells recorded in open-field environments fire regardless of the direction in which the animal is facing. Figure 2 shows the firing of a different place cell recorded while the rat foraged in a cylinder. The central panel shows the field regardless of the direction in which the animal is facing, and the four outer panels show the firing as the animal moved in different directions through the place field. One can rule out the possibility that the nondirectionality of this and similar cells is simply a response to olfactory or tactile cues on the floor of



(a)

(b)

Figure 1. [*Figure is also reproduced in color section*.] Place field of a hippocampal pyramidal cell. (a) Solid line shows the track of a rat foraging in a rectangular box for randomly located pieces of food. The red square shows the animal's location when the cell fires. (b) False color map of place field created by dividing the cell's firing rate in each location by the amount of time that the animal spent there.

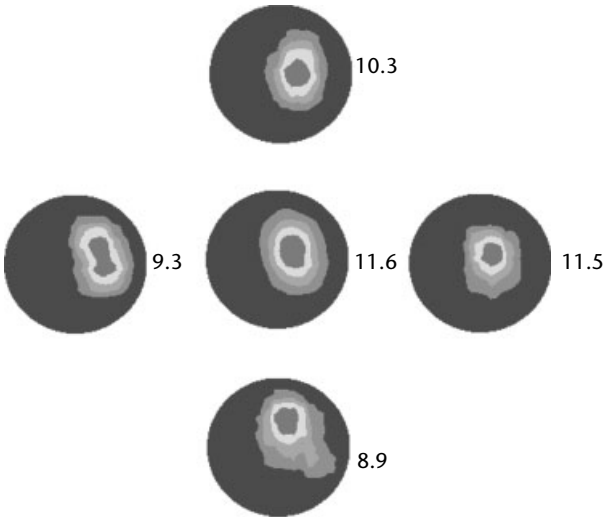


Figure 2. [*Figure is also reproduced in color section.*] Place cells are non-directional in open-field environments. The middle panel shows the firing field of a cell in a circular environment regardless of the direction in which the animal is facing. The four outer panels show the firing fields when the animal is facing north (upper), east (right), south (lower) and west (left). The number to the right of each panel is the firing rate in the hottest (red) region.

the enclosure, since the cells continue to fire in the same location when the floor is replaced or the box is rotated. We can conclude that, in open-field environments, the cells are signaling the animal's location rather than responding to some simple stimulus in that location.

Different cells identify different locations in an environment, and a collection of place cells taken together provides information about the animal's location at all points in the environment. Most place cells have a single compact place field in an environment, but a small proportion (*c*. 5%) have two or in rare cases even three such fields. Figure 3 shows the firing fields of 32 cells recorded simultaneously in a square-shaped environment. The firing fields have been organized so that cells with fields on the left-hand side of the box are shown on the left-hand side of the figure, and so on. It is clear that even in a small sample of cells there is one active field wherever the animal finds itself in the box. However, unlike the topographical representation of surfaces or receptors found in the neocortex, there appears to be no systematic relationship between the anatomical location of cells within the hippocampus and the places that they represent in an environment. Neighboring pyramidal cells are as likely to have fields distant from each other in an environment as to have fields close together (Redish *et al*., 2001). This simple basic fact points to a difference in reference frames between neocortical and hippocampal spatial representations.

In the neocortex, the reference frame is fixed to and centered on a sensory receptor surface such as the eye or the head, and there is systematic grouping of cells with similar response properties. These reference frames are collectively described as *egocentric*, since they are fixed to and move with the receptor surface. However, in the hippocampus no such fixed reference frame exists. This representation, which is not fixed to a body surface but to features of the environment, is described as *allocentric*. Cells are not systematically grouped within the hippocampus according to their place fields in an environment, or according to any other variable that has been identified. A given location is represented by a random subset of place cells distributed across the hippocampus. This may reflect the fact that the spatial relationships of the stimuli and features which make up a given environment cannot be known *a priori*, and the same cells can represent different locations in different environments. Therefore no predetermined topography can exist.

Place cells have been found in the CA3 and CA1 regions of the hippocampus proper, in the dentate gyrus, and in the subicular region and the entorhinal cortex. It is believed that the exteroceptive sensory information about environmental landmarks reaches these areas via the entorhinal cortex. The anatomical connections between these regions are such that the place representation in one area (e.g. CA1) may be built up through a series of stages (e.g. from EC through DG and CA3 to CA1), or it may be constructed independently on the basis of the information sent directly into each region separately from the entorhinal cortex. This anatomical organization suggests that under some circumstances, different parts of the hippocampal formation can act independently. Evidence for this view comes from experiments in which CA1 place cells can still be recorded following destruction of CA3 (Brun *et al*., 2002), and from experiments which show that CA1 place-cell activity can be dissociated from hippocampally dependent spatial learning (Jeffery *et al*., 2002). (*See* **Hippocampus**)

Not all cells have simple locational correlates. Although many complex-spike cells can be classified as simple place cells, others have more complex properties (O'Keefe, 1976). The firing rate of complex place cells is dependent on other factors in addition to location. For example, some cells increase their firing rates if the animal experiences a particular object or smell in the place field (Wood *et al*., 1999), or if it engages in a particular behavior

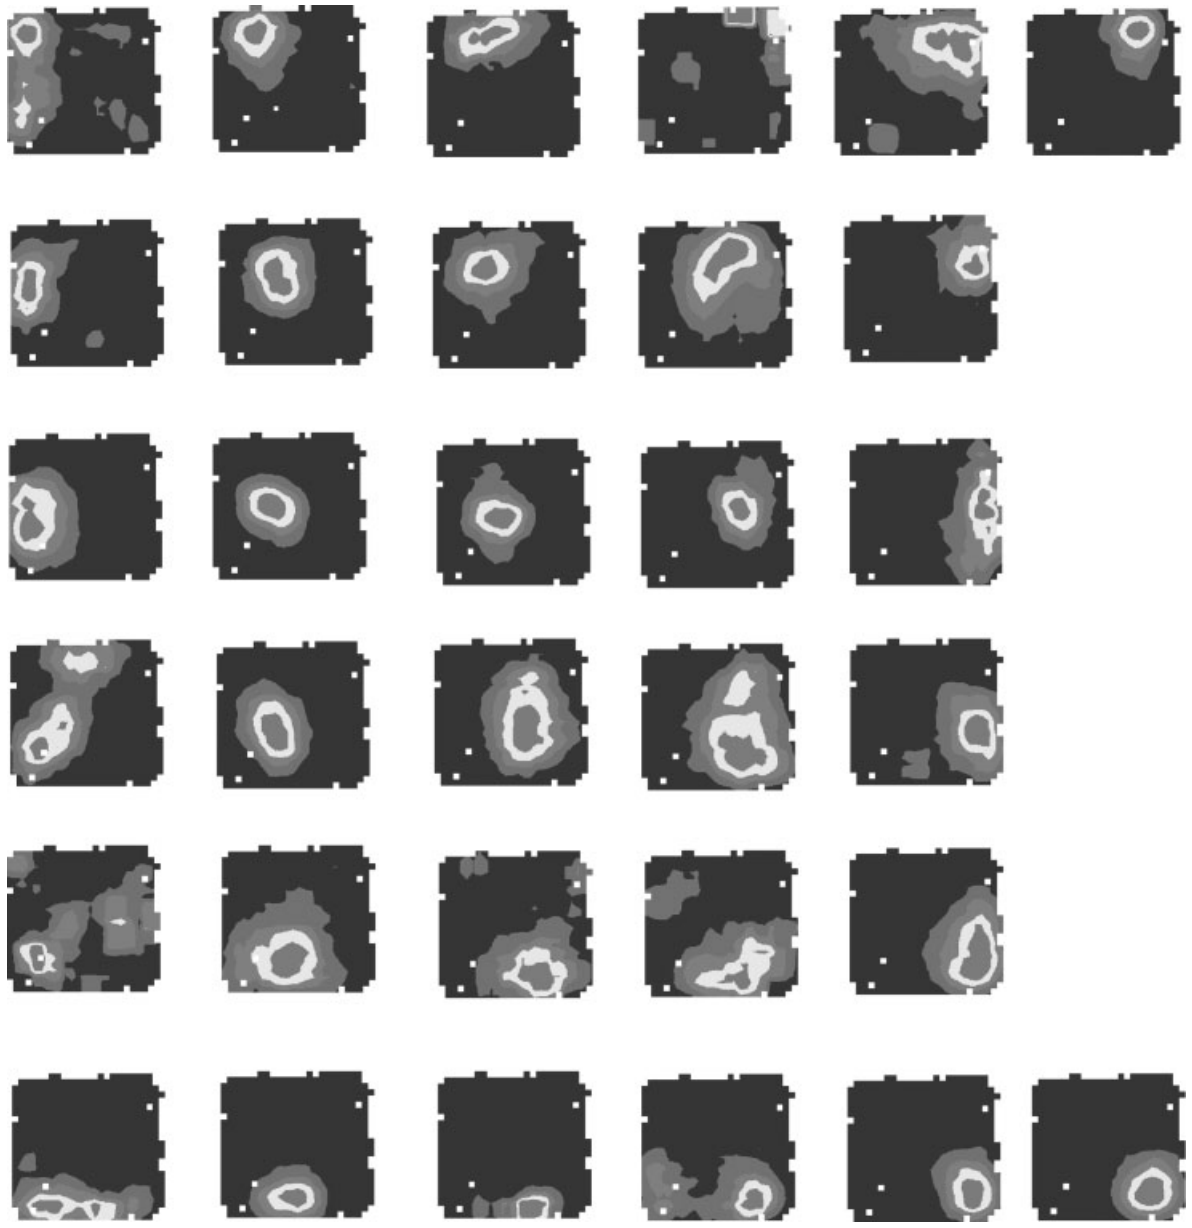

Figure 3. [*Figure is also reproduced in color section.*] Place fields of 32 simultaneously recorded hippocampal pyramidal cells. The firing fields have been organized so that fields located along the upper boundary of the testing box are located on the upper part of the figure, fields located along the left edge of the box are located on the left side of the figure, and so on. The 32 fields cover most of the environment. (After Lever *et al*., 2002.)

there. Others increase their firing rates when the animal either finds something new in the place field or fails to find something expected there. These cells are called *misplace* or *complex place* cells. As we have seen above, in open-field cylinders the place fields are non-directional (Figure 1). However, in more structured maze tasks they are highly directional. The same cells which have non-directional fields in a cylinder have directional fields in the radial arm maze (Muller *et al*., 1994). Although it is not known with certainty, the most important variable affecting directionality is likely to be whether the animal is free to face in different directions or to turn around in the place field.

Some place cells have fields in more than one environment. If the environments are different enough, there does not appear to be any relationship between the fields in terms of size, shape or location. The place cells are said to *re-map* when the animal moves from one environment to another, suggesting that the same cells participate in the representation of many environments, and that

any particular location is coded in the pattern of firing across many cells. One important exception to this rule is observed when similar environments are encountered initially, in which case there is a marked similarity between the fields in the two environments (see below).

THE COGNITIVE MAP THEORY

O'Keefe and Nadel (1978) suggested that a collection of place cells connected together in terms of the distance and direction of their fields from each other might form a spatial map. Such a map would identify the animal's location in an environment as well as the location of stimuli and objects in that environment, and would enable the animal to navigate from one location to another on the basis of any available route. As we shall see later, both directional and distance information is available to the place cells.

Are the place-cell fields hard-wired for each environment, or do they take time to develop, perhaps indicating that some learning process is involved? Wilson and McNaughton (1993) addressed this question and found that the place fields are established within the first 15 min. This suggests that any learning which takes place is very rapid, and that some aspects of the representation of an environment may perhaps be prefigured. For example, each cell may come with a small number of preselected environmental inputs to which it is sensitive, and exploratory behavior might involve the wiring together of these cells in accordance with the distance and direction between the parts of the environment that they represent. Evidence that the place fields of difference cells are linked together comes from experiments in which movements of spatial cues such as large visual stimuli at the edge of the environment cause the fields to move in concert (Muller and Kubie, 1987; Fenton and Muller, 2000). On the other hand, experiments in which changes in the shape of the environment cause place fields to move relative to each other show that the fields are not coupled to each other in any simple fashion which reflects a Euclidean metric (O'Keefe and Burgess, 1996). The form that the map takes and its exact location within the hippocampal formation are as yet unresolved.

SOURCES OF SPATIAL INFORMATION

Sources of spatial information can be external to an animal or internal, based on its own movements within the environment.

External or exteroceptive cues convey information about the large number of proximal and distal features and landmarks that are present in the environment. Internal or interoceptive stimuli are derived from idiothetic or path integration information generated by the animal's own movements. Once an animal has located itself in an environment on the basis of external sensory information, it could use this idiothetic system to calculate its subsequent angular rotations and linear translations on the basis of the predicted effect of its own movements or the optokinetic, proprioceptive and vestibular feedback from such movements.

IDENTIFICATION OF LANDMARKS

Place cells use information from different sensory modalities to identify landmarks or features of the environment. These cells are not totally dependent on any specific sensory modality for the identification of landmarks. They receive information from more than one sensory input, and they can use subsets of this total input to identify correctly their preferred place. Elimination of sensory modalities by occlusion or lesion indicates that there are still place cells after the elimination of olfactory, visual or combined visual and auditory inputs. However, vision appears to be the most important modality, even in such a relatively poorly endowed animal as the rat. The majority of place fields remain intact if the animal is placed in an environment with the lights on and the latter are then turned off (Quirk *et al*., 1990). However, if the animal is removed from the environment and then returned to it in the dark, the fields are altered in more than half of the cells tested. Furthermore, new fields can appear in the dark in the latter condition, and these are maintained even if the lights are then turned on with the rat in the environment. It appears that in the open-field cylinder or rectangle, once a pattern of place fields has been set up for a particular environment it is difficult to disrupt it without removing the animal from the environment. Another approach to the question of which cues control the place fields is to construct environments in which the distal spatial stimuli are explicitly identified and controlled (O'Keefe and Conway, 1978; Muller and Kubie, 1987). A strong visual cue or a set of four mixed modality cues (e.g. cards, lights, fans) hung around the periphery of the testing environment gain control over the angular orientation of the place fields. Rotation of the cues rotates the fields by the same amount, and removal of the cues leads to an unpredictable rotation of the field when the animal is returned to the

environment in most of the cells. In experiments where several distal spatial cues are available, removal of one or more of these shows that, while some fields are dependent on one of the four cues, the majority are maintained as long as any two of the four cues are present. Neither the shape of the field nor its distance from the walls of the box are affected in these experiments. Cues at the edge of a symmetrical environment or beyond can control the angular location of the place field, but they have much less control over its shape or its radial distance from the walls of the environment.

In contrast, the shape of the fields is primarily controlled by the walls or other barriers in the testing box or the room itself. This was demonstrated by experiments in which these walls or barriers were systematically moved relative to each other and the effect on place-field location and shape was studied (O'Keefe and Burgess, 1996; Gothard *et al*., 1996). In the O'Keefe and Burgess experiment, the same cell was studied while the rat foraged for food in four different-shaped boxes (two squares, one double the dimensions of the other, and two rectangles, each with a side equal to one of the sides of the squares). The shape and location of most fields were determined by the distance to two or more walls in orthogonal directions. For some cells, moving a wall moved the field without changing its shape, while for others, increasing the distance between two opposite walls caused the field center to shift so as to maintain the correct distance to both walls. This distorted the field shape, causing it to expand along that dimension, and it sometimes resulted in double peaks or the splitting of the field into two.

One important conclusion that can be drawn from the persistence of the dark-formed place fields when the lights are subsequently turned on in the cylinder (see above) is that visual cues cannot be the only cues that control place fields. Recent research suggests that, under these circumstances, the fields are maintained by olfactory and tactile cues on the floor and walls of the enclosure, and by internal idiothetic cues, in particular vestibular and proprioceptive ones, providing information about the animal's own movements.

Animals that were temporarily deprived of both visual and auditory sensory modalities (Hill and Best, 1981) and those that were blind from birth (Save *et al*., 1998) still had apparently normal place fields, and these were shown to be dependent on tactile and olfactory cues in combination with idiothetic information. In the experiment by Save *et al*. (1998), three large objects were placed inside the enclosure to allow the animal to orient itself, and the place fields only appeared after the animal had contacted the objects. In the experiment by Hill and Best (1981), many of the fields were disrupted by rotating the animal prior to placing it in the environment, which suggested that vestibular information was crucial. An alternative way to demonstrate this is by controlled rotation of the testing box with the animal in it, or by controlled rotation of the animal itself. In one experiment, the cylinder walls or floor were rotated separately and the manipulations were performed at either fast or slow speed, and either in the light or in the dark. It was assumed that the slow rotations were below the speed detectable by the vestibular system. The results showed that both visual and vestibular signals for rotation influence the angular location of place cells, and that the relative strength of these two influences is about equal (Sharp *et al*., 1995). Another experiment showed that slow rotation of the rat in a separate chamber outside the testing environment could also rotate the place fields by the same angle as that through which the animal was rotated (Jeffery *et al*., 1997).

PLACE CELLS ARE DEPENDENT ON HEAD DIRECTION INPUTS

Where does the directional information on which these place responses are based come from? How are the place fields being rotated around the center of the environment in the experiments described above? The most likely answer is that their angular position in an environment is dependent on inputs from the head direction system, originally discovered by Ranck and studied extensively by Taube and colleagues (Taube *et al*., 1990a, b). This second class of spatial cells is found in several parts of the brain, including the presubicular subdivision of the hippocampal formation. These cells have properties which complement those of the place cells – they ignore the animal's location, and instead signal its heading direction relative to the environmental frame. Each cell has its own particular prefered direction, and a number of these cells taken together provide information about the animal's heading across the entire 360° of the compass.

Evidence that the place cells are dependent on head-direction inputs comes from experiments by Muller and colleagues (1987), who showed that environmental manipulations which affect the place cells also affect the head-direction cells. For example, rotating prominent environmental landmark cues, such as large visual stimuli on the edge of the testing box, causes the fields of both the place

cells and the head-direction cells to rotate by an amount which maintains their spatial relationship to these stimuli. In an experiment in which place cells and head-direction cells were recorded simultaneously during manipulations which disoriented the animal's sense of direction, Knierim and colleagues (Knierim *et al*., 1995) showed that the two cell types maintained a fixed spatial relationship to each other even as they rotated relative to the environmental frame.

DETERMINANTS OF PLACE-CELL DISTANCE FROM LANDMARKS

What is the sensory source of distance, as opposed to directional, information to the hippocampal place cells? By analogy with the sources of *directional* control of these cells discussed above, information about *distances* from environmental landmarks might be given by optokinetic, proprioceptive and vestibular cues in addition to, or instead of, the distal visual cues. A good estimate of the linear distance traveled from an environmental landmark could be given by a visual cue such as the change in the angle of the cue above or below the horizon, or the size of the cue on the retina. Alternatively, the distance traveled could be derived by integrating the animal's speed of movement in a particular direction over time. At present there are three pieces of evidence which support the idea that distance could be represented in the hippocampus by information about speed of movement. First, O'Mara and his colleagues have described cells in the monkey hippocampus which respond to passive rotations or translations of the whole animal (O'Mara *et al*., 1994). Second, a small number of active speed cells have been recorded in the rat hippocampus (O'Keefe *et al*., 1998). The firing rate of these speed cells is a linear function of the speed at which the rat runs. Direction of movement appears to be irrelevant, and these cells are not activated by passive movement of the animal. Integration of the firing rate of such a cell over time would provide the distance information that is required by the place cells. Third, Czurko and colleagues have recently reported that the firing rates of the place cells themselves code for the speed of running in the place field (Czurko *et al*., 1999). They recorded from place cells with fields in a running wheel, and showed that the firing rates of the cells increased linearly with the speed of running in the wheel. Since there is no movement of the animal's head relative to the environment in this experiment, the speed signal cannot be coming from the vestibular system or from optic flow information, but must be derived from the motor system itself.

THE ROLE OF MOTIVATION, PROBLEM-SOLVING HYPOTHESES AND GOAL LOCATION

Place-field firing does not seem to depend on the reason why the animal runs through the location, as can be shown by the simple demonstration that interchanging the rewards at the ends of the different arms of a maze has no effect on place-cell firing. As is shown in Figure 3, in many environments the distribution of place fields is fairly even, with all regions being represented equally. However, there have been reports of fields shifting when rewards are moved (Breese *et al*., 1989), and of increased representation of rewarded locations (Hollup *et al*., 2001). Whether the animal is using its hippocampus to solve a spatial problem or not seems to have an influence on the number of cells with place fields in an environment (Zinyuk *et al*., 2000).

TEMPORAL PROPERTIES OF PLACE-CELL FIRING

Several studies have examined the temporal firing patterns of the pyramidal cells and sought to determine whether they convey any information. It has been known for some time that the firing of both the complex-spike cells and the theta cells bears a temporal relationship to the ongoing EEG theta wave. Theta activity occurs in the hippocampal EEG of the rat when the animal engages in behaviors which change its location in the environment. These include walking, exploring, swimming and jumping.

On the other hand, quite vigorous motor behaviors which do not change the animal's location in the environment, such as grooming, are accompanied by a different EEG pattern, with large-amplitude, non-rhythmical slow-wave activity (LIA). In addition, in some species low-frequency theta activity occurs in immobile animals in response to a stimulus such as a sound. However, in the rat it will only occur during immobility if the animal is highly aroused (e.g. in the presence of a predator) (Sainsbury *et al*., 1987).

During theta activity, all active hippocampal cells fire in bursts with the same frequency as or one close to that of the EEG theta rhythm. The theta cells do so whenever there is theta activity in the hippocampal EEG, and they always maintain a fixed correlation to a particular phase of the sinusoidal EEG wave. However, the phase relationship

of the place cells to the theta wave is different. O'Keefe and Recce (1993) studied the correlation between the two as the rat ran through the place field. In contrast to the theta cells, it was found that the phase correlation of the place cells did not remain constant, but changed in a systematic way. Each time the rat entered the field, the cell always began to fire on the same phase of theta. As the rat progressed through the field, the bursts of spikes occurred at an earlier phase of each successive cycle (Figure 4a). The phase of firing was strongly correlated with the animal's location within the place field (Figure 4b), and this correlation was stronger for position than it was for time after entry into the field. The location of an animal in an environment is coded by the temporal firing of the cells relative to the EEG theta wave, as well as by their absolute firing rate. The phase precession phenomenon is explained partly by the fact that the place-cell bursts occur at a higher frequency than the frequency of the concurrent EEG theta wave, and partly by the fact that there must be some adjustment in the relationship between the interburst frequency of the cells and the frequency of the EEG theta wave which compensates for the speed with which an animal runs through the field. Jensen and Lisman (2000) have shown that taking the phase correlate into account increases the spatial resolution of place cells by 43% above that provided by the firing rate alone.

PLACE-CELL PLASTICITY AND ITS ROLE IN SPATIAL MEMORY

Interest in the hippocampus largely stems from the belief that it is crucial for the formation and/or storage of long-term memory. There are three good examples of plastic changes in the place cells

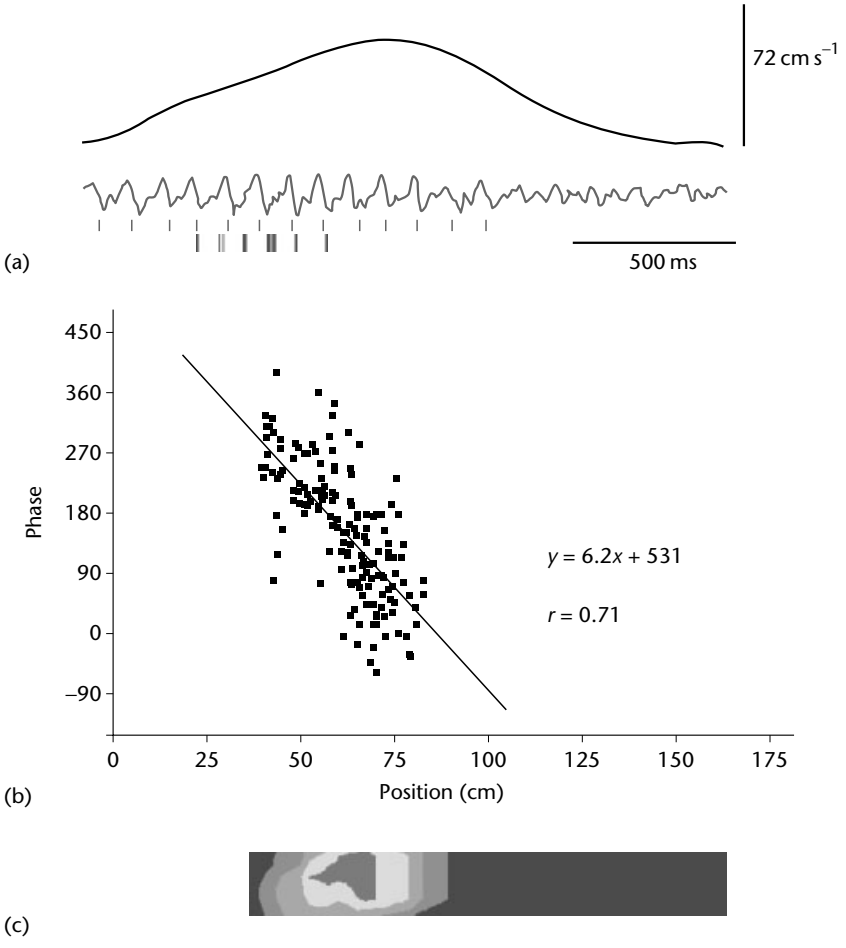

Figure 4. [*Figure is also reproduced in color section.*] Hippocampal place-cell activity changes phase with EEG theta activity. (a) Velocity profile, EEG theta rhythm and place-cell firing during a single run on a linear track. Ticks below EEG mark 0°/360°. (b) Phase of theta at which unit fires versus position on the track. (c) Location of place field on the track. (After O'Keefe and Burgess, 1999.)

which may form the bridge to the role of the hippocampus in human spatial and episodic memory, namely the short-term changes seen in the experiment of O'Keefe and Speakman (1987), the day-long changes seen in the experiment of Mehta *et al*. (1997, 2000) and the long-term longer-lasting changes observed in the experiment of Lever *et al* (2002). Finally, there is evidence that the *N*-methyl-D-aspartate (NMDA) receptor which has been implicated in long-term potentiation (LTP) also plays a role in the long-term stability of place-field firing.

O'Keefe and Speakman (1987) demonstrated that place cells exhibited a form of short-term memory in a delayed match-to-position task. Once place fields had been established on the basis of distal spatial cues, they were maintained after the removal of those cues. Tests on normal rats had previously established that well-trained animals could remember the location of the goal for periods of as long as 30 min after the cues had been removed, and lesions which disrupted hippocampal function resulted in a profound memory deficit. One suggested mechanism is a rotation of the head-direction system into alignment with the spatial cues, and a maintenance of that preferred direction after the removal of the cues. As we have seen, the orientation of the head-direction system controls the angular orientation of the place cells, and the maintenance of the new preferred head direction would be reflected in place-field location.

The second type of plasticity appears to last for at least a day. It has been demonstrated that place fields can change shape over a series of trials in which the animal always crosses the place field in the same direction. The change consists of an elongation of the field in the direction from which the animal is moving. The fact that the place fields have returned to their original shapes by the next day suggests that the change is temporary, lasting for less than a day (Mehta *et al*., 1997, 2000). Of particular interest is the fact that the change is NMDA-receptor-dependent (Ekstrom *et al*., 2001), which suggests that its synaptic basis may be the same as LTP.

The third type of plasticity takes the form of a long-term incremental change in the place fields, which may serve as the basis of long-term incidental spatial memory (Lever *et al*., 2002). Place fields in a square and circle were originally similar on initial exposure to the environments, but began to differentiate following prolonged experience. This differentiation (or re-mapping) persisted for at least a month without intervening exposure to the boxes.

Finally, NMDA-receptor antagonists do not affect the ability of place cells to differentiate between two different enclosures, but they do prevent the long-term stabilization of that differentiation (Kentros *et al*., 1998).

COMPLEX-SPIKE-CELL FIRING DURING SLEEP MAY BE MODULATED BY PRIOR SPATIAL LEARNING EXPERIENCES

It has been suggested that consolidation of memories might take place during sleep, and in particular during rapid eye movement. If this were the case, one might expect neuronal firing patterns to reflect this consolidation activity. It has also been suggested that consolidation involves the transfer of information from the hippocampus to the neocortex. In this case, one might expect an increased interaction between cells in these areas during and after sleep. McNaughton and his colleagues studied changes in connectivity between hippocampal neurons and found an increase between pairs of cells with overlapping place fields on a circular maze after the animal was allowed to run in the maze (Qin *et al*., 1997). In subsequent research there was also some indication that the temporal ordering of firing between cells with partially overlapping fields was replicated in a compressed form during sleep. Finally and most intriguingly, there was an increase in connectivity between pairs of hippocampal and neocortical cells. Wilson and his colleagues have gone one step further in this search for a reflection of the previous day's experience in the hippocampal unit activity during sleep (Louie and Wilson, 2001). They have found that when an animal is trained to run round a maze in a repetitive manner during the day, place cells become activated in the same sequence during REM sleep at night. This strongly suggests that the actual sequence of events in the maze is being replayed during dreaming sleep.

SUMMARY

The animal's location is the strongest correlate of hippocampal pyramidal-cell firing in animals such as the rat. A collection of these place cells may provide the animal with a spatial map of its environment, enabling it to navigate in a flexible, creative manner. Place cells identify locations both on the basis of environmental landmarks using visual, olfactory and tactile information, and on the basis of self-generated vestibular and proprioceptive cues which provide information about the distances and directions that the animal has moved since the last known location. One of the strongest

sources of place information is the distance of the animal in particular directions from large environmental features such as the walls of the enclosure. Directional information is provided by the head-direction cells of the presubiculum, which fire when the animal faces in a particular direction, regardless of its location in the environment. The time of firing of the place cells provides information about the animal's location in addition to the rate of firing. As might be expected from the role of the hippocampus in memory, place cells exhibit several types of plasticity on timescales lasting from a few minutes to several weeks. There is evidence that the events of the day influence the activity of hippocampal pyramidal cells during subsequent dreaming sleep.
