Intentionality

Introductory article

Akeel Bilgrami, Columbia University, New York, New York, USA

CONTENTS

'Intentionality' is a term used by philosophers to describe a property which distinguishes a subset of all the mental states there are – the representational states.

WHAT IS INTENTIONALITY?

'Intentionality' is a term used by philosophers to describe a property which distinguishes a subset of all the mental states there are – the representational states. What is meant exactly by 'representational' is not an entirely simple or uncontroversial matter, and moreover, intentionality should not to be confused with the specific representational mental state of 'intentions'. Intentions are but one example of a representational state, while 'intentionality' encompasses the entire class of representational states.

The most general way to describe intentional or representational states has been to say that they are 'about' things. Such states stand in contrast to mental states such as pain and other kinds of sensation that are not (or not obviously) about things. Equally, some emotions, such as certain forms of anxiety, or depression, or feelings of elation are not necessarily 'about' something; they may just be generalized feelings of depression, anxiety, or elation with no particular object towards which these feelings or emotions are directed. Some philosophers, however, think that sensations do involve representation and 'aboutness'. Some even think that pain is representational because it is essentially a form of perception. Thus, a toothache is one way of perceiving a certain tooth, akin to seeing the tooth or touching the tooth. But despite these controversies, most philosophers accept that there are some mental states which are not intentional at all.

Of those mental states which are intentional, which are about things, it is useful to distinguish between two types: those whose 'aboutness' or representationality are captured in clauses specifying propositions or sentences, and those which are not. Beliefs and desires are the most commonly cited examples of intentional states whose aboutness is specified by propositions. Thus, for instance, someone believes that there is a glass of water in front of her, or someone desires that she drink the glass of water in front of her. What follows the 'that' in these examples is the propositionally specified, representational element of these mental states. And philosophers often use the term 'content' or 'intentional content' to describe this sort of representational element provided by these 'that' clauses in our reports of intentional states. Further examples of such 'propositional attitudes' include hopes, wishes, supposals, and conjectures.

Not all intentional states need be specified by propositions in 'that' clauses. Love, for example, is a state of mind that is directed towards an object but is not always specified by a proposition in a 'that' clause. Love may have an object, a person, say, without the state of mind of love being specified in a 'that' clause content. Many also think that not all cases of perception or seeing are cases of 'seeing that'.

While the term 'intentional' has been used for the most part to describe and discuss states that have propositional or 'that' clause content, there has also been discussion of representational states of the other kind, where 'that' clause content is not involved, but such discussion has been carried out under the more general label 'representational'. It probably reduces confusion to follow this tendency and to use 'representational' as the more general term, reserving 'intentional' for identifying those states with propositional content specified in 'that' clauses.

The remainder of this article will focus on this latter kind of state. These states have been the subject of much diverse and interesting philosophical discussion in the last century or more. This article summarizes the two arguments which are perhaps the most current and widely discussed.

IS INTENTIONALITY A NATURALISTIC PHENOMENON?

One of the questions which has produced the most controversial discussion is whether intentionality is a naturalistic phenomenon: is it reducible to the sorts of phenomena that are studied by natural science? Some philosophers have thought that it *is* reducible, others have denied this, while a third group has said that talk of intentional phenomena is merely talk, an idiom used for convenience but with no lasting status in a complete science of the mind. Paul Churchland, following certain ambivalent remarks of Quine, has been an advocate of such 'eliminativism' in recent years, and Daniel Dennett has described our use of the idiom as an intentional 'stance' that we take toward certain sorts of phenomena we study.

Reductionism

Let us look more closely at the first group, the reductionists. Reductionists can broadly be classified into three subgroups. Some have thought that intentionality is reducible to the physical states of the brain ('materialists'), others that it is reducible to tendencies and patterns of behavior ('behaviorists'). The third group has believed that it can be reduced to purely causal or dispositional states ('functionalists').

The last might be described as akin to the dispositional state of solubility of, say, sugar, except that unlike sugar, mental dispositions are not further reducible to physical–chemical states. Behaviorism, which denies any inner reality to mental states, has been out of favor for many decades, though it once had a high degree of popularity. The materialists claim that future research will establish that each intentional state is identical with a neurophysiological state, just as research in physics has demonstrated that heat is identical with mean kinetic molecular energy. But, like the behaviorists, the materialists have also lost ground to the functionalists who favor a weaker form of reduction, one that reduces intentional states to purely causal states. Though weaker, this form of reduction can still claim that it has reduced intentional states to those which are at least naturalistic, that is to say obedient to natural science, and subsumable under causal laws.

Functionalists do not stress the intrinsic properties of intentional states but rather their functional properties or roles, properties derived from the typical causal relationships in which they stand; i.e., the states they are caused by as well as those states and behaviors which they cause. These reductionists, who think that intentional states are reducible only to causal and dispositional states and not to brain states, usually at least admit that intentional states are what they call 'supervenient' on brain states. Supervenience is a weaker form of a dependency relation of such states on physical states than reduction to them. Thus, given supervenience, if there were two subjects with identical states of the brain, there would be no reason to count one as having different mental dispositions from the other and, therefore, as having a different intentional state from the other.

Arguments Against Reductionism

Anti-reductionists deny even a weak reduction to causal or dispositional states, insisting that intentional states are completely 'stand-alone' states. Although they may have various relations to our dispositions, to our behavior, and to the states of the brain, none of these relations can be invoked to provide any form of reduction. When it comes to mental states generally, resistance to reduction is based on arguments invoking the 'multiple realizability' of mental states, invoking the fact that mental states such as pain are realized (recognized) in quite different physical structures in different species.

But when the subject is intentionality, the most interesting argument turns on considerations that are specific to intentional states. Among recent philosophers, Donald Davidson and John McDowell have taken a strong anti-reductionism line about such states. Their chief objection is that these states lack a property that is intrinsic to intentional states, their normativity. Intentional states are states that are essentially governed by normative considerations in ways that the states that are studied by natural science are not. Thus when the reductionist aspires to reduce intentional states to neurophysiological states, or to purely causal roles, or to behavior (which is not itself normatively characterized) with a view to bringing them within the purview of the methods and lawlike explanations of natural science, he is aspiring to something that misses out on this intrinsic feature.

Perhaps the simplest way to put the argument, attributed first to Davidson, is that intentional states have to meet the constraints of rationality – which are normative constraints. Thus for instance a belief, in order to be a belief, has to be understood as rational or irrational depending on whether it meets these constraints or not. And the claim is that no such constraints are placed on neurophysiological

states, or purely causal states, or states described in terms of behavior (where the behavior is itself described non-intentionally). We can always ask whether a belief is rational, but we do not have the conceptual vocabulary to ask the same of purely causal, physical, or behavioral states. Questions of rationality are simply not relevant when it comes to these latter kinds of state, whereas they are central when it comes to intentional states. Therefore, it is claimed, there can be no lawlike correlations between these two radically different kinds of state, that would allow us to see the one as reducible to the other. This is essentially Davidson's argument and it has aroused much controversy.

Eliminativism

Apart from reductionism and anti-reductionism, the third view on the matter, eliminativism, does partly concede something to the anti-reductionist. It concedes that it may not be possible to provide lawlike correlations (or 'bridge laws' as they were once called) between intentional states and the physical and other nonnormative states posited by a scientific theory. But it nevertheless resists the conclusion that the anti-reductionist comes to. It foresees that the time will come when neuroscience will advance sufficiently so as eliminate our present epistemic weakness. Then, there will be no need for these convenient attributions (convenient only while we are epistemically weak) which we presently make in intentional terms. There will be nothing for these attributions to describe which will not be better and more accurately described in neuroscientific terms; and anti-reductionists who claim that intentional states have intrinsic properties will therefore be shown to be wrong.

INTERNALISM VERSUS EXTERNALISM

The second topic that continues to attract controversy has been the question of whether intentional content is determined by the world external to the subjects who possess intentionality. Those who think that content is not beholden to the relations in which agents stand to objects and facts in the external world ('internalists') are committed to saying that content is determined wholly by facts internal to the agent, neurophysiological facts as well as the purely causal/dispositional/functional facts. In a sense, this is a modern version of an essentially Cartesian picture of the mind. In Descartes' picture, one's thoughts were determined only by the interior properties of agents; for Descartes one's thoughts were one's thoughts, even if there were no external world. Thus Descartes was an internalist: nothing external was necessary for the determination of thoughts. But Descartes, being a dualist, gave thought an independence from all things physical, so thoughts were also not dependent on any inner physical facts. Modern internalists think that the contents of our thoughts are determined by inner facts including inner physical facts – neurophysiological facts – and can therefore be understood as retaining Descartes' internalism while discarding his dualism.

By contrast, the 'externalists' think that intentional contents are determined at least partly by the causal relations in which we stand to facts and objects in the external world. Thus they think that the Cartesian method of doubt does not yield what Descartes thinks it yielded: thoughts about the external world that are (possibly all) false because there (possibly) is no external world. Rather it yields a *reductio ad absurdum*: we cannot imagine what the method of doubt asks us to; we cannot imagine that there might not be an external world on the grounds that all our thoughts about the external world are false since such thoughts could not have any content (could not, that is, be thoughts) if there were no external world.

Internalism

There are two quite different sorts of motivation that philosophers have articulated for being internalists. One motivation has been purely metaphysical. It has seemed quite intuitive to some philosophers that intentionality is supervenient on the brain. They are thus committed to a rather specific version of supervenience – not merely that intentional content is supervenient on physical facts but supervenient on internal physical facts about the central nervous system. They think that intentional states are reducible to systematically and holistically linked inner functional and causal roles, which are themselves at least supervenient on, if not reducible to, states of the central nervous system. The externalists who oppose them share no such metaphysical intuition. They do not necessarily oppose a general form of supervenience in their metaphysics whereby the intentional is supervenient on the physical generally, but they resist as bad metaphysics the idea that it should be supervenient on the *inner* physical. They think that it is quite intuitive that language and thought are dependent on the nature of the external environment with which we stand in causal relations.

A quite different motivation for internalism is this. Unless intentional states were internalistically

characterized, they would not be able to do what they are manifestly posited to do, encapsulate the inferences, theoretical and practical, that explain our behavior. This motivation is quite separate from any metaphysical considerations. The idea is that the external elements interfere with intentional content and weaken or destroy their explanatory power and potential. This is by far the more interesting motivation for internalism.

Externalism

What is the external element that determines the content of intentional states? Most externalists view this external element as derived from one of two sources.

One source is a causal account of the references for the terms that express the concepts with which we think and which are the constituents of our intentional states. Thus if someone were to think, for example, that 'London is pretty', her concept of London (whether she uses 'London' or 'Londres' or whatever) is determined by certain causal relations in which she stands to its referent (the city). Some philosophers (such as Saul Kripke) think that these causal relations go all the way back to the occasions when the cities, people, objects were originally given these names. Even our current use of a name like 'London' has its meaning determined by the fact of a chain of causal relations which connects us to that city via that original naming event. Concepts and terms which express or describe natural kinds are given corresponding causal accounts. Our current use of a natural-kind term such as 'water' also derives its meaning from its reference or extension; and that reference is determined by the property that exemplifies the essence of a paradigm sample identified in the original reference-fixing event. Other philosophers (such as Dretske and Fodor) do not appeal to the referents of our terms being determined by causal chains, going back to originary events of this kind, but rather to causal covariances between our token uses of our terms or mental tokens and their referents. Thus our term 'water' gets its meaning via the covariance that holds between instances of a substance that has a certain chemical property (H_2O) and our tokenings of 'water'. These are very different causal accounts of the 'ingredients' (concepts, terms) which compose our thoughts and the sentences which we use to express them. But both preclude the possibility of conceiving the content of our thoughts as being independent of the world around us – as the internalists would like.

The other external source externalists invoke as a determinant of content is social. Michael Dummett was among the first proponents of this, and Tyler Burge has developed the idea. According to social externalists, an agent's concepts – as well as the meanings of the terms which he uses to express those concepts – are determined by the linguistic practices of the agent's community. Thus, someone belonging to an English-speaking community, even if he knows no chemistry, nevertheless has a concept of water which the experts in the community characterize in terms of its chemical properties. The individual agent may not know that the chemical formulation of water is H_2O, but nevertheless his concept of water and the term 'water' itself are determined by his linguistic community. (This view differs from a purely causal externalist view, because, unlike that view, it does not have the consequence that English speakers in 1750, say, had the chemical concept of water we now have. The linguistic community in 1750 never had experts who identified the scientific nature or essence of water as H_2O. Because the concept of water is determined by what the experts of the community think at any given time, it is only now that the concept of water includes the chemical property of H_2O.)

Arguments and Counter-arguments

Why do internalists think that if content is determined by an external source then intentional states cannot explain behavior? With regard to the social version of the externalist notion of content, consider someone who lives in a linguistic community different from our English-speaking community in only one respect: their term 'water' is used not as it is used by English speakers to speak of a substance with the chemical property H_2O, but as it is used to talk of a substance which, though it looks just like water and has other properties of water (e.g., it quenches thirst), nevertheless has a different chemical property called 'XYZ'. According to the social externalist view, anyone who is in this community has a different concept of water than do standard English speakers. So, since concepts compose intentional contents, if someone in that community has the belief which we would quite properly report as the 'belief that water quenches thirst', he nevertheless has a different belief than we have when we have a belief that we report as the 'belief that water quenches thirst'. This strictly follows from this externalist view of content.

The internalist objection to this can be brought out by imagining an English speaker and a speaker

from that alternative linguistic community both, say, drinking a glass of something they both call 'water' in order to quench their thirst after a game of tennis. In explaining their respective actions each would invoke the belief that is quite properly reported in each case as the belief 'that water quenches thirst'. Now if the externalist is right, these are nevertheless two different beliefs. But, the internalist says, this difference should make no difference to the explanation of their actions. It is too intuitive that the explanation should in both cases be exactly the same because the difference in the chemical properties of the two substances does not make a difference to their motivational psychology which prompts them to drink. And if beliefs and desires and intentional states generally have a role to play in our motivational psychologies (which is another way of saying that they have explanatory power), then there is no need to have them determined by elements in the external world that would lead to unintuitive results in our thinking about that role.

There is another closely related point which some internalists raise against externalists. It seems that if one allowed that external elements determine intentional contents in the ways mentioned above, an agent may not know his own intentional contents for highly abstract and philosophical reasons. If some English speaker, call him Jim, knows no chemistry at all and believes that the water in front of him will quench his thirst, he will not, according to the externalist, fully *know* what he believes. He will only know it partially and inexactly. (This is a puzzle akin in many ways to the 'puzzle about belief' which Saul Kripke raised about proper names, not natural terms such as 'water'.) But it is very intuitive that we do know exactly what we believe in ordinary cases such as this. No commitment to Cartesian infallibility underlies this intuition. We may grant that there are lots of beliefs, desires, intentions, and motives of ours about which we are fallible and self-deceived, but in each of those cases there is something in the internal psychology of the agent which accounts for her failing to know her intentional states. No such psychological cause or reason can be given in the more ordinary case of Jim not knowing what exactly he believes, in believing that water quenches thirst. He fails to know what exactly he believes, not because of something in his psychology but because some professors of philosophy have a certain view about reference that they think is relevant to the determination of intentional content. According to their viewpoint, this poor man does not have to overcome psychological blocks and censors before he knows what he believes (as is necessary in the cases of self-deception); he has to learn more chemistry before he *knows* what he believes. This seems to many a very implausible consequence of externalism. And, as said above, there is nothing Cartesian in finding this implausible.

For these reasons many philosophers have thought it best to divide intentional states into two quite different sorts: one which they say possesses 'wide' content, and another which possesses 'narrow' content. Wide content captures the point and rationale that the externalist sees in intentionality, while narrow content captures the explanatory point and role of content. Furthermore, it allows us to retain the intuition that unless there are psychological obstacles of some kind, we know our own intentional states. Narrow content is also intended to fulfill the first motivation for internalism, that content should supervene on the physical states of the brain.

In general, this 'solomonic' way of dealing with the issue of internalism versus externalism by bifurcating content into two is the easier and less ambitious way out of these problems. One of the more challenging tasks in this area of philosophy is to pursue the more ambitious goal of trying to capture both what the externalist and the internalist want from content in a single notion of content. In other words, can a genuinely externalist notion of intentional content also be an explanatory notion? And can a genuinely external notion of content retain our ordinary intuitions about our self-knowledge of our thoughts? It may be that the answer to this question is 'yes', but it is unlikely that it can be 'yes' while retaining externalist notions of the orthodox causal and social referentialist sort employed by Kripke, Putnam, Dummett, Burge, and others discussed above.

Introspection

Intermediate article

William Lyons, Trinity College, Dublin, Ireland

CONTENTS

Philosophers and psychologists have both appealed to introspection as a privileged and direct method of gaining knowledge about the mind and its activities. What exactly introspection is, and what role it might play in a scientific psychology, are subjects of major debate.

INTRODUCTION

The term 'introspection' might be defined as 'the direct, conscious examination or observation by a subject of his or her own conscious mental processes'. Etymologically the term is derived from two Latin words, *intro*, meaning 'within', and *specere*, meaning 'to look at'. Throughout the long history of philosophy and, more recently, psychology, those investigating the mind have on occasion adopted introspection as an obvious, if subjective, method of gaining immediate knowledge of the mind at work.

HISTORY

It has been claimed that the ancient Greeks, at least up to and including Aristotle (384–322 BC), did not have any conception of introspection; though there is a section in the *De Anima* where Aristotle may be saying that we can reflect on our own mental states (Aristotle, 1986, book 3, chap. 4, 429b–430a). The first indisputable employment of any concept of introspective self-consciousness is probably by the Neoplatonist philosopher Plotinus (*c*. 204–270). In his essays, which were collected after his death by his disciple Porphyry as the *Enneads*, Plotinus discusses whether the One (or Absolute, the source of all existence) is self-conscious or not. Plotinus argues that the One could not be self-conscious in the usual sense because that would imply a dualism of knower and known (Plotinus, 1991, Ennead 5, tract 3). There is also discussion of introspective self-consciousness in the works of another Neoplatonist, the African Bishop of Hippo, Augustine (353–430). In his *De Trinitate*, Augustine (1955, vol. VIII, book 10, section 7) remarks: 'What then can be the purport of the injunction, Know thyself? I suppose it is that the mind can reflect upon itself.' (*See* **Self-consciousness**)

This claim, that the mind can reflect upon itself, was fairly common among the medieval philosophers, particularly among those who, like the Frenchman William of Auvergne (*c*. 1180–1249), were to some degree Augustinian. They often argued for the immateriality of the soul, and for claims about the nature of human knowledge, on the basis of the deliverances of self-consciousness. The most famous of all medieval thinkers, the Italian philosopher and theologian Thomas Aquinas (*c*. 1225–1274), was explicit about our possession of a capacity for self-consciousness. Quoting Augustine in support, he asserts in his *Summa Theologiae* that 'the mind perceives itself' (Aquinas, 1968, Part 1, question 87, article 1).

In the seventeenth century, the English political philosopher Thomas Hobbes (1588–1679), despite a commitment to materialism, laid great stress on the value of self-reflection. Though Hobbes himself did not use the term, it was in the seventeenth century that we find the first use of the word 'introspection' in English. Adopting the maxim of the Delphic oracle, Cicero, and Augustine, *nosce teipsum* ('know thyself'), Hobbes argued that only through self-reflection would humans be able to discover their own psychology and, on that basis, be in a position to 'read and know, what are the thoughts, and Passions of all other men' (Hobbes, 1996). Only when possessed of this knowledge of human psychology could anyone hope to produce an acceptable moral and political program for a civilized society.

Arguably, however, it was the French philosopher, mathematician, and scientist René Descartes (1596–1650) who introduced introspection as a

topic for discussion in modern philosophy and whose ideas ultimately led to introspection being chosen as the method for the new science of psychology in the latter part of the nineteenth century. Descartes not only believed firmly in the capacity of a human subject to gain direct knowledge of his or her own mind via introspection; he placed immense value upon that knowledge. He held that, at least when our introspections produced immediate, clear and distinct knowledge of the contents of our stream of consciousness, that is to say, of our own mind, then that knowledge was, indeed must be, infallible. For that reason introspection should be made the basis of all human knowledge (Descartes, 1954, part 4). (*See* **Descartes, René**)

In the latter half of the seventeenth century, when the English philosopher John Locke (1632–1704) put forward a new philosophy, more consonant with the new observation-based approach to science, namely empiricism, he retained the method of introspection. While claiming that the basis for all our knowledge was the information that came into the human mind via the senses, in his *Essay Concerning Human Understanding,* Locke pointed out that there was an important set of ideas and concepts, such as those of the intellect and will, which could be gained only by 'reflection', his term for introspection (Locke, 1924, book 2, chap. 6). While Locke's conception of psychology was soon challenged, notably by the Irish philosophers Peter Browne (1666–1735) and George Berkeley (1685–1753) and by the German philosopher Gottfried von Leibniz (1646–1716), his *Essay* was the most influential book on human psychology throughout Europe for the next hundred years.

In the late eighteenth and early nineteenth centuries, philosophy appears, at least in retrospect, to have been dominated by the work of the German philosopher Immanuel Kant (1724–1804), who, in his own words, produced a kind of Copernican revolution in epistemology. Copernicus had pointed out that it was in fact the movement of the Earth that produced the apparent movement of the Sun and stars around us, not a movement of Sun and stars around a stationary Earth. In a similar act of reversal, aimed at empiricism, Kant stressed that human knowledge was not a passive reception on the part of the senses of information about objects and events in the world. It was an active creation by the mind of such fundamental categories as 'object' and 'event' out of the material of sensations. For Kant, self-consciousness, or 'apperception', a term he borrowed from Leibniz, had a role to play in our knowledge of these categories. Apperception had two forms, an ordinary empirical form and what he referred to as a transcendental form (Kant, 1993, Transcendental Logic: First Division, book 1, chap. 2). In its empirical form, apperception was more or less Cartesian or Lockean introspection. It gave us an awareness of the ever-changing thoughts that were the contents of our own consciousness. In its transcendental form, however, it gave us an insight into the very nature of thought itself. This insight included an inchoate apprehension of the unity of the self that made connected and so logical thought possible, and thereby created the possibility of human understanding. One of Kant's criticisms of Descartes was that he had coalesced and confused these two quite different forms of apperception. (*See* **Kant, Immanuel**)

In comparison with both Cartesian and empiricist philosophy, introspection, or empirical apperception, had a minor role in Kant's philosophy. He was really interested in transcendental apperception. Thus his influence was mainly on idealist philosophy rather than on empirical psychology. It was the return to a more Cartesian approach, particularly in the work of the German philosopher Franz Brentano (1838–1917), that brought introspection back to the forefront of philosophical discussion and led eventually to the foundation of the new science of psychology.

Though influenced by the work of Aristotle as well as that of Descartes, Brentano thought of himself as an empirical psychologist as well as a philosopher, as the title of his masterpiece, *Psychology from an Empirical Standpoint* (Brentano, 1973), makes clear. For Brentano, there were two sorts of psychology, both empirical. There was physiological psychology – such as was being practiced in Germany by Ernst Weber (1795–1878), Gustav Fechner (1801–1887) and Hermann von Helmholtz (1821–1894) – and there was descriptive psychology. The latter, sometimes also called by Brentano 'descriptive phenomenology', was a program of gaining knowledge about the 'ultimate elements' of the human mind by introspection, much in the way Descartes would have envisaged. One first introspected, and then took as knowledge about the mind itself whatever presented itself introspectively as 'evident' or 'self-evident': this was Brentano's version of Descartes' 'clear and distinct' ideas. Introspection was an empirical process because it was a direct experience of the mind. It was the mind as eyewitness of itself. But Brentano added a signficiant qualification to this Cartesian approach. He distinguished carefully between 'inner perception' (or the passive, 'out of the corner of the mental eye', process of self-consciousness) and

'inner observation' (or the active process of introspection). He felt that only the former was guaranteed not to interfere in what it was observing. He also pointed out that inner perception, although a passive and 'by the way' form of noticing, could be improved by training. The psychological introspectionists were to take this idea very seriously. (*See* **Fechner, Gustav Theodor**)

Besides being a powerful personality, Brentano must have been a remarkable teacher, because many of his students did remarkable work. His pupils included Freud, the founder of psychoanalysis, Tomáš Masaryk, a philosopher who became president of Czechoslovakia, Alexius Meinong, who became an influential philosopher, Carl Stumpf, a gifted musician and psychologist who wrote an important text on the psychology of sound, and Christian von Ehrenfels, one of the founders of Gestalt psychology. (*See* **Freud, Sigmund**)

From the point of view of the history of introspection, Brentano's most important pupil was the German philosopher Edmund Husserl (1859–1938). While Husserl made introspection the basis of his new science of phenomenology, he also pushed introspection further away from the empirical world of ordinary experience. For Husserl, phenomenological investigation, while it might begin with the introspection of the contents of consciousness, was essentially a non-empirical endeavor. It was an *a priori* contemplation of conscious experience as such, in order to understand its essence. In a phenomenological investigation of the experience of seeing a red tomato, for example, you must first set aside and so transcend any knowledge that there is a tomato present, or that it is one that you grew in your vegetable garden, or anything else particular about it. Then you must seek to penetrate to the pure experience of redness itself, the 'universal redness', while at the same time gaining an insight into the nature of the subjectivity involved in having a conscious experience. In effect, Husserlian phenomenological investigation was a return to a Kantian transcendental apperception with the addition of some Platonic contemplation of forms (Husserl, 1999, chap. 19). (*See* **Phenomenology**)

There is some speculation as to why, when the new science of psychology came into being, it became an introspective psychology rather than, say, a physiological psychology in the tradition of Fechner, Weber, and Helmholtz. A plausible reason is that the founders of the new science of psychology, such as Wundt and Stumpf, believed that a truly autonomous psychology must be a study of the mind as such, and so distinct from physiology. They believed that the foundations for this new science of psychology already existed, for example, in the philosophical psychology practiced by Franz Brentano in Germany and John Stuart Mill (1806–1873) in England. To turn the old philosophical psychology into the new science of psychology, one just had to make introspection scientific. This transformation was to be effected by regulating the process of introspection according to good experimental practice. In turn, this was to be achieved by carefully classifying every aspect of the introspective process, by making use of laboratories with specially trained subjects and scientific instrumentation, and by repeating experiments many times. As William James put it, 'these new prism, pendulum and chronograph-philosophers … mean business, not chivalry' (James, 1950, vol. I, pp. 192–193). (*See* **James, William**; **Helmholtz, Hermann von**)

Wilhelm Wundt (1832–1920) is generally regarded as the founder of the new, introspective, science of psychology. Wundt studied medicine and was for a very short time an assistant in physiology to Helmholtz at the University of Heidelberg. However, Wundt was dissatisfied with his physiological studies and, in his first book, on perception (published in 1862), he coined the term 'experimental psychology' for the introspective approach to knowledge of the mind. (*See* **Wundt, Wilhelm**)

After he took the chair of philosophy at the University of Leipzig, the central theme of Wundt's lectures was that the correct method for this new experimental psychology was introspection organized along scientific lines, and that its goal should be the analysis of conscious experience into its elements, and the discovery of the laws of association of these elements. He claimed that his experiments showed that there were two sorts of element, sensational (or pertaining to the senses) and affective (or feeling). Wundt established the first ever psychological laboratory (Wundt, 1896, lectures 1 and 2; Schultz and Schultz, 1996, chap. 4). Through Wundt's teaching, this new introspective psychology was spread around the world. It flourished until behaviorism – which had no use for the notions of introspection or consciousness – dictated a new method for a science of psychology. The ascendance of this new behavioristic method in psychology, and the related behavioristic analyses in the philosophy of mind, was accompanied by severe criticisms of the employment of introspection in psychology (Watson, 1995, 1930). (*See* **Behaviorism, Philosophical**)

Now that behaviorism has been largely superseded and cognitive psychology is widely studied,

there is again much discussion of the use of introspection in psychology. There is a renewed interest in consciousness and an admission of the conspicuous failure of either psychology or the brain sciences to tell us much about it. In 1979, the journal *American Psychologist* published an article by D. A. Lieberman (1979) entitled 'Behaviorism and the mind: a (limited) call for a return to introspection'. Introspection is now sometimes employed in experiments where subjects are asked to relate their feelings or thoughts about something that is going on around them, but there has been no return to the introspective laboratories of Wundt, Titchener, and Kulpe. There is also little interest in renewing discussion of introspection as a psychological method, because it is believed that certain objections to introspective psychology (see below) have never been satisfactorily answered.

There have been similar developments in philosophy. After behaviorism, the majority of philosophers adopted the view that the mind was to be identified with brain states or brain functions. They retained a traditional role for introspection, but translated the two-level Cartesian and Wundtian account of introspection into wholly physical terms. The two-level, Cartesian, process of conscious observer and observed became one part of the brain scanning another, or one part of the brain accessing another, similarly to one part of a computer accessing another. A limited revival of interest in a more orthodox account of introspection came in the wake of a major revival of interest in consciousness itself. This revival came about through the work of several philosophers of mind, notably the Americans Thomas Nagel (1995) and John Searle (1992), who claimed that any theory of mind that tried to reduce the subjectivity of consciousness to non-subjective brain states or functions was misguided.

PHILOSOPHICAL DISCUSSION OF INTROSPECTION

In philosophy, in orthodox Cartesian terms, introspection would have been analyzed in terms of a subject's capacity to observe, in a non-sensuous, private, privileged, incorrigible, subjective and, arguably, comprehensive fashion, events in that person's own stream of consciousness. Until comparatively recently, much of this analysis was still being defended. (*See* **Consciousness, Stream of**)

The process of introspection was held to be non-sensuous because it was not to be considered as an additional sense to be added to those of taste, touch, hearing, smelling, and sight, and it was not to be associated with any sense organ. Although it was a real form of observation, it was held to be one that was stripped of sensory features. Introspection was considered to be private because it was part of a person's inner private life of the mind, as opposed to that person's publicly observable life of behavior, gesture, expression, and speech. Introspection was considered to be privileged because the introspecting subject alone had this access to his or her own stream of consciousness. Introspection was considered to be incorrigible because introspective reports, being private and privileged, were not open to correction by anyone else. Some philosophers went further and claimed that introspection was infallible. Being immediate, simple and direct, there was nothing that could ever go wrong with the introspecting process. The objects of such direct knowledge were therefore held to be 'self-intimating' and the resulting beliefs about them 'self-verifying'. Also, given the requisite command of language, an introspector could not misreport on an introspection. A few philosophers have claimed that introspection was comprehensive, in the sense that all mental events were in principle introspectible. This view made sense, of course, when it was prefaced with the claim that the mind was coextensive with consciousness. Finally, introspection was considered to be subjective. It was subjective epistemologically, that is, as a type of knowledge, because it only provided knowledge to a single subject in respect of that subject's own stream of consciousness. It was subjective ontologically, that is, as regards its mode of existence, because it only existed as a conscious activity of a conscious subject. When a subject was asleep or in a coma, then the subjective point of view, including the introspective one, ceased to exist.

Many of the above claims have been challenged by philosophers, particularly in the latter half of the twentieth century. Many philosophers have pointed out that introspective reports are not incorrigible, especially in relation to reports of complex mental states. For example, at the conference cocktail party, Fred might claim, sincerely, that he must have spilt his drink because he was astonished by anyone in the twenty-first century defending introspectionism in psychology. Everyone else realized that he spilt his drink because he was angry and embarrassed because it was Mary, whom everyone knew had recently divorced him, who was defending introspectionism. Philosophers have also pointed out that introspection cannot be strictly comprehensive in its knowledge of the mind: since the time of Freud, it has become a common belief that many of our strongest desires

and beliefs and motivations exist and operate below the threshold of our consciousness.

The most important of these criticisms, however, have been about the very structure of the orthodox Cartesian account of introspection. This orthodox account is a two-level account. It analyzes introspection into an activity of consciously observing a conscious process. Philosophers have argued that this splitting of consciousness into observer and observed is bound to cause problems in regard to the introspection of complex mental processes. If the introspective task is to observe one's own conscious process of, say, multiplying 2634 by 1292, then, the more one concentrates on the introspecting, the more likely one is to make a mistake with the mental arithmetic.

Philosophers have also argued for a judicious employment of Ockham's razor, or the principle of parsimony, which, in this context, dictates that one should not multiply levels of consciousness beyond theoretical necessity. Neither the introspection of complex mental processes nor that of simple mental states requires a two-level explanation. The introspection of complex mental processes can be adequately explained as a replay, via short-term memory, of just the first-level mental process. To introspect your mental arithmetic is simply to recall the steps you made in arriving at your answer, immediately after they have occurred. The introspection of simple mental states can be explained in terms of focusing one's attention by banishing distractions. To introspect the pain in your stomach, in response to your doctor's query, is to concentrate your attention on your stomach in order to say how it feels.

The above is a 'middle of the road' account of current philosophical views of introspection. In fact there are many variations, and considerable debate about a number of its claims. For example, when rejecting the two-level account of introspection, some, notably Sydney Shoemaker (1996), have argued for a one-level account in terms of a concept of self-intimation. Shoemaker argues that there is no such thing as introspective perception of the self, or indeed of anything else. On the other hand, we do have various forms of self-knowledge. One central form of self-knowledge – indeed, the one that people mistakenly interpret in terms of a two-level account of introspection – occurs in so far as certain very basic mental states, such as being in pain, are self-intimating. By 'self-intimating', Shoemaker means that there is an internal connection between being in a mental state of that kind and having, or at any rate being disposed to have, the introspective belief that one has it. In short, 'introspection' is just the misleading name we give to the fact that some mental states imply others: to be in a certain mental state is *ipso facto*, and necessarily, to generate a meta-belief that one is in that mental state. Shoemaker's argument involves the claim that the proper functioning of human rationality in normal humans requires this to be so.

In contrast to this (by now fairly common) rejection of any two-level account of introspection, David Rosenthal (e.g. 1997) argues robustly for a return to a two-level account of introspection. He argues that, while introspection is not a form of inner perception, it is a form of inner, second-level attention. When one introspects, say, one's mental act of thinking about the conference dinner last night, one is both thinking about the dinner and thinking about one's thinking about the dinner. Furthermore, such second-level thinking is a conscious, occurrent process. Thus introspection consists in conscious, attentive, higher-order thinking about conscious, attentive, ground-level thinking, and introspective reports are therefore real reports about real inner events.

Any detailed interpretation of introspection is bound to be affected by the current debate in the philosophy of mind about 'internalism' (the view that all mental states are wholly identifiable in terms of their inner, nonrelational characteristics) and 'externalism' (the view that mental states, or at least those that involve things like thoughts, are partly identifiable in terms of the meanings of their contents, which in turn involve a relation to some external, communal, states of affairs). In particular, this debate has a bearing on the authority of the introspecting subject's account of his or her own mental states. If some version of externalism about mental states is correct, then a subject can much more easily be wrong about the nature of his or her own inner mental states than if internalism is correct (e.g. Davidson, 1994; Burge, 1994). (*See* **Externalism**)

PSYCHOLOGICAL DISCUSSION OF INTROSPECTION

Whereas most philosophical discussion has been about the theory of introspection, psychological discussion has focused on introspection as a scientific method.

In the first decades of the twentieth century, psychologists questioned whether introspection could or should be part of any scientific psychology. They argued that only objective methods were truly scientific. By this they meant that

scientific experiments must be both observable by two or more people as they are taking place, and repeatable in every important respect. *Ex hypothesi*, introspective experiments could involve only one observer. Strictly speaking, they were also unrepeatable, because it was impossible to ensure that a subject's inner mental acts, which comprise both the observing and observed aspects of the introspective experiments, were similar each time the experiment was repeated.

Psychologists also pointed out that introspection experiments produced unreliable data. There were no agreed results. While there might be almost unanimous agreement about some introspection finding among the psychologists of one laboratory, this might be disputed by those from another introspection laboratory. Notoriously, there was the dispute between those who asserted that their introspection experiments found that conscious episodes of thinking always employed some sensory medium, and so were in the form of heard speech, visualized representations or something similar, and those who asserted the opposite. There were many other disputes along the same lines, which began to weaken the confidence of psychologists in the value of data from introspection experiments.

Some psychologists also conducted experiments about the very possibility of splitting consciousness in the way that seemed to be demanded by the orthodox two-level account of introspection. Although this matter is still disputed, many psychologists believed that their experiments showed that we cannot attend carefully to two cognitive tasks at the same time. This is so, whether the tasks are driving through heavy and volatile traffic on an unfamiliar route while at the same time discussing the theory of introspection with a fellow passenger, or pondering upon Pythagoras' theorem while at the same time introspecting it in such a way as to be able to report on it. The best one can do is to oscillate one's attention, one's focus of consciousness, between the two tasks, or else focus on just one of the tasks and try to accomplish the other automatically.

THE ROLE OF INTROSPECTION IN COGNITIVE SCIENCE

Leaving aside the debates about the correct explanation of what is going on when we introspect, and about the status and reliability of the data of introspection, it is certain that we report on and express our inner conscious states. We do talk about our thoughts, our pains, our hopes, our plans, our beliefs and our desires, and many other inhabitants of our inner life of the mind. Sometimes, too, we display or express our conscious states, say, of pain or disgust, in our gestures or facial expressions or body postures. Both our reports and our expressions are clearly data of a psychological sort, and so cannot be ignored in any reasonable cognitive science.

Few would dispute that part of any complete psychological account of someone's being in pain, or being disgusted, or being angry, or being depressed, or being puzzled, or being astonished, includes an account of the outer expression – in gesture, posture, facial expression, tone of voice, and behavior – of inner conscious states. It is the strictly introspective reports of inner conscious states or processes that have always raised doubts.

The best way of treating an introspective report of an inner conscious state may be to consider it as having more or less the same status as a single independent eyewitness account of some event. Eyewitness acounts are useful but need to be treated with circumspection. Take the case of a single eyewitness report of a road accident. The investigating police officer would want to check it, if he or she could, by reference to more objective evidence. If the eyewitness said that the car skidded and then drove straight into a tree on the left-hand side of the road, the police officer might note both that there were no skid marks on the road and that the area of initial impact was not the front of the car. Again, an introspecting patient might tell the doctor, quite sincerely, that he has a heart pain but, after some tests, the doctor might tell him that it is merely indigestion. Or an introspecting patient in a psychotherapy session might say, again quite sincerely, that it was a lack of interest that made her skip her psychology lectures on motivation, whereas the therapist might realize, from the patient's past history, that the reason was agoraphobia.

Nevertheless the patient in the doctor's surgery and the one in the psychotherapy session have revealed something about themselves. In the first case, the patient directly revealed that he was in pain, and indirectly that he had a fear of heart attack. In the second case, the patient directly revealed that she had a reluctance to go to her psychology lectures, and indirectly that she was in denial as regards her previous history of agoraphobia.

Cognitive science needs to take account of all available data, including introspective reports, when building up a complete picture of a human's cognitive life. (*See* **Metacognition**)

Inverted Spectrum

Intermediate article

Martine Nida-Rümelin, University of Fribourg, Fribourg, Switzerland

CONTENTS

If person A sees as green what person B sees as red, and person A sees as red what person B sees as green, and if some other simple conditions are met, A is said to have an inverted spectrum with respect to B.

WHAT IS AN INVERTED SPECTRUM?

Is it possible that one person sees as green what another sees as red, and, equally, that the first sees as red what the second sees as green? If so, then the difference would also apply to mixed colors: surfaces that appear greenish to the first person (e.g. turquoise) would appear reddish to the second person (violet) and vice versa. Both people would have learned to call red things 'red' and green things 'green', so the difference between them might go unnoticed. This is a case of an inverted spectrum (IS). In more precise terms, A has an *inverted spectrum* with respect to B if

(C1) A and B have the same overall set of color experiences, but
(C2) things appear in color systematically different to A and B, and
(C3) the difference in color perception between A and B does not and cannot manifest itself in behavior.

The claim that cases of IS are possible has been called the 'Inverted Spectrum Hypothesis' (ISH). The ISH has received extensive discussion in the philosophical literature but very little discussion within empirical color vision science. There is no commonly accepted view about whether the ISH is true or false (in any of the possible interpretations distinguished below).

The definition above captures the notion of an *inter*subjective IS (the difference exists between different perceivers). *Intra*subjective IS concerns the same individual at different times. An intrasubjective spectrum inversion would normally manifest itself in behavior. In the following, IS without a qualification stands for intersubjective IS.

DIFFERENT VERSIONS OF THE INVERTED SPECTRUM HYPOTHESIS

Sometimes a weaker notion of IS is used in the literature, a notion that only requires the conditions C1 and C2. Most authors require something like condition C3 for a case of fully-fledged IS, but often it is not quite clear precisely what third condition they have in mind. At least three different versions of the third defining condition are frequently assumed and should be distinguished:

(C3a) The difference does not and cannot manifest itself in behavior with respect to normal life situations.
(C3b) The difference does not and cannot manifest itself in behavior of any kind (including behavior in sophisticated psychophysical experiments).
(C3c) There is no relevant functional difference: although person A and person B have inverted color sensations, the inversion leaves the causal roles of color sensation untouched.

If, for example, A and B are red–green inverted with respect to each other, then (according to condition C3c) red experiences occupy the same causal role in A as green experiences occupy in B (they have the same causes, interact in the same way with other mental states and lead to the same kind of behavior). C3c could be further subdivided according to different accounts of causal role and correspondingly different notions of functional difference.

The claim that cases of IS are possible (the ISH) has different content depending on which of these conditions is implicitly presupposed. In addition, the notion that such a possibility is involved has at least three different interpretations: the logical possibility, the nomological possibility, and the metaphysical possibility. IS is logically possible if there is no hidden contradiction in its assumption (if a case of IS can be coherently conceived), it is nomologically possible if the occurrence of a case of IS is compatible with the laws of nature. Metaphysical

possibility is a possibility in a mind-independent way and thus may be called a 'real' possibility as opposed to a merely apparent possibility (but it does not coincide with a nomological possibility; many situations that are excluded by the laws of nature are considered metaphysically possible). According to many philosophers some situations are conceptually possible but metaphysically excluded. A famous example is a situation where the Morning Star is not identical with the Evening Star. This is in some sense conceptually possible, but not 'really' possible since Venus is necessarily identical with Venus. Combining the three different conditions (C3a–C3c) that may be presupposed in the ISH with the three possible interpretations of possibility, we get six variants of the ISH. Each must be judged on the basis of quite different considerations.

PHENOMENAL STRUCTURE AND COLOR INVERSION

The way a red–green inverted person would see the color circle (see Figure 1) can be shown by exchanging F1 with F9 and by rearranging the binary hues accordingly.

Other types of inverted color vision can be represented in the same way by permuting the colors of the circle in Figure 1. But not every arbitrary permutation of colors in the circle represents a possible case of IS. Just exchanging F1 and F2 would represent a color inversion that certainly would manifest itself in verbal behavior (the person would make different color similarity judgments and different judgments about color composition). The transformation that consists in a simple exchange of F1 and F2 does not preserve the relations that obtain in the appearance of the colors; it does not preserve what has been called 'phenomenal structure'. Aspects of phenomenal structure concern the similarity of colors, the relation of being phenomenally composed or mixed of two basic colors, the relation of being complementary to each other, and many other features. (Phenomenal mixture or composition should not be confused with light mixture or pigment mixture. A color is phenomenally composed of two components if it *appears* to contain these two colors). If one restricts the set of permutations that represent possible candidates for an IS to those that preserve phenomenal structure, then only those permutations remain that map each unitary color into a unitary color and rearrange the binary colors accordingly. These permutations are obtained by appropriate rotations (90°, 180° or 270°) or by appropriate reflections (vertical or horizontal axis, axis through F3 and F11, or axis through F15 and F7). All the other permutations violate the above mentioned constraint: they do not preserve phenomenal structure for obvious reasons (similarity relations or relations of phenomenal composition would be changed).

The truth or falsity of the ISH thus depends on whether there are color transformations that preserve phenomenal structure. The latter question is a lot more complicated than the above simple description might suggest. Phenomenal structure

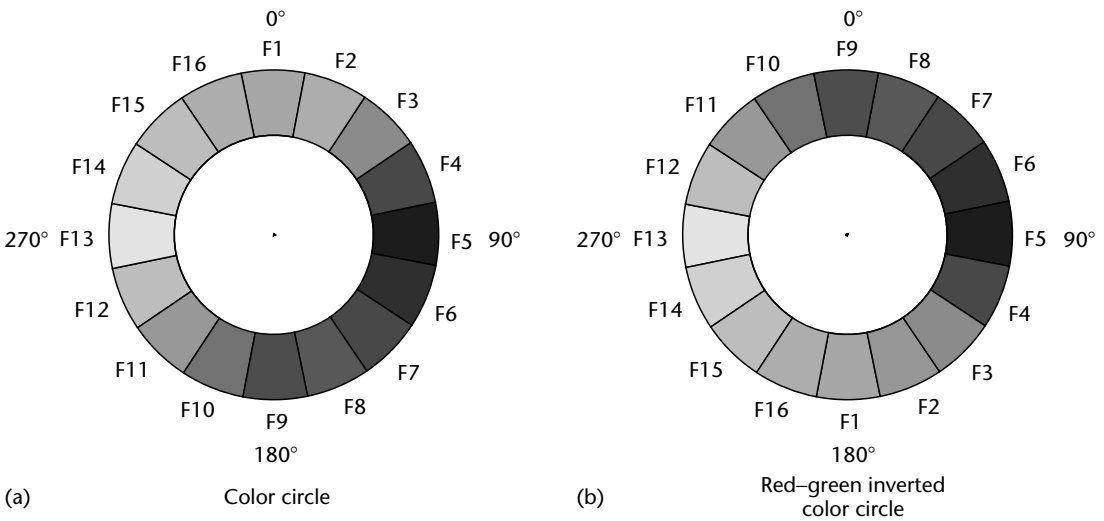

Figure 1. [*Figure is also reproduced in color section.*] (a) Circle representing color spectrum. (b) Circle representing inverted spectrum.

must be described in a way that takes further aspects of colors into account (the third dimension: black–white or brightness), saturation, and maybe further features such as the warmth (coolness) of colors and their role in depth perception.

Some aspects of phenomenal structure may, however, be due to of learning processes (maybe red is experienced as warm because it is associated with fire or experienced as alarming because it is associated with blood) and to sociocultural factors. If these features are not preserved by some color transformation, the transformation may nonetheless represent a metaphysically, nomologically, and logically possible case of IS (in all three senses distinguished above by C3a–C3c).

HISTORY OF THE INVERTED SPECTRUM

The idea of an intersubjective IS occurs in John Locke (1690, book 2, ch. 32, sec. 15). In the first decades of the twentieth century ISH was a favorite example of logical positivists to explain, illustrate, and discuss their verificationist theory of meaning. The idea of intrasubjective IS occurs in the writings of Wittgenstein in the context of his private language argument. In contemporary philosophy IS is of particular interest as a potential counterexample to materialist theories about the nature of phenomenal consciousness.

PHILOSOPHICAL ISSUES ABOUT THE INVERTED SPECTRUM

The ISH plays a prominent role in the debate about what makes an experience an experience of a specific phenomenal (or qualitative) kind, e.g. about what it *is* that red experiences have in common. (Talk of 'red experience' is not meant to imply that the experience is literally red. The expression is used to refer to a specific phenomenal kind of experience.) Phenomenal kinds are distinguished by how it is to be in the state at issue (by their subjective character). The properties that different instances of one phenomenal kind (e.g. the kind specified by 'being a red sensation') have in common are called 'qualia'. According to widespread opinion, qualia represent a serious problem for physicalist (materialist/naturalist) theories of the mind. The idea of an IS has been used in arguments for the claim that some or all materialist theories of the mind fail to capture qualia. In particular it has been used to argue against functionalism.

The Inverted Spectrum and Analytical Functionalism

There would be no qualia problem for physicalism if what it means to be in a state of a particular phenomenal kind could be stated in nonmental terminology. If this were true then the apparent problem of qualia could be resolved on the basis of *a priori* conceptual analysis of terms like 'has a red experience' or 'object O appears red to person P'. Analytical functionalism (as advocated by Lewis (1980a)) proposes a solution of this kind. According to analytical functionalism, to have an experience of red means to be in a state that plays a specific causal role in the functioning of the organism (where the causal role is defined, approximately, by the way the state is normally caused, by its causal interaction with other inner states, and by its causal relevance for behavior). Many have argued that analytical functionalism does not capture the meaning of phenomenal terms like 'red experience'. What it means to have an experience of a particular phenomenal kind (e.g. a red experience) appears to be understandable (for those who have had the experience at issue) without any reference to the causal role of the state at issue (to the way it is caused, to the behavior it typically produces, or to its impact on other mental states). This natural intuition has been justified and illustrated on the basis of the idea of an IS. If it is logically (conceptually) possible that color experiences of one phenomenal kind (e.g. red experiences) occupy in one person the causal role occupied in another person by color sensations of another phenomenal kind (e.g. by green experiences) and vice versa, then at least a particular version of analytical functionalism (a version that defines phenomenal states by their causal role in the individual at issue) must be false. One possible reply has been proposed by David Lewis (1980b), who defines phenomenal kinds by reference to their normal causal role in a given population (according to this view a person can have a red experience relative to one population but a green experience relative to another). Analytical functionalism does not have many adherents today. Most philosophers admit that cases of an IS, even in the strongest sense (presupposing condition C3c), are coherently conceivable.

The Inverted Spectrum and Empirical Functionalism

The conceptual possibility of IS in all three senses can be accepted by empirical functionalists, who

admit that phenomenal concepts (the concept of having a red experience) cannot be defined in nonmental terminology but insist nonetheless that the properties referred to or expressed by phenomenal concepts are functional properties. According to their view, the property of having a red experience consists in being in an inner state that occupies a particular causal role, although *a priori* reasoning about our concept of red experiences does not reveal this truth. In their view, it is the task of empirical science to describe the exact features of the causal roles at issue. According to the empirical functionalists, cases of IS (in the strongest sense; see C3c) appear possible (they are coherently conceivable), but they are not *really* possible (they deny the metaphysical possibility of an IS in the relevant sense). The appearance of such a possibility – they may add – can be explained by our conceptual make-up (our phenomenal concepts and our functional concepts are conceptually independent). It has been argued, however, that in the particular case at issue conceptual possibility implies metaphysical possibility. The issue depends upon one's view about the relation between phenomenal concepts and the corresponding phenomenal properties. Those who think that a person who has the phenomenal concept of a red experience (on the basis of her own red experiences), and thereby knows what is essential for having that kind of experience, will typically deny empirical functionalism and insist on the metaphysical possibility of IS in all three senses.

Some philosophers accept the metaphysical possibility of IS (in all three senses), deny empirical functionalism for the particular case of phenomenal states (while accepting it for other mental states, e.g. beliefs and desires) and propose to conclude that phenomenal states are identical with the particular neurophysiological states that occupy the causal roles at issue (Horgan, 1984). Against this view it has been argued that there is just as good reason to accept the metaphysical possibility of inverted color vision in two subjects that are molecule-by-molecule duplicates as there is to accept the metaphysical possibility of IS in people that are functionally alike. If the former metaphysical possibility must be accepted, then property dualism is the only viable alternative. Property dualism claims that what it is to have an experience of red cannot be captured in physical terminology at all (where physical terminology is meant in a broad sense, including chemical, biological, physiological, and functional descriptions). Property dualism does not have many adherents in contemporary philosophy of mind, but it has gained some ground in recent years (for a dualist conception of phenomenal properties see Chalmers, 1996).

Intrasubjective Color Inversion

Intrasubjective IS is not directly relevant to the debate about functionalism, but the thought experiences of someone who undergoes an intrasubjective color inversion have been used repeatedly to argue for the ISH. The possibility of intrasubjective IS is harder to deny, since it would manifest itself in behavior (the person would surely say that things don't look the same). Suppose a normally sighted person undergoes an intrasubjective spectrum inversion (suddenly grass looks red and sunsets green) but after some years she becomes accustomed to the new look of things and even forgets about the inversion event. She now behaves like a normally sighted person and thus is at least a case of an IS in its weakest sense (C3a). Thus it may seem that those who accept the logical (or metaphysical) possibility of an intrasubjective IS (which is hard to deny) should also accept the logical (or metaphysical) possibility of intersubjective IS (which threatens functionalism). This line of argument has been discussed in Shoemaker (1982), who also develops a possible functionalist response along the following lines: talk of differences or sameness makes sense only within one and the same individual (here difference and sameness can be functionally defined) and does not make sense when applied to experiences of different individuals (here difference and sameness cannot be defined in functional terms).

Inverted Spectrum and the Explanatory Gap

According to the explanatory gap thesis, it is impossible to understand why certain physiological processes are accompanied by experiences of a specific qualitative kind (Levine, 1983). The claim was originally motivated by pointing out the conceptual possibility of an extreme case of IS (where even the physiological details remain the same): even if we knew every physical–functional detail about the physiological state responsible for red sensations, we could still coherently conceive of a situation where this kind of state was accompanied by sensations of another phenomenal kind (e.g. by green experiences). It has been objected that the possibility at issue is only apparent. According to Hardin (1986, 1997), the case will cease to be conceivable once we know enough about the

phenomenal structure of color experience and about the functional structure of the underlying processes. It should be noted, however, that the explanatory gap thesis does not depend on the conceivability claim at issue. Even if Hardin is right, it may still be an open question as to why the physiological processes underlying color sensations lead to phenomenal experiences of a particular given kind: they could have led to hue experiences of a different kind (colors we humans actually do not know) with the same phenomenal structure.

Philosophical Discussion in the Light of Empirical Results

A great part of the philosophical discussion about IS has been led quite independently of color vision science, but some important work about the topic has been done on the basis of detailed knowledge of related empirical results. A prominent example is the work of C. L. Hardin, who assumes that any possible correlation between color sensations and physiological processes is structure preserving in the following sense: the phenomenal structure of color experience must be mirrored in the functional structure of the underlying physiological processes. He then goes on to argue that given the rich phenomenal structure of color experience, it is very plausible (already on the basis of what is known today) that there is just one structure that preserves mapping from brain processes to human color sensations, namely the one actually realized in nature.

Although Hardin's argument uses empirical results, quite unsurprisingly it does not reach its conclusion without additional philosophical assumptions about what is metaphysically possible. For his argument to carry he has to assume that the phenomenal structure of our color experiences is in part metaphysically necessary. Some of these additional assumptions have been questioned (see Levine, 1991).

Alien hues

Several other authors have argued that to attack functionalism one need not argue about the possibility of an IS in humans. Even if the human color space contains asymmetries that render a case of IS metaphysically impossible, this need not be true for other species (Shoemaker, 1982). If there is no reason to deny the metaphysical possibility of such creatures then empirical functionalism is in trouble. This line of argument presupposes that it makes sense to talk of alien colors, colors that we are in principle unable to imagine but that are experienced by other sentient beings. This presupposition may appear strange but becomes quite natural when considering the case of beings who can be shown to have more color dimensions than normal human perceivers. There is empirical evidence that animals with four or five color dimensions exist (see Thompson *et al.*, 1992).

Pseudonormal Vision

The empirical hypothesis that red–green inverted people might be among us (note that this implies that you might yourself be one of them) is a consequence of a model about the inheritance of red–green blindness proposed by Piantanida (1972). In normal humans, red experiences occur if R-cone activity (R-cones are receptor cells on the retina) prevails over G-cone activity and green experiences occur if G-cone activity prevails over R-cone activity. If, however, both kinds of receptor cells are filled with the same photopigment, then their activity in response to light stimuli will always be about the same and the person at issue will never see anything in a color that contains a component of red or green; she will be red–green blind. According to Piantanida's model this condition is caused in two ways: one type of inherited red–green blindness is due to the fact that the person's R-cones and G-cones both contain the photopigment normally contained only in R-cones (it is called 'the red pigment'); another kind of red–green blindness is due to the fact that the R- and G-cones both contain the photopigment normally contained only in G-cones (the green pigment). Now if a person has both genes for red–green blindness the filling of the G- and R-cones will be reversed with respect to normality (Piantanida calls people with this condition 'pseudonormal'). As a consequence of the pigment inversion, red objects will have exactly those effects on a pseudonormal human visual system that green objects have on a normal human color system and vice versa . It has therefore been concluded that pseudonormal people 'would be expected to have normal color vision except that the sensations of red and green would be reversed – something that would be difficult if not impossible to prove'. (Boynton, 1979, p. 356). Note that pseudonormal people (if they are red–green inverted) need not be a case of IS in any of its three senses. Whether they are depends on empirical issues such as the question of whether the coolness of green is due to environmental influences (if so, red might appear cool to pseudonor-

mals; if not, pseudonormal people should be detectable even on the basis of their behavior in normal life situations).

Some philosophical theories about phenomenal consciousness (in particular analytical functionalism and externalist versions of representationalism about qualia) are incompatible with the view that pseudonormal people (if they exist) are red–green inverted. One may be tempted to conclude that these theories have been refuted by empirical science. But the conclusion would be hasty. It can and has been argued that a scientist who predicts red–green inverted vision for people with the pseudonormal condition implicitly presupposes philosophical premises (the falsity, for example of qualia externalism, the supervenience of phenomenal experience on instrinsic properties of the visual system) that cannot be settled by empirical research. But maybe these 'philosophical' premises are nonetheless scientifically justified by certain successful underlying assumptions or methodological principles. It seems quite clear that the issue about whether pseudonormal people if they exist would be red–green inverted requires both the clarification of empirical issues and metatheoretical (philosophical) reflection about the meaning and relevance of phenomenal terminology in color vision science. There has been some discussion about this issue within philosophy (Ross, 1999) and apparently no discussion about it within color vision science. Since 1972 theories about the genetics of red–green blindness have of course become far more complex, and the empirical issue of whether there are pseudonormal people (people with green pigments in their R-cones and red pigments in their G-cones) does not seem to have been settled (for a review article of relevant research see Nathans, 1999). But then the question has not received much discussion. Surprisingly enough, Piantanida's hypothesis that there might be red–green inverted people among us has failed to initiate any vivid debate within empirical color vision science.

Representationalism

The ISH is relevant to the debate about representationalism vis-à-vis qualia. Weak representationalism with respect to qualia claims that they do represent external properties. Strong representationalism says that to represent a specific objective property is all that it is to be in a specific phenomenal state (representationalist views about qualia are proposed by Lycan, 1996; Tye, 1995; and Dretske, 1995). According to the latter view, to have a red experience is to visually represent the property red. What this means is often defined in functional terms while what it means for a given state to represent something is normally defined in a way that requires the state be reliably caused by things with the represented property. Representationalism is naturally combined with objectivism about colors (colors are objective properties of physical things and can be defined without reference to the way they appear to humans) and with externalism about qualia, the view that the kind of phenomenal experience people have can depend on their causal relations to their environment and does not depend on their inner intrinsic properties alone. Most versions of externalist representationalism have to deny the possibility of inverted color vision (a red–green inverted person has reliably red experiences in the presence of green things). Externalist representationalism is incompatible with the plausible assumption that the kind of color experienced (whether it is a red experience or a green experience) depends on intrinsic properties of the brain and not on how the instatiation of these properties is caused by external stimuli. Some representationalists wish to avoid this consequence and propose an account of representationalism that is compatible with the denial of externalism about qualia (see Rey, 1998). In the recent debate about representationalism the ISH has played a minor role compared to the thought experiment involving an inverted earth (introduced by Block, 1990) that is related but different.

Other Philosophical Issues about the Inverted Spectrum

IS is mainly discussed within the philosophy of mind, but it is also relevant to philosophical questions belonging to other domains of philosophy. Any theory of meaning in the spirit of verificationalism needs to be tested intuitively by applying it to versions of the IS. Intrasubjective and intersubjective IS raise the question of whether or in what sense it may be possible to refer to one's own inner (i.e. not publicly accessible) states by employing public language terms and whether the specific quality experienced can be communicated to others (see Strawsen, 1989). Finally, IS raises the question of whether and how we can know about the existence and the contents of other minds. If the ISH is correct, then I cannot deny that you see green where I see red. Can I nonetheless claim to know that we both have green experiences in the presence of green objects? The fear that any acceptable theory of knowledge combined with the

ISH would imply that I cannot (and in this sense leads to skepticism about other minds) is one reason that some philosophers reject the ISH.

EMPIRICAL ISSUES INVOLVING 'IS'

The empirical question of whether there are in the human case color transformations that preserve those aspects of phenomenal structure that can be assumed to remain unchanged under different learning conditions is discussed in detail by Palmer (1999). He argues that all but three transformations can be ruled out from is known about phenomenal structure. The three remaining candidates are: red–green inversion; blue–yellow inversion combined with black–white inversion, and the combination of inversions with respect to the three color dimensions (red–green inversion plus blue–yellow inversion plus black–white inversion). According to Palmer, whether any of these really is structure preserving in the sense just mentioned depends on empirical issues that have not yet been settled.

RELEVANCE OF THE 'IS' TO COGNITIVE SCIENCE

In their study of color vision cognitive scientists are typically interested in the causal structure and the causal mechanisms of those processes that are responsible for the capacity of an organism to distinguish surfaces according to their light reflectance properties. This aspect of color vision can be studied independently of issues related to the idea of an IS. But color vision in the case of humans and many other species also has a subjective side: color experiences have particular phenomenal characters. There are many questions concerning phenomenal character that a science of color vision can legitimately try to answer: e.g. what hues are experienced by color-blind people in its various forms? Would pseudonormal people be color inverted? At what stage of evolution does color experience (in the sense of having a particular phenomenal character) occur? Do other animals know hues that we cannot imagine? Many think that questions about phenomenal character are beyond the reach of empirical science, but this is far from obvious and should be discussed in a metatheoretical study that requires both scientific and philosophical competence. Such a study would have to clarify questions about (a) the meaning of phenomenal terminology in scientific theories of vision and (b) about the possible limitations of scientific approaches to the subjective side of experience. The idea of IS is potentially relevant for this kind of metatheoretical reflection in a way that may not yet have been sufficiently recognized (for a beginning of an interdisciplinary discussion about these issues see Palmer, 1999 and the various comments in the same journal issue).

James, William

Introductory article

E Taylor, Saybrook Institute, San Francisco, California, USA and Harvard University, Cambridge, Massachusetts, USA

CONTENTS

William James (1842–1910) made significant contributions to the fields of psychology and philosophy. He is perhaps best known for his monumental work the Principles of Psychology *(1890) which introduced several influential concepts, amongst the most notable being the 'stream of consciousness'.*

SCIENTIFIC LINEAGE

William James (1842–1910), physician and philosopher-psychologist, taught at Harvard University from 1873 to 1907. Weaned on the Swedenborgian and transcendentalist philosophy of his father, Henry James Sr, and his godfather, Ralph Waldo Emerson, James matriculated at Harvard in 1861, where he studied chemistry under Charles William Eliot at the Lawrence Scientific School. He entered Harvard Medical School in 1864 to study comparative anatomy under Jeffries Wyman; microscopy, anatomy, and physiology under Oliver Wendell Holmes Sr; and vivisection under Harvard's first professor of neurology, Charles Edouard Brown-Sequard. James's training in basic science was eclectic but distinguished. He derived his evolutionary theory from the Harvard botanist Asa Gray, a member of Darwin's inner circle. He gleaned reductionstic positivism from the philosopher Chauncey Wright; and his logic of the scientific method he learned from Charles Sanders Peirce, the originator of pragmatism. James's emphasis on clinical applications came from the attitude of *la clinique*, derived from Pierre Marie through Oliver Wendell Holmes Sr, while his expertise in experimental methods came from his training in surgical dissection, this provided an insight into structure and function in a lineage that can be traced through Holmes and Brown-Sequard back to the experimental physiology of Claude Bernard, Francois Magendie, and Xavier Bichat.

According to Walter Bradford Cannon, in the early 1870s James and his medical school colleagues Henry Pickering Bowditch and James Jackson Putnam conducted the first studies in experimental neurophysiology in the United States. These studies, which were conducted in Bowditch's laboratory, involved surgical dissection of dogs' brains and were designed to settle issues involving the localization of function.

James began teaching anatomy and physiology in 1873, taught the first course in physiological psychology in America in 1875, and opened the first laboratory of experimental psychology devoted to student instruction that same year. He awarded the first doctorate in the new experimental psychology to G. Stanley Hall in 1878. At the same time, James continued to involve himself in experimental studies of the nervous system, eventually proposing a cure for seasickness derived from the study of dizziness in deaf mutes. These studies were further corroborated when the New York neurologist George Miller Beard replicated them in 1878.

PSYCHOLOGY AND PHILOSOPHY OF CONCIOUSNESS

Meanwhile, James taught psychology and philosophy throughout the 1870s and 1880s, marching through the categories of abstract philosophy and appropriating them one at a time for the new physiological psychology. His success led to a contract for a textbook in the new psychology in 1878, to be delivered in two years, but it took him 12. Periodic ill health intervened as did the death of his father and mother, and then his godfather, the great Emerson, within months of each other. There was also the intrusion into his psychology of new techniques in experimental psychopathology and psychical research, among them: hypnosis, crystal gazing, and automatic writing. James refitted the experimental laboratory at Harvard to accommodate these

methods and began to investigate dissociation theory as an explanatory mechanism for the altered states of consciousness seen in the mediumistic trance as well as the symptoms of neurasthenia and hysteria observed in patients suffering from functional rather than organic diseases of the nervous system. Hypnosis became for him a research tool for experimental induction as well as extinction of such phenomenon. In this, James proved himself to be a skilled hypnotist.

His work was to have a profound influence on the course of experimental psychopathology and the newly emerging field of psychotherapeutics, as his publications on these subjects from the viewpoint of physiology allowed neurologists such as James Jackson Putnam at the Massachusetts General Hospital and Morton Prince at the Boston City Hospital to introduce psychotherapeutic methods into the outpatient clinics in the treatment of the ambulatory psychoneuroses. His work also influenced Binet, Janet, and Ribot in France, among others. Later, James's studies would also have an impact on the evolution of his thinking about a new metaphysics underlying the way experiments should be conducted in psychological science, if we were to understand the problem of consciousness. He would call this new metaphysics 'radical empiricism'.

COGNITIVE PSYCHOLOGY OF THE OBJECT

Finally, in 1890, ten years late, James's monumental *Principles of Psychology* appeared to international acclaim. It filled two volumes and was over a thousand pages long. Joking but exhausted, James declared that he was finally glad to get that 'dropsical, tumescent mass', off his desk. Its main point was the development of a cognitive psychology of consciousness, focusing on an analysis of objects as they appear at the center of the field of attention. Its epistemological basis was reductionistic positivism, James said, because no other philosophical metaphysics of scientific experimentation superior to it had yet been articulated.

The work opened with an up-to-date survey of brain neurophysiology, followed by a trenchant scientific and philosophical analysis of topics that stand to this day. Instincts are emotions, he said, frozen into the nervous system because of their supreme evolutionary utility. Between the gross and the subtle, whatever emotion we experience, however, is dependent on our perception of the event. Emotions are the great flywheel of society, the habit system being in effect an early version of the cognitive system. Within the cognitive field, all attention is based on interest, reminding us that while what we see is obviously important, equally significant is what we do not see. To see, therefore, means that discriminative attention is what saves us from being constantly inundated by the 'blooming buzzing confusion'. Thus, all culture, James said, begins with rejection. As consciousness is always flowing onward, it is appropriate to speak of a stream of thought and feeling. What we attend to usually takes up the center of the field, however, while the margin of consciousness controls meaning. Every thought is warmed by an emotion, making it our own, and our emotions are implicated in the meaning of each event, although our emotional attachment to an idea remains hidden just below the surface of consciousness, or associated with ideas and stored subconsciously as memory. Our sense of self is made up of a biological, material, and psychological sense of who we are, compounded by our social self, which is made up of as many different selves as we have human relationships. In this regard, the social self mirrors the basic nature of personal consciousness, which is an ultimate plurality of states, not a unity as we would like to believe.

The two-volume 'James' was quickly cut and pasted into the more convenient one-volume 'Jimmy' in 1892, and released as *Psychology: Briefer Course*. The shorter work then became a standard college text for the next 20 years. A recent reassessment of *The Principles* suggests that virtually nothing new has been discovered since the work was first published. It is still considered possibly the greatest general work on psychology in the discipline's history.

SUBCONSCIOUS AND MYSTICAL AWAKENING

After 1890, James began to turn his attention to the scientific study of consciousness beyond the everyday waking state of awareness. Consciousness, he said, was 'a field with a focus and a margin'. He now proposed to study consciousness beyond the periphery: in other words, the penumbra or halo of thought. This took him out of the realm of pure cognition into the domain of the emotional and the imaginal. The problem he faced was an epistemological one, however. The limits of what we would now call 'cognitive neuroscience' were, and still are, clearly defined by the dictates of reductionistic positivism. Experimental science deals only in the rational and the empirical, meaning that its methods are limited to the rational

ordering of sense data. Hence, the new psychology was based on what could be measured, and largely defined by advances in physiology and psychophysics. There were also the new methods of mental testing, which were usually paper-and-pencil tests and therefore similarly constrained by language.

Important new advances in dissociation theory coming from the French experimental psychology of the subconscious around Charcot, Binet, Janet, Bernheim, and others suggested to James, however, the reality of interior states of consciousness. James declared in his presidential address to the American Psychological Association in 1894 that he was no longer going to defend the metaphysics of positivism as the foundation for experimental science, based, he said, on the new evidence coming in from French psychopathology. These states were radically different from the normal everyday waking condition where the cognitivists had exclusively focused their definition of scientific psychology. Moreover, dissociation theory, which was the basis for understanding the effects of hypnosis and the probable mechanisms at work in conditions such as hysteria and multiple personality, had grown out of French neurophysiology, and thus had its own scientific foundation. The principal contribution of the French neurological tradition, corroborated by the replication of its studies through the British psychical researchers, was the psychogenic hypothesis – that ideas can cause physical symptoms. After the early mesmerists had tried and failed to convince the French medical establishment of the scientific validity of hypnosis, and long before the concept of psychogenesis was associated with Freud and psychoanalysis, French, Swiss, British, and American researchers had confirmed the reality of the 'buried idea'. Experiences perceived as traumatic by the individual could be stored in the subconscious. There they existed as unintegrated fragments, floating around in the form of a single powerful but buried idea, collecting similar experiences to themselves until they gained enough energy to appear in the field of consciousness as a physical symptom, or even burst forth into the field looking like a fully developed, independent personality. Here, James was closely following the work of F. W. H. Myers.

After 1890, James, along with others such as James Mark Baldwin, became the principal interpreter of the French dissociation school to American psychologists. In this context, James was also the first to introduce the work of Breuer and Freud to the American psychological public in 1894, in the inaugural issue of James Mark Baldwin and James McKeen Cattell's *Psychological Review*. In that context, he cited Breuer and Freud as providing corroboration for 'Janet's already old findings'.

James went on with this work to pioneer in what we would identify today as the origins of personality, abnormal, and social psychology. After visiting Charcot at the Salpêtrière in 1882, he significantly influenced Ribot's conceptions about the pathology of the emotions; from his background in chemistry he coined the term 'dissociation' as a psychological concept in order to trump the associationists, and his own hypnotic investigations inspired the young Morton Prince to enter the field. In the midst of other classes in psychology and philosophy, from 1893 to 1898, James taught the first graduate course at Harvard in experimental psychopathology, and his previously unpublished 1896 Lowell Lectures on 'Exceptional Mental States' further confirmed the previously loose-knit endeavors of the so-called Boston School of Psychopathology thereafter.

The Lowell Lectures outlined James's conception of a dynamic psychology of the subliminal, or subconscious, as it was variously called, and particularly focused on experimental evidence for the hypnagogic state, the twilight region between waking and sleeping where dreaming naturally occurs and hallucinations appear when there is a fall of the threshold of consciousness in the waking state. Exploration of the subconscious put us in touch with the deepest regions of human nature, James said.

The Exceptional Mental States Lectures investigated the psychopathic region of the subconscious, while James's *Varieties of Religious Experience*, delivered in 1902, presented evidence for a growth-oriented dimension to personality. Within this dimension, James showed, mystical experiences can occur that have ultimately transforming effects on the person. Such philosophical implications of non-ordinary states of consciousness called into question the limitations experimental psychologists put on their subject matter by having decided too quickly that their underlying philosophical metaphysics would be the same as physics and biology.

METAPHYSICS OF EXPERIENCE

But this was a time when scientific psychology was establishing itself in the newly founded American graduate schools, experimental laboratories were being established, and philosophy was being more clearly differentiated from scientific psychology. To all appearances, James seemed to be bringing

philosophy back into psychology. For this, to this day he remains grossly misunderstood. Within the field of philosophy he had just established his doctrine of the will to believe – choosing the good as a commitment to the moral and ethical life even though evil always waited *in potentia* – and in 1898 he formally launched the philosophical movement called 'pragmatism', which soon became international in scope. The true heart of his philosophical metaphysics, however, was radical empiricism, by which he meant pure experience in the immediate moment, before the differentiation between subject and object.

Traditional philosophers had differentiated rationalism from empiricism, the word 'empirical' referring to the data of the senses. James's empiricism was more radical, he said, because he meant for the word to mean not sense perception alone but the full spectrum of a person's experience. This meant that the subjective and the objective were both equally valid points of view within the larger theater of experience. Radical empiricism he conceived as a new metaphysics for experimental psychology and in science generally, because it established the phenomenology of the science-making process as a crucial element, not to be controlled against but to be accounted for, in the conduct of the scientific experiment. Without including this crucial element, he said, a science of consciousness was not possible.

Radical empiricism had far-reaching implications because it purported to replace reductionistic positivism with an observationally grounded phenomenology. It overthrew the doctrine of representation in psychophysics, since there were not two sets of words, the one in front of us at this moment and the one in our mind as we read them. There is only one set, and that exists at the intersection between the history of the text and our immediate autobiography. It also made psychology not derivative but foundational to all the basic sciences, since there could be no measurements or laws without some consciousness somewhere to perceive and interpret them.

But, due to a variety of factors – James's continuing ill health, his first invitation in 1897 to give the Gifford Lectures on Natural Religion, the years of preparation and postponement that ensued, and the international attention afforded pragmatism – the doctrine of radical empiricism was to remain James's great unfinished arch. Nevertheless, when he died in 1910, it was generally acknowledged that an international figure in psychology and philosophy had passed from the scene.

CONTEMPORARY RELEVANCE

Since then, James's ideas have touched almost all aspects of modern psychology. Cognitivists, behaviorists, psychoanalysts, existentialists, phenomenologists, and humanistic and transpersonal psychologists have all variously claimed parts of him. Experimental psychologists will not read him after 1890, however; religious scholars study only his *Varieties of Religious Experience* from 1902; while philosophers continually try to cast him into the mold of the Western analytic tradition, meanwhile ignoring his psychology, his studies in psychical research, and his philosophy of mysticism.

Modern researchers in the cognitive neurosciences also continually go back and take pages from James, mainly from his *Principles of Psychology*, although neurophilosophy and now neurotheology are just beginning to cover the same ground that James had broken in his Exceptional Mental States lectures and in *The Varieties of Religious Experience*. Francis Crick's article on brain neuroscience in *Scientific American* begins with a full portrait of James. Thomas Natsoulas has been developing a cognitive theory of James's stream of consciousness for a number of years, while Bernard Baars has evolved a cognitive workspace theory of consciousness which comes close to James, as does Max Velmans's reflexive theory of consciousness. Since James's time, the mind/brain interface has once again become a central problem in the philosophy of science. What this new revolution in the neurosciences seems to be telling us is that, as science gets closer to understanding the biology of consciousness, the more a phenomenology of the science-making process and the scientific method itself come in for closer scrutiny. James predicted this would happen when, in one of the last statements he made before he died, he advised psychologists to study the fall of the threshold of consciousness in all its manifestations, 'even though we may not understand these phenomena or their far-reaching implications for several generations to come'.

Knowledge Argument, The

Intermediate article

Adam Vinueza, University of Colorado, Boulder, Colorado, USA

CONTENTS

The knowledge argument purports to show that there are nonphysical facts – facts that cannot be expressed in physical terms – because one can know all the physical facts without knowing facts about what it is like to have an experience.

INTRODUCTION

The knowledge argument is against physicalism, the doctrine that all facts are physical facts. Physicalism is a notoriously difficult doctrine to state clearly and plausibly, but we can explicate its main idea by taking a physical fact to be a fact that can be expressed in the language of physics. Thus, to say that physicalism is true is to say that all facts can be expressed in the language of physics.

The knowledge argument purports to show that there are facts about what it is like to have an experience, and that these facts cannot be expressed in the language of physics. If you have never tasted asparagus (or anything relevantly like it), you do not know what it is like to taste asparagus: there is a qualitative aspect to tasting asparagus that you have never experienced. Likewise, if you are an achromat, you have never had color experiences, so you do not know what it is like to have such experiences. These aspects of experience are called *qualia* (singular *quale*): there is a unique quale to tasting asparagus, a distinct unique quale to seeing vermilion, and so on. Thus, the knowledge argument purports to show that certain facts about qualia cannot be expressed in the language of physics.

SIGNIFICANCE AND HISTORICAL CONTEXT

The knowledge argument (Jackson, 1982, 1986) is usually introduced with the following thought experiment. Imagine that some person, Mary, has been confined from birth to a black-and-white room, and has been educated through black-and-white books and through lectures and discussions relayed on black-and-white television. Let us also imagine that Mary, in this room, has been taught all the physical facts – she has learned all the facts one can learn through studying physics, chemistry, neurophysiology, and so on – and that these theories are all complete and correct. Then if physicalism is true, Mary knows everything, because the physical facts are all the facts. But according to Jackson, Mary does not know everything, because if she were to leave her black-and-white environment she would see her first color: she would have her first experiences with color qualia, and would thereby come to know – that is, to learn – what it is like to have color experiences. If she knows all the physical facts before leaving the black-and-white room and learns what it is like to have color experiences upon leaving it, then what it is like to have color experiences is something Mary learns that is not a physical fact. So, according to Jackson, there are things one can know, some facts, that are not physical facts.

If the knowledge argument is sound, physicalism is false. But physicalism is a methodological assumption that guides all scientific inquiry. We reject explanations inconsistent with physical explanations – such as explanations of events that appeal to miracles – on the ground that they are physically impossible, and it is arguable that the only way we can make sense of this dependence of all explanations on physical explanations is by supposing that all the facts, ultimately, are physical facts. Physicalism is also foundational for cognitive science, which is guided by the hypothesis that all features of our mental lives can be explained by appeal to functional (in particular, computational) processes. So if the knowledge argument is sound, the central hypothesis guiding cognitive science is false, and arguably cognitive science is misguided.

That the knowledge argument has such far-reaching consequences can easily lead one to reject it out of hand: one might think that if it entails that physicalism is false, then the argument simply has to be unsound. But this does not explain precisely

where it goes wrong. In this article, we will see the main ways in which philosophers have tried to show that the knowledge argument is unsound, and examine their strengths and weaknesses.

The intuition motivating the knowledge argument goes back at least to Leibniz, who argued that mentality cannot be explained by appeal to physical principles. Leibniz imagined a machine that thinks and perceives; he claimed that if we looked inside, we would never see anything that could explain perceiving (Leibniz, 1981, pp. 66–67).

Leibniz' claim was almost universally accepted by philosophers until the middle of the twentieth century, when philosophical orthodoxy shifted from Cartesian dualism to materialism. The knowledge argument arose during this period of materialist orthodoxy, when many philosophers had begun to feel unsatisfied with materialist explanations of mentality. Nagel (1974) famously expressed this dissatisfaction by arguing that we cannot know what it is like for bats to echolocate, for the simple reason that we cannot have anything relevantly like echo-locatory experiences. This argument, often conflated with the knowledge argument, is weaker: at most it shows only that we cannot form the concepts necessary for recognizing the truth of physicalism. But it is related to the knowledge argument, and may have inspired it.

RESPONSES TO THE KNOWLEDGE ARGUMENT

Let us express the knowledge argument more formally, in order to classify responses to it more easily:

When she leaves her black-and-white environment, Mary comes to know a fact – namely, the fact of what it is like for her to see colors. (1)

Mary did not know what it is like to see colors before leaving her black-and-white environment. (2)

If physicalism is true, then Mary's knowledge of what it is like to see colors is not a fact she did not know before leaving her black-and-white environment. (3)

Therefore, physicalism is false. (4)

Premise 3 follows directly from physicalism and the assumption that Mary knows all the physical facts, so the only premises that can be questioned are 1 and 2. Those who challenge the knowledge argument either deny that what Mary comes to know is a fact (premise 1), or they deny that it is a fact she did not know before leaving her black-and-white environment (premise 2). Let us call a response of the former sort a no-fact response, and a response of the latter sort an old-fact response.

No-fact Responses

No-fact responses may take two forms. The most popular form is known as the ability hypothesis: the hypothesis that knowing what it is like to have an experience is not propositional knowledge (knowledge that something is the case), but instead just know-how, the possession of an ability (Nemirow, 1990; Lewis, 1983, 1988; Churchland, 1985). The other form of no-fact response holds that knowing what it is like to have an experience is what Russell (1910) called knowledge by acquaintance, an intuitively immediate, nonpropositional awareness of a property (Conee, 1990).

The ability hypothesis implies that knowing what it is like to have an experience is knowing how to imagine or re-identify that experience. Of course, knowing how to do many things involves factual knowledge: knowing how to drive a car requires knowing many facts about how the car works, for example. But one can know all the facts about cars without knowing how to drive a car. Mary surely gains abilities when she leaves the black-and-white room – such as the ability to imagine and re-identify new color experiences – and Mary's knowing what it is like to have an experience arguably consists in her having those abilities. Because one cannot plausibly imagine or re-identify experiences one has never had, ability hypothesists can explain why Mary learns something upon leaving her black-and-white environment without denying physicalism, because what Mary acquires is not factual knowledge, but know-how.

The ability hypothesis is controversial, in part because most cognitive theories of know-how in general explain it as the possession of tacit factual knowledge: for example, our ability to produce and understand sentences of a natural language is know-how, but is arguably best explained in terms of tacit knowledge of a grammar for that language, a set of rules determining the grammatical structures of its sentences (Chomsky, 1965). Another objection is a semantic one: the semantics of 'knows *wh*-' constructions in general has them being true in virtue of the knower's having factual knowledge. For example, to know where Tanzania is is to know that it is at such-and-such a place, and to know why Smith murdered Jones is to know that

Smith murdered Jones for such-and-such a reason. Likewise, to know what it is like to have an experience is arguably to know that having that experience is like such-and-such (Lycan, 1996). And if semantics dictates that sentences of the form 'X knows what it is like to have experience E' are true in virtue of the knower's knowing that something is the case, then the ability hypothesis cannot be true.

The acquaintance hypothesis implies that knowing what it is like to have an experience is to be acquainted with it, where knowledge by acquaintance is an intuitively immediate (non-inferential) and nonpropositional form of knowledge. Examples of acquaintance include the awareness we have of our own conscious mental states, and our perceptual awareness of colored patches in the visual field. Nemirow (1990) and Churchland (1985) offer versions of the acquaintance hypothesis, but analyze acquaintance in terms of the possession of abilities; for this reason, many identify the acquaintance hypothesis with the ability hypothesis. Conee (1990) does not analyze acquaintance in this way, but does not say precisely what knowledge by acquaintance is.

The acquaintance hypothesis faces objections analogous to those faced by the ability hypothesis. Acquaintance – at least, understood as perceptual awareness – is arguably best characterized as awareness that something is the case: perceptual awareness is typically characterized by cognitive scientists in computational terms, and computational states typically have propositional content. Also, Lycan's argument about the semantics of 'knows what it is like' applies with equal force to the acquaintance hypothesis.

Note that these objections to the ability and acquaintance hypotheses are not objections against either the view that knowing what it is like is an ability or the view that it is a kind of acquaintance; but they imply that knowing what it is like, whatever it is, is nevertheless a kind of factual knowledge. One might accept that knowing what it is like is a kind of factual knowledge, yet hold that it is, under an unfamiliar guise, knowledge Mary already has. However, this is a kind of old-fact response, not a no-fact response.

Old-fact Responses

Old-fact responses take the form that while Mary does come to know a fact when she leaves her black-and-white environment, this fact is just one of the facts she already knew. Arguably, one can know the same fact in various ways: for example, the fact that Mark Twain is Mark Twain is seemingly identical to the fact that Mark Twain is Samuel Clemens, even though one can know that Mark Twain is Mark Twain without knowing that Mark Twain is Samuel Clemens. Intuitively, knowledge is a relation between a knower and a true proposition, and on certain views different propositions can be true in virtue of the same facts holding. Arguably, then, to learn a fact is to learn a proposition that is true in virtue of that fact holding; hence, one can learn a fact in as many different ways as there are propositions corresponding to that fact.

Old-fact responses are the most popular sort of response to the knowledge argument (e.g. Churchland, 1985; Bigelow and Pargetter, 1990; Loar, 1990; Lycan, 1990, 1995, 1996; Pereboom, 1994; Tye, 1986.) The burden on those who make this sort of response is to make it plausible that what Mary learns is an old fact under the guise of a different proposition. This is usually attempted by drawing analogies between Mary's situation and situations in which it is uncontroversial that someone comes to know a new proposition without learning any new facts. For example, suppose some person, Bill, knows that Mark Twain wrote *Huckleberry Finn*, but does not know that 'Mark Twain' is a pseudonym for Samuel Clemens. When he learns that Samuel Clemens wrote *Huckleberry Finn*, this is plausibly not a new fact for Bill, but a fact that Bill already knows under a different guise. If what Mary learns in learning what it is like (say) to see red is factual knowledge, then we may suppose that what Mary learns is that seeing red is like Q, where Q is the name of the quale Mary has when she sees red things. Therefore, on the old-fact view, Mary already knows that seeing red is like Q, but in virtue of her knowing a different proposition.

The holder of the old-fact view argues in the following way. Plausibly, the propositions that Mark Twain is Samuel Clemens and that Mark Twain is Mark Twain are distinct, yet the fact that Mark Twain is Samuel Clemens is the same fact as the fact that Mark Twain is Mark Twain; analogously, the propositions that seeing red is being in a certain physical state P and that seeing red is like Q are distinct, yet correspond to the same facts, because being in P just is being in a state like Q.

The main challenge for this sort of response derives from the standard explanation of not knowing a proposition while knowing the fact corresponding to it, viz., that one knows some but not all of a thing's properties. If one knows that Mark Twain wrote *Huckleberry Finn* but not that Samuel Clemens did, that is arguably because there are some

properties of Twain that one does not realize he has, viz., being named 'Samuel Clemens'. But Mary is not in this position: if she knows all the physical facts and physicalism is true, then she knows all the properties of every thing. This means that one who maintains an old-fact response must offer some other explanation of not knowing a proposition while knowing the fact corresponding to it.

Old-fact theorists have offered several alternative explanations. The most prominent, due to Loar (1990) is that concepts of qualia are those whose possession requires having certain experiences, and that Mary has not had the experiences requisite for having such concepts of color qualia. These concepts, called phenomenal concepts, enable one to recognize one's own qualia when one has them: they are those concepts in virtue of which one can self-ascribe sensations. (For closely related views see Lycan (1995, 1996) and Tye (1986).) If knowing what it is like to have an experience with quale Q is knowing that the experience is like Q, and the concepts of Q required for having this knowledge are phenomenal concepts, then old-fact theorists can explain why Mary does not know what it is like to have color experiences by pointing out that she lacks the requisite concepts, while denying that knowing what it is like to have experiences is knowledge of distinct facts.

Interestingly, this sort of old-fact response leads to a different, though related, worry. According to Leibniz' law, if any thing X is identical to a thing Y, then whatever is true of X is true of Y. And because X is necessarily identical to X, it follows that X is necessarily identical to Y. Nevertheless, many identities can seem to hold only contingently, because one can coherently conceive them to be false, and we need to do empirical investigation to find out whether they hold: the standard example is the identity of water and H_2O. This would suggest that what we can coherently conceive is not a reliable guide to what is possible: water is necessarily identical to H_2O, but we can coherently conceive that water is not H_2O. But an influential argument from Kripke (1980) seems to show that these sorts of examples do not show that conceivability is no guide to possibility. (For further developments of this argument, see Chalmers (1996) and Jackson (1997).)

Kripke's argument is as follows. Because water is necessarily H_2O, there is no possible situation where water is not H_2O; therefore, when we claim we can conceive that water is not H_2O, we are either not conceiving any situation at all, or what we are conceiving is something that we might legitimately confuse with this impossible situation. When we claim to be able to conceive that water is not H_2O, Kripke argues, we are conceiving a situation in which something that has the properties we normally associate with water – say, being a colorless, odorless potable liquid that flows in our rivers and streams – is not H_2O. This something would surely seem to be water, although it would not be (given that water is H_2O). Such a situation may be possible, but it is not a situation in which water is not H_2O, because that situation is impossible. We mistake one situation for the other; and this explains why it can seem possible that water is not H_2O. We mistake a possibility in which something that seems to be water is not H_2O for a possibility in which water is not H_2O.

Now, physicalists are committed to the view that certain physical properties are identical to qualia, and old-fact theorists claim that phenomenal concepts pick out the very same properties as certain physical concepts. Because these properties are identical, they are necessarily so; but because one can fail to realize that phenomenal concepts and physical concepts pick out the same properties, it may seem to one that the properties picked out are not the same. Hence, it can seem possible that some physical property P is not identical to a quale Q, even if they are identical. Can we explain this 'seeming' in the same way? Kripke argues that we cannot. His reason is that, although there are situations in which something that seems to be water is not water, there is no situation in which something that seems to be a certain quale is not that quale. Whenever it seems to one, say, that one is in pain, Kripke argues, one is in pain; so we cannot say in this case that we are mistaking a possibility in which something that seems to be pain is not such-and-such a physical property for a possibility in which pain is not that physical property. If this is the correct explanation for why identities can seem contingent, old-fact theorists must still explain why the identities of qualia with physical properties can seem contingent. And if they cannot explain this, one may legitimately suppose that the fact that we can coherently deny these identities means that they simply do not hold – that is, that qualia are not physical properties, and physicalism is false.

Of course, this argument is not Jackson's knowledge argument, but an important related one. Anyone who claims that Mary simply learns an old fact under a new guise when she comes to learn what it is like to have color experiences must have some response to it. Current discussions of the knowledge argument tend to focus on what that response should be. Yablo (2000) and others

have argued that we have independent reasons for thinking that conceivability is not a reliable guide to possibility.

CONCLUSION

As yet, there is no decisive refutation of the knowledge argument. This is no reason for theorists in cognitive science to reassess the import of their research; but it should make them pause to think about the philosophical issues their research raises. We cannot simply dismiss the knowledge argument as a piece of fallacious reasoning. That it has survived all attempts at refutation shows that solving the mind–body problem calls not only for a good empirical theory of mind, but also for clear, careful thinking about such philosophical issues as the nature of facts and the epistemology of modal truths.

Language of Thought

Intermediate article

Georges Rey, University of Maryland, College Park, Maryland, USA

CONTENTS

A language of thought is a language that is proposed by philosophers and psychologists as the medium in which people, and probably many animals, actually think.

WHAT IS A 'LANGUAGE OF THOUGHT' (LOT)

The Computational–Representational Theory of Thought (CRTT)

A language of thought (LOT) (sometimes called 'mentalese') is a language that is proposed by philosophers and psychologists as the medium in which people, and probably many animals, actually think. Although conceivably such a language could be encoded in some dualistic, 'immaterial substance', contemporary interest lies in the further view that it is encoded in the brain, rather in the way formal languages are routinely encoded in computers, a view that has come to be called the 'computational–representational theory of thought'.)

'Thinking' here is a generic word for processes involving propositional attitudes, which are mental states that are usually distinguished by words that take a 'that' or 'to' clause as their direct objects; e.g., 'think that', 'hope that', 'want to'. Such states are discernable in at least two ways: by their contents (e.g. believing *God exists* versus believing *God doesn't exist*), or by the different relations the agent may have to the same such objects e.g. (*believing* versus *hoping* versus *fearing* that God exists). According to CRTT, different propositional attitudes of an agent involve different computational relations to LOT sentences that express the content of the attitude. To a first approximation (cf. Field, 1978):

(CRTT-I) For any agent x, time t and propositional attitude, A, there exists some computationally definable relation C_A such that: x A's that p at t iff there is some sentence in a LOT such that

(i) x stands in some computationally specifiable relation C_A to that sentence that is encoded in x's brain.

and

(ii) that sentence means that p.

For example, *Jane notices that the sun has set* would be true iff she stands in some computationally defined relation to a sentence in her brain that means that the sun has set. CRTT then claims that thought processes consist of computations on those sentences.

The two clauses of (CRTT-I) raise very different issues. Clause (i) requires spelling out the computational architecture of the brain, the multitudinous relations between subsystems e.g. (sensations, perceptions, reasoning, judgments, memory, linguistic competence, wishes and intentions) that comprise the organization of a person's mind. CRTT hopes to capture these relations by specifying computer programs and flow charts indicating where and how different LOT sentences are stored and accessed under various conditions. Thus, a *noticing* might be the output of either a perceptual or a reasoning system that serves as the input to a decision-making system (the material from perception and thought that would provide, with an agent's preferences, a basis for action). Some writers (e.g. Schiffer, 1981) think of CRTT as involving a 'belief box', containing the sentences that express the contents of someone's beliefs. Although the metaphor is harmless, it shouldn't be thought to commit CRTT to any specific form of localization in the brain: a 'sentence' is, after all, simply an abstract structure that can be entokened in an indefinite number of ways: pronounced, written down, encoded in a cipher, or stored in diverse media (e.g. magnetically charged particles on tape or in a computer). They might also be coded by

electrical patterns distributed in different regions of the brain, available for some computations and not others. They need not be parts of any natural, spoken language. The only requirement for a sentence is to be a representation with logico-syntactic structure, such as the sort of grammatical structure defined recursively in logic texts in terms of names, predicates ('is bald'), variables (x, y), connectives (and, only if), quantifiers (all, some), and various operators (probably, necessarily), and that can be set out as a kind of 'spelling'. And so the LOT hypothesis could also be expressed as a hypothesis that the brain has elements in it with causally efficacious, logico-syntactic structure, at least some of whose parts are (per clause (ii)) semantically meaningful. (*See* **Language, Connectionist and Symbolic Representations of**)

Clause (ii) of (CRTT-I) raises the fundamental issue of intentionality: namely, what makes it true that some state means (or 'is about') one thing rather than another, or even anything at all? In the case of sentences of spoken language, a standard approach to the answer would involve citing facts about, for example, the intentions and other mental states of the speaker; i.e. it would involve what is called *derived intentionality*. The question raised by clause (ii), however, concerns how these mental states themselves get their meaning (*original intentionality*) in the first place. Various proposals have been made in philosophy, almost any could be adapted to fit the needs of clause (i).

CRTT'S Rival: Radical Connectionism ('RCON')

CRTT arose in reaction to the failures of 'radical behaviorism', which was the modern version of the associationism advocated by the seventeenth-century empiricist David Hume. Associationism itself has made something of a comeback in the form of 'radical connectionism'. Connectionism in general is an approach to computers that treats them as vast networks of interconnected 'nodes', the connections between which are modified in the light of 'training'. Proponents are attracted by the apparent affinity between such networks and the patterns of neural connections in the brain. However, it should be borne in mind that this affinity is only partial (see Smolensky, 1988), and, in any case, may not reveal anything important about the actual mental architecture of the brain, since a connectionist physical architecture could be merely an implementation of a classical LOT architecture just as (ironically enough) most connectionist programs are actually implemented on classical machines. RCONists reject this mere implementational conception, regarding CRTT models as too rule-bound, rigid, and inefficient, in comparison with the 'softer' connectionist networks (Smolensky, 1988). (*See* **Behaviorism, Philosophical**; **Hume, David**; **Connectionism and Systematicity**)

HISTORY

Suggestions about a LOT can be traced back to William of Occam, Hobbes, Descartes, and Leibniz. Its modern appearance occurs, somewhat obliquely, in the work of Wilfred Sellars (1956/97) and then in Newell and Simon (1972) and Gilbert Harman (1972). It has been most systematically and energetically pursued, however, in the work of Jerry Fodor (1975).

The chief inspiration for Fodor's work was, first, the development by Gottlob Frege of formal logic, and then Alan Turing's conception of a Turing machine, or idealized computer, which shows how, among other things, Frege's logic could be realized as a form of mechanically produced computation. (*See* **Turing, Alan**; **Frege, Gottlob**)

These developments suggest the general idea that thinking consists of applying rules to syntactically specified strings of symbols, or strings of letters specified by their spelling, on the model of proving theorems in symbolic logic. The only difference is that, whereas the rules of logic are ordinarily applied by us consciously following the rules, for CRTT the rules are applied by virtue of the causal structure of the brain. For example, where in elementary logic we follow the rule *modus ponens* – e.g. from 'Dogs bark' and 'If dogs bark, then cats meow' derive 'Cats meow' – for CRTT the brain is so constructed that, if it's in a state that represents the premises, then it is (sometimes) compelled to enter a state that represents the conclusion.

This promises to account for people's quite general ability to reason deductively, because the logically relevant syntactic parts of the states (e.g. the 'if…then…') are presumed to be causally efficacious: it is in virtue of the premises and the conclusion having a certain logico-syntactic form that the transition in thought is made. Indeed, CRTT might equally well be regarded as a *causal* representational theory of thought, since what Turing showed us is that anything that is computational could also be mechanically causal. Given the Turing thesis that anything that is computable is computable by a Turing machine, similar hopes arise for formalizations of nondeductive reasoning: induction, abduction, and decision theory.

In a widely read critique, Searle argued that since computations are specified merely syntactically, they lack semantic properties: they are mere manipulations of 'meaningless symbols'. But this is a logical error: that something is specifiable without certain properties doesn't entail that it fails to possess those properties (e.g. bachelors can be bald, even though what it is to be a bachelor can be specified without mentioning baldness). Indeed, even though the computations of Turing machines are specified syntactically, they standardly have a semantics: for example, the symbols are often numerals representing numbers. In any case, clause (ii) explicitly claims that LOT sentences do have a semantics, and Fodor and others have devoted considerable energy to providing a theory about exactly what that semantics might be.

ARGUMENTS FOR A LOT/CRTT

A number of philosophers (e.g. Davies, 1991; Lycan, 1993; Rey, 1995) have advanced *a priori* arguments for a LOT (based, for example, on the Kantian insight that even the simplest thoughts require something analogous to logico-syntactic structure). However, the chief arguments that have been the focus of discussion are *empirical*, according to which a LOT offers the best explanation of the following phenomena – or at least more promising arguments than its rival, RCON:

The Propositional Structure of Attitudes

It is no accident that attitudes such as thought or belief are standardly picked out by sentences: the thoughts themselves seem to possess something very like a sentential structure. Russell (1903: sect. 54) noticed this when he worried about what he called 'the unity of the proposition', or how to distinguish a proposition from a mere list; e.g., how to distinguish between the thought 'Socrates is bald' and a thought involving a list of the ideas, *Socrates, is* and *bald*. Another example might entail different thoughts such as 'Romeo loves Juliet', 'Juliet loves Romeo', and the list in this case 'Juliet', 'love', 'Romeo'. CRTT captures propositional structure by defining different computational roles for different sorts of symbols (predicates, singular terms, variables, quantifiers) to play. Thus, 'Romeo loves Juliet' is subject to different computations than 'Juliet loves Romeo', as is 'someone loves everyone' versus 'everyone loves someone'.

CRTT and Psychology

Fodor (1975) argues that CRTT is presupposed in most current psychological theorizing. For example, many theories of vision account for visual illusions by presuming that the visual system is engaged in computing inferences about the three-dimensional world on the basis of the evidence provided by the surfaces, contours, and textures of objects detected by retinal stimulation; similarly, theories of language acquisition assume that a hearer is representing phonological features, sentence structures, and rules and principles of alternative grammars; and in theories of decision-making it is presumed that an agent is representing alternative states of affairs and courses of action. In order to systematically represent such information (e.g. *that the dog is in front of the fence, that English is a head-first language*, or *if I don't choose red, I'll either receive a shock or another choice*), the representations must be *sentential*.

But perhaps the appeals these psychological theories make to computation and representation are really just a *façon de parler*, a convenient way of presenting these theories informally and not to be taken as part of their literal truth (see Chomsky, 2000, 2002). However, this is to ignore a difficulty first raised by Fodor (1986): many organisms seem sensitive to arbitrary phenomena in a way that is difficult to explain in physical terms alone. For example, there are the sensitivities of even young children to phonological and grammatical categories of natural language, such as to nouns, verbs, main versus dependent clauses and the like (see, e.g. Pinker, 1994). More generally, Rey (1997) has argued that human beings are sensitive to nonlocal and nonphysical properties (e.g. the age of a rock, the authorship of a book), but how can a *local, physical* system such as a brain exhibit such sensitivities? CRTT attempts to answer this question by suggesting that the system performs computations, not on the properties themselves but on their *representations*. It does this in such a way that allows it, for example, to confirm a hypothesis representing those nonlocal, nonphysical properties by mechanically computing on the representations of local, physical properties (e.g. loudness, pitch).

The Productivity of Attitudes

People seem to be able to think a potential infinitude of thoughts. People can (in principle) think indefinitely complex extensions of simple thoughts. Even children can think 'This is the house that Jack built',

then 'This is the rat that lived in the house that Jack built', 'This is the cat that chased the rat …' and so forth, with apparently no upper bound to the nested clauses, except for such 'performance' factors as patience and memory.

Some theorists have objected to the substantial idealization that this involves, and so Fodor (1987: appendix) proposed a related but more modest claim.

The Systematicity of Attitudes

Anyone who can think a thought, *p*, can think any logical permutation of *p*. For example, if someone can think that 'Ann hates Bob only if Charles loves Di', she can also think that 'Charles loves Di only if Ann hates Bob', 'Di loves Charles only if Bob hates Ann' and so forth, for all permissible logical permutations. CRTT captures both productivity and systematicity by presuming that any system in which the logico-syntactic elements of a LOT are causally efficacious is one in which they are readily available for recombination. Without recourse to such a structure, RCON would seem to be unable to explain such regularities in general (although it might be able to handle particular cases).

Rational Relations Among Attitudes

Many forms of reasoning are patently structure sensitive, involving issues of quantifiers, negations, antecedents, and consequents of conditionals, and application of these things. Again, CRTT's insistence on the causal efficacy of logico-syntactic structure affords a systematic way of explaining such sensitivity, where RCON would seem at a loss, since the only account we know of logical relations in general is a 'Fregean-style' description that exploits such structure.

Irrational Relations Among Attitudes

Thoughts can also be irrational, but the patterns in this case nevertheless can be sensitive to syntactic structure. For example, fallacies in reasoning can be due to confusions surrounding negations, antecedents, and consequents; to necessary versus sufficient conditions; and to the limitations of operators (e.g. confusing 'everyone strives for an end' with 'there's an end for which everyone strives'). Obviously any theory that is committed to the existence of causally efficacious logico-syntactic structures (indicating, for example, the scope of quantifiers) stands a better chance of explaining these patterns than a theory such as RCON that does not have such a commitment.

The (Hyper)intensionality of Attitudes

Propositional attitude ascriptions are 'referentially opaque', or 'intensional' (note difference from 'intentional'): *terms that refer to the very same thing cannot be substituted for one another without risking a change in the truth-value of the whole*. For example, there is a difference in thinking that water is wet, or that H_2O is wet, or that the stuff of rain is wet, despite the fact that water = H_2O = the stuff of rain. CRTT makes a distinction among these attitudes by differenciating syntactically between differing symbolic structures to which an agent can be related. (It can do this even when the structures have the same 'meaning', as in hyperintensional cases such as remembering that a fortnight is a fortnight versus remembering that a fortnight is two weeks; or in cases of indexical thought, where for example the thought that Sam might express by 'I am in danger' is different from the thought he'd express by 'Sam is in danger'.) It's difficult to see how a theory like RCON that doesn't exploit such structural differences could capture these distinctions in thought.

The Causal Efficacy of Attitudes

An RCONist might argue that the above rational, irrational, and fine-grained patterns of thought could be regarded simply as patterns of interpretation of an agent (as in Dennett, 1987; see below), not involving the causally efficacious thought structures posited by CRTT. In contrast , a defender of CRTT is impressed by the causal relations among attitudes, not only '(ir)rationalizing' but also causally explaining their changes of state and behavior in virtue of their syntactic and semantic properties. CRTT can thereby explain the possibility of mental–physical interaction, as well as how a reason may also be a cause. Moreover, CRTT can also explain how mental states may have physical effects that they do not 'rationalize'. For example, Sam's thought 'I am in great danger', expressed by a LOT sentence entokened in his brain, might well cause a release of adrenalin (compare: a computer is so wired that typing out the sentence 'Begin print' causes the printer to print).

The Multiple Roles of Attitudes

Different attitudes can focus on the same thoughts. People often *wish* for the very thing that they *believe* does not presently obtain; they often come to think what previously they only *feared*. CRTT captures this by positing different computational relations

to the same internal representation. Since for RCON theories data structures don't exist separately from the associative processes in which they appear, it is unclear how the same structure that expresses the content of a desire could also express the content of a belief.

SOME COMMON OBJECTIONS TO A LOT/CRTT

Introspection

Many people claim not to 'think in words'. But CRTT is not meant to be establishable by introspection; it is a hypothesis intended merely to explain the phenomena mentioned above, but not necessarily to explain how experience appears.

On a related issue, although some philosophers (e.g. Harman, 1972; Carruthers, 1996) have argued that the LOT is largely one's natural, speaking language, such as English or Chomorro, CRTT does not require that this be the case. Indeed, natural languages, with their manifold syntactic and semantic ambiguities, would seem to be ill-suited to the formal needs of the mechanical computations postulated by CRTT. So, even if one doesn't employ words of one's mother tongue when thinking, or even, as in the case of infants and animals, one has no mother tongue at all, one might still be thinking in a LOT.

On the other hand, CRTT might be able to explain certain introspective phenomena. By careful delineation of the different computational roles of specially restricted representations, some philosophers (Lycan, 1996; Rey, 1997) have argued that CRTT is able to capture the phenomena of subjectivity and even intense sensory experience.

Imagery

Many people think that CRTT conflicts with the evidence that people 'think in images'. However, although images may have some role to play in thought, even defenders of such claims acknowledge that purely imagistic systems don't seem adequate to represent all thought. How can images unambiguously represent logically complex thoughts, such as negations ('there are no ghosts'), conditionals ('if there are ghosts, then …'), and nested quantifications ('every ghost loves another')? Moreover, images are multi-ambiguous in ways that formal languages need not be: an image of a Paris street could represent a general category (cities, pollution), or a particular instance (Paris), or just that very specific street itself, depending upon the sentential context in which it is embedded. It is difficult to think of any serious alternatives to sentences, if the mind (and therefore the brain) is to be capable of representing the full range of human thought. (*See* **Mental Imagery, Philosophical Issues about**)

Homunculi

An extremely common objection to CRTT is that it presupposes precisely those processes it purports to explain. In particular, if there's a LOT, don't we need a 'little man' in the brain to read it (Ryle (1949)? CRTT answers this objection by emphasizing Turing's proposal for computation in general, whereby brute causation replaces human calculation. Specifically, a 'cursor' simply determines whether, for example, a '1' or a '0' is inscribed in a single 'cell' on the machine's 'tape', a purely mechanical task for which no intelligence whatsoever is required.

Artificial Intelligence and the Turing Test

The history of work on computers has led to a number of confusions about the commitments of CRTT that should be disentangled:

- CRTT is not committed to just *any* computer having mental states: only a computer with the very specific underlying structures that psychology and (philosophical) reflection ultimately reveal to be essential to specific mental states and processes. And many defenders of CRTT (e.g. Fodor (2001) himself) are quite pessimistic that those structures are likely to be understood in the near future, if ever.
- Consequently, CRTT is not committed to the widespread projects that go under the rubric of 'artificial intelligence' (AI) that, by and large, are concerned not with actually creating a system with genuine mental states, but with creating systems that can do some of the things that systems with mental states can do, whether or not their systems accomplish these things by means of mental states themselves. Of course, if one were a behaviorist there would perhaps be no serious distinction between these two tasks. And many of those interested in AI have been behavioristically inclined. However, most defenders of CRTT subscribe to *functionalism*, or the view that what is essential to most mental states is not merely how a system outwardly *behaves*, but how it is internally *structured*; and there's seldom any reason to think that the programs proposed by proponents of AI remotely capture the internal structures of genuinely thinking systems (consider 'Deep Blue', the computer that recently beat

the world chess champion, patently not through the kind of subtle strategies of chess masters but simply through working at lightening speed through massive numbers of permutations of possible moves).

- The confusion of CRTT with AI has been aggravated by the fact that, in addition to his work in the theory of computation, Turing also proposed what he regarded as an intuitive test of 'intelligence', what has come to be called the 'Turing test'. In brief, a machine is intelligent, according to this view, iff normal people are not able to distinguish teletype exchanges they might have with the machine from those they might have with a normal human being. Needless to say (at least for any functionalist), this could be (and has been!) accomplished by equipping the machine with a mere bag of simple tricks. Turing, like many thinkers of his time, was in the grip of behaviorism. (*See* **Turing Test**)

In contrast to behaviorism, CRTT is most naturally concerned with the characterization of sub*systems* of the mind, in considerable abstraction from actual behavior. For CRTT, the right way to produce genuine artificial intelligence, as opposed to merely fooling people, would be to construct theories about human cognitive competencies, *vis-à-vis*, for example, perception, scientific reasoning, decision-making, and language comprehension and production. Only afterwards should an attempt be made to integrate these systems into one that might conceivably behave with anything like the sophistication of human beings in a natural environment.

Searle's "Chinese Room"

In a widely discussed article, Searle (1980/91) presented what he and others have often regarded as a devastating blow against CRTT. Briefly, he imagines someone entirely ignorant of the Chinese language being placed in a room with a manual for 'understanding Chinese' according to 'correlation rules' that specify which Chinese characters he is to hand out of the room in response to characters that are handed in, so that, were a normal Chinese speaker to view the entire exchange of characters, she would find it indistinguishable from a normal Chinese conversation. The 'room' (or the person in the room, if that person had memorized the manual) would thus pass the Turing test (see above). However, Searle claims, the person in the room carrying out such a program patently doesn't understand a word of Chinese: he is merely following rules relating one set of (for him) meaningless characters to another. Consequently, Searle concludes, no CRTT program can be sufficient for understanding Chinese, or any other natural language. Indeed, 'not the slightest reason has been given to suppose that [programs] are necessary conditions or even that they make a significant contribution' (1980/91a, p. 511).

A number of problems arise when relating Searle's example to CRTT. As stressed above, there is every reason to suppose that CRTT is not committed to the Turing test, much less to a 'conversation manual' account of linguistic competence. More plausibly, CRTT would require that the system be able to access recursive syntactic and semantic rules along the lines of serious contemporary linguistic theory. It might also require that those rules be embedded in a larger system of perception, reasoning, and decision-making that is plausibly essential to something having any sort of mind at all. Once these conditions are met, it is not clear what might be said about the 'mental states' of the resulting 'room', or of the person in it, who (to pass the test) would have to be frantically consulting probably thousands of computer programs simultaneously, and, moreover, would now be only one small part of an enormously complicated system. Further there would be no reason to assume that the mental states of an entire system would be inherited by all its parts.

Searle is right, however, to point to the need for a theory of meaning as part of any AI effort to produce a genuinely intelligent computer, and that, *pace* the suggestions of some CRTTists (e.g., Jackendoff, 1987), a computer program by itself wouldn't be sufficient for all aspects of meaning. However, CRTTists have not been shy in trying to spell out clause (ii) of CRTT-I, providing at least sketches of how a suitably programmed machine could acquire meaning by being appropriately situated in an environment (e.g. Field, 1978; Fodor, 1987; Lycan, 1987; Neander, 1995; Rey, 1997). But few are under any illusion that any adequate theory of meaning has been supplied for CRTT – or, for that matter, for *any* theory of mind; see Rey (1997: chap. 10) for further discussion.

INTERPRETATIONISM

Searle (1993) has argued that computation exists only in relation to someone who consciously interprets a physical process as a computation. Only conscious agents literally follow rules; computers only seem to 'follow rules' because they are created and used by conscious agents. Therefore, CRTT presupposes the existence of mentation and so cannot explain it.

Davidson and Dennett (1987) had actually suggested a variant of this view some years earlier, except for them, unlike Searle, consciousness fails to provide any help. They argue that attitude

ascriptions are not actually determinately true of anything, not even of human beings, but are merely 'interpretations' of behavior that facilitate prediction of behavior. Consequently, such ascriptions do not require corresponding sentences to be in anyone's head. For example, we might say of a chess-playing computer that 'it likes to get its queen out early', even though no corresponding sentence might exist in the computer's program.

Both Searle's and Dennett's views, however, need to explain why ascriptions of rules and attitudes manage to be so explanatorily successful, and why both machines and human beings display their intelligent regularities. Perhaps in some cases (e.g. a thermostat) the explanation can proceed without taking such ascriptions as being literally true. Moreover, a CRTTist could argue that, without an internal sentence, the ascription of an attitude isn't literally true. However, it is by no means obvious that the regularities in the behavior of all modern computers, or the behavior of people and animals, can seriously be explained without taking the ascriptions literally. Again, how are we to explain the sensitivities of people to nonlocal, nonphysical phenomena?

HOLISTIC CONFIRMATION

Interestingly, the very philosopher who has been the most vocal champion of a CRTT has also argued for its severe limitations. Fodor (1983, 2001), following Quine (1956/76; see also Quine and Ullian, 1978), argues that the confirmation of most hypotheses, both in commonsense and science, seems to be both 'Quinean' (or holistic: a hypothesis is assessed by the overall coherence it brings to a system as a whole), and 'isotropic' (any belief in the system is potentially relevant to the (dis)confirmation of any other belief). The very locality feature that is part of the explanatory attractiveness of Turing machines appears to be incompatible with these global features of reasoning. However, whether this apparent incompatibility is a real one should perhaps be regarded as an open question, pending a deeper understanding of the considerable resources of Turing computation.

In any case, as Fodor would be the first to insist, the problems here would at worst show that while CRTT is not sufficient as an account of mental processing, it is still necessary in any such account.

Levels of Analysis, Philosophical Issues about

Intermediate article

Allen Y Houng, National Yang-Ming University, Taiwan

CONTENTS

The world, including cognitive systems, is organized into hierarchies of levels. Levels of analysis represent different stances from which predictive and explanatory theories are constructed.

WHAT IS A LEVEL OF ANALYSIS?

The term 'level' can be used in several different ways. People talk about levels of existence, levels of organization, levels of complexity, levels of description, levels of analysis, levels of explanation, levels of abstraction, and so on. Levels of existence, levels of organization, and levels of complexity represent the integrated organization of a system. The other usages in the above list have to do with the ways we look at or theorize about the world. These two aspects of the concept of levels – i.e. levels as natural qualities and levels as conceptual or theoretical constructs – are concerned with two different sets of issues.

Organizing the world into hierarchical levels is quite natural to most scientists and philosophers. Many claim that the prevailing 'synthetic' approach to biology is too simple and reductionistic, and that an evolutionary theory must take into account the hierarchies found in nature. In cognitive science, levels of organization arise in the anatomical structure of the brain. Exactly how many levels of organization there are in the brain is an empirical question. The most commonly postulated levels of organization of the brain include, from the bottom up, molecules, synapses, neurons, local networks, layers and columns, topographic maps, and systems (Churchland and Sejnowski, 1992).

Corresponding to each level of organization, there is presumably a level of analysis, which can be taken as a stance or viewpoint, or as a conceptual framework from which theories can be constructed. A level of organization consists of a collection of entities, properties, relations, processes, causal regularities, and other relevant phenomena; a level of analysis consists of a collection of terms, predicates, theories, and so on. A level of analysis can be specified as a set of conditions or principles for classification of theories (or models). It must at least contain conditions specifying what sort of entities and structures are to be considered, what sort of regularities are to be captured, and what phenomena are to be explained or predicted. Hence the specification of a level of analysis resembles a very general specification of a research program, under which several competing or complementary theories can be considered as belonging to the same level.

PHILOSOPHICAL VIEWS OF LEVELS OF ANALYSIS

The central philosophical issue concerning the levels of analysis in cognitive science is the relation between theories at different levels of analysis. Reductionism, for example, claims that higher-level theories such as those of psychology can be reduced to neuroscience. We should note that this refers to 'interlevel' reduction, in which the domains of reducing and reduced theories at different levels are different. The other notion of reduction is 'intralevel' reduction, in which the domains of reducing and reduced theories are the same. Examples of intralevel reduction include the reductions of Newtonian mechanics to special relativity, and of macroscopic thermodynamics to statistical thermodynamics. In the case of intralevel reduction, a reduced theory is regarded as a special case of or an approximation to its reducing theory. On the other hand, in the case of interlevel reduction, a reduced theory is regarded as a derived consequence of its reducing theory, with some bridge laws associating entities in the two domains. Although intralevel reduction has been successful in many domains, successful interlevel reduction is very rare.

Levels in a hierarchically organized system are integrated in a certain way; they are not mutually independent. For example, the cellular level and the molecular level in a biological system are not separate subsystems. Processes and properties at two different levels, especially at two adjacent levels, causally interact with one another. The lower-level processes or properties realize those at higher levels.

A higher-level cognitive function can be realized by a variety of different lower-level substrata. But this does not imply that lower-level theories cannot be used to explain the nature of higher-level cognitive functions. In other words, the multiple realizability of cognitive functions does not imply that neuroscience is irrelevant to cognitive modeling. The lower-level properties and processes do impose severe constraints on the space of possible realizations of higher-level properties or processes. For example: the processing speed in the brain is limited; most synaptic connections are between, not within, cell classes; and the brain is a highly parallel machine. These lower-level properties impose constraints on the realization of higher-level cognitive functions in the brain. If lower-level constraints are not taken into consideration, the result could be very speculative higher-level theories (Sejnowski and Churchland, 1989).

Downward integration takes the opposite direction. Higher-level processes or properties constrain, organize, regulate, or coordinate the otherwise unstructured or unorganized lower-level processes or properties. Some higher-level properties are referred to as 'emergent' because they are not apparently reducible to lower-level properties. These higher-level emergent properties impose structure or organization on lower-level processes or operations. They constrain the lower-level components to be such as to generate certain integral patterns at higher levels.

One purpose of higher-level analysis is to discern the structures or organizations required for lower-level mechanisms to realize higher-level regularities, or law-like behaviors, which would be unlikely without these higher-level constraints namely, the structures or organizations mentioned above. For example, consider Rumelhart and McClelland's model of the acquisition of the English past tense (Rumelhart and McClelland, 1986). This model is considered a successful low-level model for learning the past tense. It has been argued that its success is due to its implicit assumption of a higher-level linguistic theory. The role of higher-level theories is to provide organizational or structural constraints on lower-level theories (Pinker and Prince, 1988).

Not all theorists agree on the necessity for higher-level constraints in developing lower-level theories. Eliminative materialism (represented in the works of P. M. Churchland and P. S. Churchland) claims that psychology should be replaced by neuroscience. Although P. S. Churchland sees the relationship between the theories of psychology and neuroscience as co-evolving rather than strictly reductionistic, she maintains that psychology that commits to propositional attitudes is in principle replaceable by neuroscience, and that co-evolution between psychology and neuroscience, will eventually lead to the elimination of folk-psychological categories (Churchland, 1986).

ROLES OF LEVELS OF ANALYSIS IN COGNITIVE SCIENCE

Researchers in cognitive science employ the concept of levels for various purposes. Pylyshyn (1984) argues that at least three distinct levels of analysis are needed: the physical level, the symbolic (or functional) level, and the semantic (or representational) level. At the physical level, generalizations can be formulated only in the language of physical science. At the symbolic level, generalizations are expressible in terms of predicates referring to the properties of the functional architecture. (The functional architecture of a system is analogous to the operating system of a computer.) At the semantic level, generalizations can be formulated in terms of the contents of mental representations. For example, in a computer system, a physical level of analysis would be sufficient to describe the electronic properties of a computer. But to understand how a program works, we need to appeal to the architecture of the underlying virtual machine. And to understand how a program acts as a model of certain cognitive phenomena, we need to consider the contents of the symbols used in the program.

Marr's three levels of analysis for the science of the mind are also well known. These are the computational, the algorithmic, and the implementational levels. Marr's algorithmic level is similar to Pylyshyn's symbolic level, and the implementational level is similar to the physical level. The computational level is more difficult to understand. According to Marr, it is concerned with abstract and theoretical issues. Marr alludes to Chomsky's distinction between competence and performance and hints that the computational level is somewhat

like a competence theory of the mind. It is a formal analysis of the nature of the mind. With the aid of this level of analysis, Marr wishes to eliminate the ad hoc assumptions and unprincipled restrictions of a model, and a misguided and erroneous level of analysis in cognitive modeling. This is a level of theoretical and methodological consideration (Marr, 1982).

Hofstadter (1979) offers an extensive but somewhat perplexing discussion of levels of analysis. He claims that the explanations of emergent phenomena in our brains should be based on a kind of 'strange loop', a two-way causal interaction between levels. The bottom level in his hierarchy is the neural level. Hofstadter calls it the 'inviolate level' because the way neurons operate in the brain at that level is not changeable by mental activities. Above the inviolate level, there is the 'tangled level', at which the 'tangled hierarchy' resides. The tangled level should be further divided into a hierarchy of levels, since we need a distinct level of analysis to capture the generalizations of each level in the strange loop. But since we use the same kind of language for all cognitive levels, levels become mixed and incorrect theories are articulated. To solve this problem, Hofstadter proposes a multi-level approach to the mind, and suggests that there could be many different undiscovered levels of analysis within the tangled level employing different languages for cognitive modeling.

The debate between symbolism and connectionism in cognitive science since the 1980s is concerned with the cognitive architecture of the mind. The concept of levels of analysis plays a central role in this debate because the choice of level of analysis for cognitive theorizing constrains the choice of cognitive architecture.

Symbolism claims that any adequate cognitive model has to assume a symbolist architecture, i.e. mental representations with constituent structure and mental operations sensitive to that structure. According to this view, cognitive processes operate on symbolic mental representations in accordance with the constituent structure of those representations, and this class of cognitive models defines the proper level of analysis for cognitive modeling. Any model outside this class is either cognitively irrelevant or just an implementation of a model within the class (Fodor and Pylyshyn, 1988).

The level of analysis for distributed connectionist models is neither the neural nor the symbolic level, but rather the subsymbolic level. Smolensky (1988) contends that precise, formal descriptions of the dynamics of cognitive behavior are possible only at the subsymbolic level. The processing units at the subsymbolic level have no semantics: semantic content can be attributed only to patterns or representations residing at the symbolic level. This is a dual-level view of cognitive architecture, in contrast with the single-level view of symbolism.

Fodor and Pylyshyn argue that since connectionist architecture does not allow cognitive processes to operate in accordance with the syntactic structure of mental representations, important cognitive phenomena such as systematicity, compositionality, and inference coherence cannot be explained by connectionism. Therefore, connectionist architecture is not adequate for modeling the mind. Connectionists have argued, with some success, that connectionist architecture can explain compositionality and other important mental phenomena without assuming a symbolic architecture.

Besides symbolism and connectionism, there are two other views of cognitive architecture that deserve mention. The 'hybrid' approach supports a form of division of labor, dividing cognitive functions into higher functions, such as thinking and reasoning, and lower functions, such as perceptions and skills. Symbolist architectures are best suited for the higher functions, and connectionist architectures are best suited for the lower functions. The basic idea of the 'multi-level' approach is to regard a cognitive system as a system organized into a hierarchy of many levels. The discipline of cognitive science involves cultural studies, anthropology, sociology, psychology, artificial intelligence, biology, neuroscience, chemistry, and physics. This diversity may suggest that cognitive science is a special kind of science in that it incorporates theories at many different levels of analysis.

Materialism

Intermediate article

William G Lycan, University of North Carolina, Chapel Hill, North Carolina, USA

CONTENTS

According to the doctrine of materialism, the mind is no more than a complex arrangement of physical matter. This is maintained by most philosophers of mind and presupposed by cognitive science, but it is difficult to make precise and it faces some formidable objections.

INTRODUCTION

Materialism is, in full, the thesis that only physical matter exists. However, in the context of cognitive science and the philosophy of mind, the term is used to mean the less ambitious claim that nothing psychological or mental exists that is not entirely constituted by physical matter. Traditionally, the main opposing theory has been mind–body dualism of the kind defended by Descartes, according to which minds are purely spiritual and entirely nonspatial, having neither size nor location nor any other physical property. According to the dualist view, a normal living human being or person is an immaterial mind somewhat mysteriously paired with a physical body.

A less radical opposing theory is 'property' dualism, which does not posit immaterial things or beings such as Cartesian minds, but does maintain that human beings and other sentient creatures have some nonphysical or immaterial properties, i.e., properties that are not constituted just by an arrangement of physical matter. Such properties might include the content properties of thoughts, such as my having a thought about the Wife of Bath, or phenomenal properties of sensations, such as the mountains subjectively looking blue to me.

At first sight, these formulations seem fairly clear, but philosophers have had trouble making them precise enough to create a genuine contrast between the materialist and the dualist views.

WHAT IS MATERIALISM?

How are we to understand the phrase 'physical matter'? (This is what Montero (1999) calls the 'body problem'.)

The things that we ordinarily think of as physical objects are made of tiny particles, which are the subject matter of microphysics. One might, therefore, simply define 'physical matter' as matter that is entirely composed of such particles. But this suggestion immediately meets a well-known problem. By 'microphysics', should we mean the present microphysical theory, or should we mean some (unspecified) improved or idealized theory? Suppose the former. Then there is probably no 'physical matter' in the sense defined, since the present microphysical theory is probably incorrect in some respects. But if 'microphysics' does not mean the present microphysical theory, what improved or idealized theory does it mean?

The most common answer is: 'final microphysics' – not in the sense of whatever microphysical theory will in fact be the last to be offered by a living scientist, but of an ideal theory that would be true and would explain everything dynamic and kinematic that needs explaining. One may suspect that the terms 'dynamic' and 'kinematic' already presuppose the concept of physical matter. But the main problem for the appeal to final microphysics is how to assure ourselves that such an ideal theory would contain only things and properties that we now consider physical. It is tempting to think that fundamental physics is largely finished; but that has been thought many times before and always wrongly. Physics has persistently encountered new phenomena, and acquired new theories, in a way that shocks the older generation conceptually: action at a distance; electromagnetism; relativity; Riemannian space-time; quantum indeterminacy; the paradoxes of quantum mechanics;

tachyons; antimatter. Already some quantum physicists have gestured towards panpsychism – the view that every bit of matter, however small, has some irreducibly mental properties – by positing a 'consciousness' that resolves quantum indeterminacies; and some philosophers follow Sellars (1981) in arguing that physicists will ultimately have to recognize some irreducibly mental properties along with their other physical primitives. The result is that if one defines 'matter' by reference to final microphysics, it may follow that 'materialism' is true despite the existence of irreducibly mental entities or properties. Thus would be unacceptable to most current 'materialists'.

A second strategy for maintaining the distinction between materialism and dualism is to follow Descartes in making spatiality the criterion. The physical, we may say, is the spatiotemporal, meaning that to be physical is to be located within the same space-time as are London, North Carolina, the Andromeda galaxy, the Moon, Julius Caesar's left elbow, your body and mine.

But it is not obvious that, necessarily, everything spatiotemporal is physical. Ghosts and disembodied spirits supposedly move about in space; and space-time points themselves are arguably abstract rather than physical objects. Moreover, some dualists have insisted that their posited immaterial items have spatial location.

A third strategy is to abandon the attempt at a direct characterization of 'physical matter', and appeal merely to sameness of composition: materialists hold that creatures with minds are made entirely of the same ultimate components as are ordinary inanimate objects, and that their properties are entirely constituted by the ways in which those components are arranged and related to external things. Descartes would not have accepted that claim.

This strategy faces two objections. The first is that 'materialism' as thus defined is compatible with panpsychism, since if every rock and every subatomic particle has some irreducibly mental properties, sentient creatures are not thus distinguished from rocks; but panpsychism is a form of dualism. The second objection, probably decisive, is that it might turn out, scientifically, that a distinctive kind of basic particle occurs only in the brains of human and other sentient beings. In that case, even if the particle in question were purely physical by any standard, 'materialism' in the present sense would be refuted. This scenario seems unlikely; but even hypothetically it should not refute materialism in its proper sense.

A fourth strategy, suggested by Campbell (1967), is to start with some paradigmatically mental properties, or (better) a list of all the known mental properties, and some paradigmatically physical ones, and then characterize dualism as bluntly separating the two at the level of fundamental entities. 'Materialism' would then be the claim that none of the world's basic components has any of the mental properties; anything with mental properties must be composed only of basic elements that individually do not have them, and its mental properties must consist entirely in an arrangement of these basic elements.

Here there is no appeal to final microphysics, or to spatiality, or to sameness of composition. And if final microphysics should turn out to posit mentalistic properties, then materialism as here characterized would be refuted, as is right.

This strategy does run into a version of the main objection to the first: Even if none of the world's basic components has any of the known mental properties, basic particles might turn out to have strange properties that seem more like the known mental properties than like paradigmatic physical ones. But this does not seem as serious as the objections to the other strategies.

VARIETIES OF MATERIALISM

In the twentieth century, there were three main materialist philosophical theories of the mind: behaviorism (*c.* 1930–1960), the type identity theory (1960–1970), and functionalism (from 1970).

Reacting against what they considered to be scientifically implausible features of dualism, the analytical behaviorists claimed that mental ascriptions simply mean things about behavioral responses to environmental impingements. Thus, 'Roy is in pain' means nothing about Roy's so-called inner life or any episode taking place within Roy, but just that Roy either is actually behaving in a wincing-and-groaning sort of way or is disposed to behave in that way (i.e., he would if something else were not preventing him). It should be noted that a behaviorist need make no claim about the meanings of mental expressions. One might be a reductive behaviorist, and hold that although mental ascriptions do not just mean things about behavioral responses to stimuli, they are, in reality, made true just by properties of actual and counterfactual responses to stimuli. Or one might be an eliminative behaviorist, and hold that there are no mental states or events at all, but only behavioral responses to stimuli, all mental ascriptions being false or meaningless. But to any behaviorist, what

has come to be called the 'Turing test' is decisive: psychological differences cannot exceed behavioral differences. Organisms (as well as computers and other machines) whose actual and counterfactual behavior is alike must be psychologically alike.

Philosophical behaviorism adroitly avoided a number of nasty objections to Cartesian dualism, but it could not allow that any mental states and events are genuinely inner and genuinely episodic. The type identity theorists overcame this shortcoming, denying that mental states are to be identified with outward behavior or even with hypothetical dispositions to behave. But, contrary to the dualists, they claimed that episodic mental items are not ghostly or nonphysical either, but neurophysiological. They are numerically identical with states and events occurring in their owners' central nervous systems. To be in pain is to have (for example) one's c-fibers firing; to believe that erysipelas is nasty is to have one's B_{en}-fibers firing, and so on.

By making the mental entirely physical, the type identity theory, like behaviorism, avoided the serious objections that plagued dualism; but it also accommodated the inner and the episodic. For according to the type identity theory, mental states and events actually occur in their owners' central nervous systems; hence they are inner in an even more literal sense than could be granted by Descartes. The type identity theory also abandoned the Turing test, admitting that organisms could differ mentally despite total behavioral similarity (since clearly organisms can differ neurophysiologically in mediating their outward stimulus–response regularities).

However, Putnam (1960) pointed out a presumptuous implication of the type identity theory understood as a theory of 'types' or kinds of mental items: that a mental state such as pain has always and everywhere the neurophysiological characterization initially assigned to it. For example, if pain is identified with the firings of c-fibers, it follows that a creature of any species (even extraterrestrial) could be in pain only if it had c-fibers and they were firing. But such a constraint on the biology of any being capable of feeling pain is both gratuitous and indefensible: why should we suppose that any organism must have the same biochemistry as we, in order to have what can be accurately recognized as pain? The type identity theorists had overreacted to the behaviorists' difficulties and focused too narrowly on specifically human biology.

Putnam advocated the obvious correction: what was important was not that c-fibers were firing, but what those firings were doing, i.e. what their firing contributed to the operation of the organism as a whole. The role of the c-fibers could have been performed by any mechanically suitable component, without changing the psychology of the containing organism. Thus, to be in pain is not *per se* to have c-fibers that are firing, but merely to be in some state or other, of whatever biological description, that plays the same causal role as did the firings of c-fibers in the human beings we have investigated. We may continue to maintain that pain 'tokens' – individual instances of pain occurring in particular subjects at particular times – are strictly identical with particular neurophysiological states of those subjects at those times, namely, with the states that happen to be playing the appropriate roles. This is the thesis of 'token identity' or 'token physicalism'. But pain itself can be identified only with something more abstract: the causal or functional role that c-fiber firings share with their potential replacements or surrogates. Types of mental state are identified not with types of neurophysiological state but with more abstract functional roles, as specified by state-tokens' causal relations to the organism's sensory inputs, motor outputs, and other psychological states.

Putnam compared mental states to the functionally or computationally characterized states of a computer: just as a computer program can be realized or instantiated by various physically different hardware configurations, so can a psychological 'program' be realized by various organisms of different physiochemical composition, and that is why different physiological states of organisms of different species can realize one and the same type of mental state. Where a type identity theorist's type-identification would take the form 'to be in a mental state of type *M* is to be in the neurophysiological state of type *N*', Putnam's functionalism (as it is called) has it that to be in *M* is to be in some physiological state that plays role *R* in the relevant computer program (i.e., the program that at a suitable level of abstraction mediates the creature's total outputs given its total inputs, and so serves as the creature's global psychology). The physiological state 'plays role *R*' in that it stands in a set of relations to physical inputs and outputs and other inner states that matches (in a one-to-one fashion) the abstract relations between inputs, outputs and computational states codified in the computer program.

There is another version of functionalism that appeals to 'function' not in the computational sense but in the biological sense. In this version the role with which a mental state is to be identified is characterized teleologically, in terms of what the

state, or its containing neurophysiological device, is for: what it contributes to the subject's behavioral capabilities.

Of course, one need not apply the same theory to all kinds of mental state. One might, for example, be a behaviorist about beliefs, a type identity theorist about very specific sorts of sensation, and a functionalist about visual perception.

Two minority materialist views should be mentioned. One is anomalous monism (Davidson, 1970), according to which mental 'types' are irreducible. The anomalous monist grants, indeed insists on, the truth of the 'token identity' thesis, but maintains that mental types are *sui generis*: there is nothing reductively or nontrivially common to various people's beliefs that sugar is sweet, even though each of those tokens is identical with some particular token of a brain state. Mental types form a closed family, and we ascribe them according to their own proprietary epistemology.

Finally, there is eliminative materialism (Churchland, 1981), the view that mental states do not exist. Defenders of this paradoxical thesis argue that the common-sense concept of the mental is vague and incompatible with a scientific view of human beings. They claim that the common-sense or 'folk' theory of human behavior in which our mental concepts are embedded is, on various grounds, a bad theory, and should be replaced by a better and scientifically more successful one; moreover, they contend, the folk theory requires entities of a kind that are unlikely to be found in our biological structure.

ARGUMENTS FOR MATERIALISM

Four main arguments have been put forward.

First, physics presupposes a closed causal order entirely governed by precise (possibly stochastic) mathematical laws. Moreover, if one is trying to explain a physical phenomenon, one is methodologically required to seek a physical explanation; only if the phenomenon is inconceivably strange may one venture to suggest a nonphysical, immaterial or ghostly explanation. Thus, if materialism is not true, something must be wrong with physics as we know it. And it would be surprising if physics could be criticized and corrected by purely philosophical argument.

Second, there is the famous interaction problem, which even Descartes could not solve to his own satisfaction: minds and mental events cause physical behavior, and mental events and states are caused by physical impingements on subjects' sense organs. How is it possible, or even imaginable, for an entirely immaterial entity thus to interact causally with the physical world? The difficulty is not much less acute for the property dualist; for how can nonphysical properties interact with physical ones, given (again) the causally closed nature of the world as described by physics?

Third, philosophers talk of 'supervenience': a type of property *supervenes* on another type of property if the distribution of properties of the first type is entirely determined by the distribution of properties of the second type. Thus, chemical properties supervene on microphysical ones: if two possible worlds are exactly alike microphysically, they must also be alike chemically. Now it seems to most philosophers, even to some dualists, that mental properties supervene on (broadly speaking) physical ones: if two possible worlds are physically exactly the same, then they cannot differ mentally. The obvious explanation (though not the only conceivable explanation) of this supervenience is that mental properties are just complexes of physical properties.

Fourth, Armstrong (1968) maintained that mental terms were defined causally, in terms of mental items' typical causes and effects. For example, the word 'pain' simply means a state that is typically brought about by physical damage and that typically causes withdrawal, complaint, desire for cessation, and so on. Now if by definition pain is whatever state plays a certain causal role, and if, as is likely, scientific research reveals that that particular role is in fact played by some neurophysiological state, it follows that pain is that neurophysiological state.

PROBLEMS FOR MATERIALISM

The difficulties facing the materialist position fall into two main categories, corresponding to the two most distinctive features of mental states and events. Philosophers call these features, respectively, *intentionality* and *qualia*.

The term 'intentionality' is used by philosophers, not as applying primarily to actions, but to mean the property of being about something. Mental states and events are intentional in this technical sense. For example, beliefs and desires and hopes are about things, or have 'intentional objects': I have beliefs about B. F. Skinner; I want a ham sandwich and a cure for my hypertension; and I hope for peace on earth. What is both most distinctive and most troublesome about intentionality is its indifference to reality. An intentional object need not actually exist or obtain: the Greeks worshipped Athena; a friend of mine believes that corks grow on trees; and

even if I get the sandwich, my hope for world peace is probably going to remain unfulfilled.

For materialists, the problem is that it is hard to see how a purely physical or material object could have intentional properties. How could any purely physical entity or state have the property of being about a nonexistent state of affairs? Surely, the argument goes, a brick cannot do that, nor a subatomic particle, nor a collection of subatomic particles, however large.

But materialists are not without resources here. One is the computer or information-processing model of the mind, put forward by Putnam as mentioned above and endorsed by almost all cognitive psychologists. The internal states of a computer make reference to external things, depending on the subject matter of the computing and what program is running. So there can no longer be much doubt that physical states of a purely physical device can be about things, including nonexistent things. Of course, computer states are about things only by virtue of the intentional states of the human beings who design and use the computers; so it remains to be seen whether an adequate materialist account can be given of the intentional contents of human brain states.

The qualitative character of experience also poses a major set of problems for materialism. The *quale* of a mental state or event is that state or event's subjective feel, its introspectible 'phenomenal character'; for example, the distinctive felt quality of a backache, or the vivid green colour of an afterimage (even when one knows that the green afterimage is the phantom by-product of a red light flashing). Many philosophers have objected that no materialist metaphysics can explain, illuminate, acknowledge or even tolerate the notion of what it subjectively feels like to be in a given kind of mental state (Nagel, 1974; Jackson, 1982; Chalmers, 1996). Yet, say these philosophers, the feelings are quintessentially mental; they make the mental states what they are. Something, therefore, must be drastically wrong with materialism.

This suspicion has given rise to a number of distinct objections to materialism, among which are the following.

1. Early critics of the type identity theory argued that the fact that we have immediate mental access to qualia suggests that they are not features of any purely behavioral or neurophysiological item. Surely we do not have immediate, transparent access to (even our own) physical states.
2. Many philosophers have proposed counterexamples to various materialist views: hypothetical examples in which some creature seems to satisfy all the right materialist conditions but whose qualia are of the wrong kind, or which lacks mentality or one of its crucial aspects entirely (Block, 1978; Chalmers, 1996).
3. Nagel (1974) argues for the existence of a special, intrinsically perspectival kind of fact, the fact of 'what it is like' to have a mental experience of a given kind, which intractably and in principle cannot be captured or explained by physical science. Jackson (1982) contends that a brilliant scientist could know all the scientific and other physical facts about color and about people seeing color, yet not personally know what it is like to see green; thus, there is a kind of fact that materialism leaves out.
4. It seems that in consciousness we are presented with mental individuals that themselves have phenomenal, qualitative properties. As before, when a red light flashes in front of you, your visual field contains a green after-image – which is a thing that is really green, has a fairly definite shape and exists for a few seconds before disappearing. If there are such things, they are entirely different from anything physical to be found in the brain of a (healthy) human subject. In fact, if there are such things then materialism is false, since they themselves are immaterial entities. At least, it is hard to see how a purely physical brain could apprehend them.
5. Even if God were to assure us that, say, the Type Identity theory is true, there would still be a problem: Why on earth does such-and-such a firing of fibers going on in my brain feel to me like … *this*?—or for that matter, like anything at all? It seems inexplicable, an insoluble mystery (Levine, 1993).

This is a formidable set of objections, and each seems plausible. Needless to say, materialists have responded at length: there is an enormous literature on objections to materialism based on qualia.

MATERIALISM AND COGNITIVE SCIENCE

Cognitive science is founded on the computer model of the mind, which is also what, on some accounts, allowed materialism to account for intentionality.

It is widely thought that cognitive science, like biology, chemistry and physics, presupposes materialism. Methodologically, that is certainly so: no cognitive scientist is allowed to sidestep a difficulty by appealing to an immaterial entity or mechanism ('at this point a miracle occurs'). But cognitive science does not itself entail materialism. Cognitive science may not address all of what is mental. Some philosophers (such as Chalmers (1996)) hold that although many types of mental event or state, and perhaps all purely cognitive states, are material, the qualia specifically featured in sensory states are not. Furthermore, if functionalism is true, then

even if all psychofunctional roles are in fact played by material states and events, it is still at least conceivable that they might have been played by an immaterial or ghostly substance. The first of these possibilities matters at least slightly to cognitive science itself, the second not at all.

Meaning

Intermediate article

Kent Bach, San Francisco State University, San Francisco, California, USA

CONTENTS

Sentences have meanings, and speakers mean things in using them. The meaning of a sentence is determined by the meanings of its constituents, together with its syntactic structure, but what a speaker means in using it is often not determined by what it means: the speaker may mean something more or something else.

INTRODUCTION

Language is used to express thoughts and to represent aspects of the world. What thought a sentence expresses depends on what the sentence means, and how it represents the world also depends on what it means. Moreover, it is ultimately arbitrary, a matter of convention, that the words of a language mean what they do. So it might seem that what they mean is a matter of how they are used. However, they need not be used in accordance with their literal meanings. One can speak nonliterally, and convey something other than what the sentence means ('The look on his face spoke volumes'), or speak indirectly, and convey something more than what the sentence means ('I wonder if you know the time'). Linguistic communication requires knowledge of linguistic meaning, on the part of both the speaker and the speaker's audience, but it requires extralinguistic knowledge as well.

THEORIES OF MEANING

Words have meanings, and sentences have meanings. Assuming a principle of semantic compositionality, according to which the meaning of a sentence is determined by the meanings of its constituents and its syntactic structure, the aim of a semantic theory is to give an account of how meanings of complex expressions are determined by the meanings of their simplest meaningful constituents. A theory of meaning should explain what meanings are.

Linguistic Meaning

It is plausible to suppose, at least as a first approximation, that what a declarative sentence means is what is asserted by a speaker using it literally, and that what the speaker thus asserts is the belief he or she is thereby expressing. So, for example, if you utter the sentence, 'giraffes do not use periscopes', you are asserting, and expressing the belief, that giraffes do not use periscopes. If you are sincere, you actually believe what you are asserting, and that is the very thing that comprises the meaning of the sentence you uttered. Call this thing a proposition, in this case the proposition that giraffes do not use periscopes.

That analysis leaves open what sort of thing propositions are. Presumably they are abstract entities, independent both of mind and of language. Some philosophers think of them as structured, composed of the semantic values of sentence constituents; others think of them as sets of circumstances or possible worlds with respect to which a given sentence is true. Some are reluctant to speak of propositions at all and prefer to speak of the truth conditions rather than the propositional contents of sentences. To remain neutral on this issue, let us use 'proposition' to mean the truth-conditional content of a (declarative) sentence, whether this is something that has a truth condition or simply is the truth condition. A proposition is something that different people can believe or assert and that different sentences, in the same or different languages, can mean. The truth or falsity of sentences, beliefs, and assertions depends on the truth or falsity of their propositional contents. So, in particular, the truth or falsity of the sentence, 'giraffes do not use periscopes', or of the belief expressed and the assertion made in uttering it, depends on the truth or falsity of the proposition that giraffes do not use periscopes. (*See* **Categorial Grammar and Formal Semantics**; **Possible Worlds Semantics**)

It is widely thought that the meaning of a sentence is determined by the meanings of its constituents and how they are arranged syntactically (in linguistic terms, the meaning, or semantic interpretation, of a sentence is a projection of its syntax at the level of logical form). From this perspective, it is reasonable to identify the meaning of a constituent of a sentence with the contribution it makes to the propositional contents of sentences in which it occurs. Different sorts of expressions make different sorts of contributions. For example, whereas 'giraffes' and 'periscopes' mean things of certain types, 'use' means a relation between agents and instruments, and 'not' is a negation operator.

Some words clearly have meanings and yet their meanings are not clear. With vague words, like 'red', 'old', and 'rich', there is no clear boundary between what they do and do not apply to. They appear to have borderline cases, although it has been argued (most notably by Williamson, 1994) that the boundaries are definite but unknowable. Also, different words can have the same meaning. For example, in one of their senses, 'correct' and 'right' are synonymous. So are 'teacher' and 'instructor', and 'consume' and 'devour'. And, of course, a word can have more than one meaning. Typical examples of ambiguous words are the nouns 'bat', 'club', and 'stroke', the verbs 'cut', 'draw', and 'lie', and the adjectives 'hard', 'high', and 'true'. (*See* **Vagueness**)

The occurrence of an ambiguous word in a sentence, as in 'George never goes near a golf club', renders the sentence ambiguous. But sentences can also be structurally ambiguous, as with 'German history teachers are pedantic', in which 'German history teachers' may mean 'teachers of German history' or 'German teachers of history'. Less apparent is the source of the structural ambiguity in 'The chicken is ready to eat', which can mean that the chicken is ready to do some eating or that the chicken is ready to be eaten. However, if we posit the covert presence of empty categories before and after the infinitive 'to eat', a plausible explanation for the ambiguity is that different empty categories are tied to 'the chicken', as indicated by the different indexing in 'the chicken$_1$ is ready e_1 to eat e_2' and in 'the chicken$_1$ is ready e_2 to eat e_1' (Chomsky, 1986).

Finally, the references of many words that are univocal in meaning can vary from use to use. These include personal pronouns like 'I', 'you', and 'she', temporal terms like 'today', 'tonight', and 'last week' (also tense indicators), demonstratives like 'this', 'those', 'here', and 'there', and even relational nouns like 'enemy', 'neighbor', and 'disciple'. (*See* **Indexicals and Demonstratives**)

Semantics

There are two fundamentally different, though related, conceptions of semantics in the literature. One conception takes semantics to be concerned with the linguistic meanings of expressions (words, phrases, sentences). On this conception, sentence semantics is a component of grammar. It assigns meanings to sentences as a function of the meanings of their semantically simple constituents, as supplied by the constituents' lexical semantics, and their constituent structure, as provided by their syntax. The other conception takes semantics to be concerned with the truth-conditional contents of sentences (or, alternatively, of utterances of sentences) and with the contributions expressions make to the truth-conditional contents of sentences in which they occur. The intuitive idea underlying this conception is that the meaning of a sentence, the information it carries, imposes a condition on what the world must be like in order for the sentence to be true. (*See* **Lexical Semantics**; **Syntax**)

The linguistic and the truth-conditional conceptions of semantics would be equivalent if, in general, the linguistic meanings of sentences determined their truth conditions, and they all had truth conditions. Many sentences, however, are imperative or interrogative rather than declarative. They do not have truth conditions, but compliance or answerhood conditions instead. Even if only declarative sentences are considered, in a great many cases the linguistic meaning of a sentence does not uniquely determine a truth condition. One reason for this is ambiguity, either lexical or structural: the sentence may contain one or more ambiguous words, or it may be structurally ambiguous. Another reason is that the sentence may contain indexical elements. Ambiguity makes it necessary to relativize the truth condition of a declarative sentence to one of its senses, and indexicality requires relativization to a context. Moreover, some sentences, such as 'Jack was ready' and 'Jill had enough', though syntactically well formed, are semantically incomplete. That is, the meaning of such a sentence does not fully determine a truth condition, even after ambiguities are resolved and references are fixed (Bach, 1994; Sperber and Wilson, 1995). Syntactic completeness does not guarantee semantic completeness.

The apparent conflict between these two conceptions of semantics can be resolved if it is

supposed that they have different subject matters: linguistic semantics targets sentences, whereas truth-conditional semantics targets utterances of sentences. But it should not be supposed that an utterance encodes anything that is not encoded by the sentence itself. Information available in a context of utterance may be tied to constituents of the sentence as uttered, but it is not encoded. Such information is combined with the encoded information to produce an interpretation of the utterance. Also, the speaker may convey additional information when speaking indirectly or nonliterally. So we need to distinguish between information encoded by a sentence, information tied to its utterance, and information conveyed in uttering it. The first is the province of linguistic semantics, the second of truth-conditional semantics, and the last of pragmatics.

What Are Meanings?

A traditional theory of meanings, going back to Plato, is the so-called 'idea' theory. It regards meanings as concepts and complexes of concepts. The meaning of a word (or a morpheme) is the concept (or concepts, if it is ambiguous) conventionally associated with it (a full account of what this association involves would be partly philosophical, partly psychological, and partly sociological). The meaning of a phrase is a complex concept made up of the simpler concepts associated with the words it contains, and the meaning of a sentence is the thought made up of the concepts expressed by its constituents, in accordance with how they are arranged syntactically.

An alternative theory is the so-called 'thing' theory: meanings are the references of expressions, as opposed to the concepts they express. 'Things' here include not only particular objects and events but also properties, relations, and other abstract objects. The proposition expressed by a sentence consists of a structured entity made up of the referents of its constituent expressions. In the simplest sort of case, the sentence 'Koko is hungry' expresses the proposition that Koko is hungry, whose constituents are Koko and the property of being hungry.

PHILOSOPHICAL ISSUES OF MEANING

The apparent conflict between the idea theory and the thing theory can be resolved by viewing them as answering two different questions: what confers meanings on words, and what comprises the meanings of words? This resolution distinguishes the cognitive contents of words, the ideas or concepts they express, from their semantic contents, what things (or properties or relations) they stand for. It respects the fact that words are used to talk about things, not ideas, and yet are used to express ideas.

Sense and Reference

The most influential implementation of such a two-tiered approach has been Frege's (1892). He distinguished the sense of an expression from its reference. The sense is the expression's 'cognitive value', but it also determines the expression's reference, if any. The sense of an expression imposes a condition that the reference must satisfy and does not depend on whether or not there is a reference. As Frege explains, 'the thought remains the same whether "Odysseus" has reference or not'. The sense of an expression is its contribution to the thought expressed by a sentence in which it occurs. But words are used to refer to objects of thoughts, not ideas of those objects. Even so, since the same object can be thought of in different ways, under different 'modes of presentation', how the object is thought of, and hence the sense of the expression used to refer to it, enters into the thought expressed. This, Frege suggests, explains how it is possible to think or say that Elton John is a singer and yet sincerely deny that Reginald Dwight is a singer, even though Elton John is Reginald Dwight. (*See* **Sense and Reference**)

By supposing that expressions have both sense and reference, Frege could explain how expressions that are distinct in meaning can have the same reference and how referring expressions without reference, like 'Odysseus', can still be meaningful. Nevertheless, one might ask whether what determines the reference of a referring expression – such as a proper name, an indexical, or a demonstrative – is part of the semantic content of sentences in which the expression occurs. According to the doctrine of direct reference (Kaplan, 1989), such expressions refer directly to particular individuals. This is not to deny that there are conditions that something must meet to be the referent, but only that such conditions are part of semantic content. So, for example, if someone says 'I love you', he is using 'I' to refer to himself and 'you' to refer to his listener. However, the fact that he is the speaker and the fact that the other party is the listener do not enter into what the speaker says. (*See* **Reference, Theories of**; **Direct Reference**)

Analyticity

It seems that some sentences are true (or false) solely by virtue of their meanings. For example, to understand the sentence 'All sofas are couches' is to know that it is true. In contrast, one can understand 'All snails are slow' without knowing it to be true (its truth depends on an empirical fact about snails). The first sentence is evidently analytic, the second synthetic. However, despite the glaring intuitive difference between the two, the analytic–synthetic distinction was vigorously attacked by Quine (1951) and others. Quine argued that this distinction cannot be explained in an illuminating way (i.e. without appeal to equally 'obscure' notions like synonymy, translation and, indeed, meaning itself), and he suggested that it is, at best, a matter of degree. Grice and Strawson (1956) appealed to the obvious intuitive difference between, for example, the two sentences mentioned above, to maintain that the analytic–synthetic distinction, whatever it is, is genuine.

Even if Grice and Strawson are right about this, it doesn't follow that analytic truths are true by definition. For it is arguable that most words do not have definitions, at least of the sort that provide singly necessary and jointly sufficient conditions for their application. Wittgenstein (1953) challenged the Platonic assumption that all the items to which an unambiguous word applies must have something in common. And Fodor *et al*. (1980) marshalled a variety of examples and considerations to show that Wittgenstein's famous example of 'game' is not a special case. This raises the question of what word meaning (and knowledge of it) consists in.

Meaning Skepticism

The notion of analyticity, or of synonymy, is no more puzzling than the notion of meaning itself. If a sentence has a certain semantic content, there is no reason why another sentence cannot have the same semantic content and thereby be synonymous with it. Quine's attack on analyticity is ultimately a form of meaning skepticism. Wittgenstein (1953) and Kripke (1982), developing Wittgenstein's ideas, have offered other reasons for such skepticism (the complex debates they have generated are reviewed in Hale and Wright, 1997, chapters 8, 14–17), arguing that meaning cannot be fixed by facts about individual speakers. They appeal to social facts to explain how meaning can be determinate, but it seems that the same skeptical reasons, if valid at all, apply to this social explanation.

Are Meanings in the Head?

Putnam (1975) used an ingenious thought experiment to argue that at least some linguistic meanings are not 'in the head' (and do not supervene on what is in the head). Imagine a distant planet, Twin Earth, where everything is just as it is here, except that there the clear, tasteless liquid that falls from the skies, fills the seas and quenches thirst is composed not of H_2O but of some other stuff XYZ. It is 1750, and people on either planet could not, if given the opportunity, tell the difference between H_2O and XYZ. There is no psychological difference between the two populations with respect to the word 'water'. Nevertheless, claims Putnam, 'water' means something different on each planet. Accordingly, an Earthian suddenly transported to Twin Earth would incorrectly (relative to what it means on Earth) apply the word 'water' to the common liquid he sees there, which is not water but 'twin water'. Similarly, a Twin Earthian transported to Earth would wrongly apply the word 'water', as used on Twin Earth, to the common liquid he sees here, which is not twin water but water (H_2O). So, Putnam concludes, the reference of 'water' depends on the underlying nature of the clear, plentiful liquid around us and not just on how we think of that liquid.

In another thought experiment (Burge, 1979), an arthritic patient called Art complains to his doctor, 'my arthritis has spread to my thigh'. Nothing in his acquisition of the term 'arthritis' has kept him from supposing that this inflammatory disease can occur in the limbs as well as the joints. Meanwhile, his Twin Earth counterpart Bart registers a similar complaint. There, however, the term 'arthritis' is used to refer to an inflammatory disease of either the joints or the limbs. Bart's exposure to the term 'arthritis' is the same as Art's, but, given how it is used on Twin Earth, he understands it correctly. Now, observes Burge, when Art says that his arthritis spread to his thigh he is speaking falsely, but when Bart says the same thing, using 'arthritis' as it is used on Twin Earth, he is speaking truly. Therefore, what they are saying about themselves is different, even though there is no subjective difference between them. What they mean by 'arthritis' is partly a social matter.

These thought experiments have met with considerable enthusiasm but also with criticism (e.g. Unger, 1984; Bach, 1987, chapter 13). Putnam does not explain why the term 'water' should be (and was in 1750) relevantly different from such terms as 'earth', 'air', and 'fire'. These terms do not denote natural kinds: there is no chemical restriction on the

sort of soil to which 'earth' can apply; 'air' is not restricted to any particular mixtures of nitrogen, oxygen, and carbon dioxide found in Earth's atmosphere; and 'fire' does not apply only to flame-producing chemical reactions that involve oxidation. As for 'water', although it applies (on Earth) to H_2O but not to XYZ, is this because of what 'water' means or because, as a consequence of what we have learned from modern chemistry, we count as water only stuff that is chemically like these samples? It was a discovery that this stuff, unlike earth, air, and fire, is a chemical natural kind. It is not evident why this should show that the term 'water' has a different sort of meaning, with its reference determined in a different way, from 'earth', 'air', and 'fire'.

The arthritis argument depends essentially on the supposition that one can have beliefs with meanings one 'incompletely understands'. It assumes, for example, that Art not only misunderstands the word 'arthritis' but operates with the concept arthritis rather than with some broader concept ('tharthritis') that he mistakenly associates with the word. So, it might be objected, Art understands the term 'arthritis' in precisely the same way as Bart does, and has the very same belief, namely that his tharthritis has spread to his thigh. Whatever evidence there is that he also believes that his arthritis has spread to his thigh is overridden by his idiosyncratic grasp of the term 'arthritis'. We are not tempted to say that he believes that he has inflammation of the joints in his thigh, and this should disincline us to suppose that he means that his arthritis has spread to his thigh. Because of how he misuses the term 'arthritis', he means what Bart means by it.

MEANING AND COMMUNICATION

The distinction between speaker's and linguistic meaning is needed to accommodate the fact that what a speaker means in uttering a sentence can, and often does, diverge from what is meant by the sentence he utters (even if it is neither vague nor ambiguous). A speaker can mean something other than what the sentence means, as in using 'nature abhors a vacuum' nonliterally, or something more, as in using 'it's getting cold in here' indirectly to ask someone to close the window. In general, an utterance can be literal, nonliteral, or indirect (Bach and Harnish, 1979, chapter 4), depending on the relationship between what the sentence means and what the speaker means in uttering it. In so far as the two diverge, which is usually, successful communication requires the listener to fill in the gap inferentially.

Speaker's Meaning and Linguistic Meaning

Grice had two further reasons for invoking the distinction between speaker's and linguistic meanings. Firstly, he thought that linguistic meaning could be reduced to speaker's meaning. This reductive view has not gained wide acceptance, partly because of the extreme complexity of its detailed formulation (e.g., 1989, chapter 6; Schiffer, 1972), and partly because it requires the controversial assumption that language is essentially a vehicle for communicating thoughts and not a medium of thought itself. Still, many philosophers would concede that mental content is more fundamental than linguistic meaning, and perhaps even that semantics reduces to the theory of mental content.

Secondly, Grice invoked the distinction between speaker's and linguistic meaning to counter certain extravagant claims, made by so-called 'ordinary language' philosophers, about various important philosophical terms, such as 'believes' and 'looks'. For example, it was suggested that believing implies not knowing, because to say, for example, 'I believe that dolphins communicate' is to imply that one does not know this, or to say 'Jenny's eyes look blue' is to imply that Jenny's eyes might not actually be blue. However, as Grice (1989, chapter 2) pointed out, what carries such implications is not what one is saying but that one is saying it, rather than the stronger 'I know that dolphins communicate' or 'Jenny's eyes are blue'. He also objected to certain ambiguity claims; for example, that 'or' has an exclusive as well as an inclusive sense, as in 'I would like an apple or an orange', by pointing out that it is the use of 'or', not the word itself, that carries the implication of exclusivity. Grice's 'modified Occam's razor' ('senses are not to be multiplied beyond necessity') helped to clarify the distinction between (linguistic) meaning and use, and has since helped linguists to appreciate the importance of separating, as far as possible, the domains of semantics and pragmatics. (*See* **Implicature**)

Communicative Intentions

Grice's concept of speaker's meaning (1989, chapters 5, 14, 15) was an ingenious refinement of the crude idea that communication is a matter of intentionally affecting another person's psychological states. He discovered that there is a distinctive, rational means by which the effect is achieved: by way of getting one's audience to recognize one's intention to achieve it. The intention includes,

as part of its content, that the audience recognize this very intention by taking into account the fact that they are intended to recognize it. A communicative intention is thus a self-referential, or reflexive, intention. Grice observes that 'this seems to involve a reflexive paradox, but it does not really do so' (1989, p. 219), but he does not explain why not.

Consider his example of deliberately frowning to communicate that one is displeased. Since frowning is a natural sign of displeasure, frowning deliberately might lead another to believe that one is displeased. The simplest scheme would be to misleadingly intend the other person to take one's deliberate frown for a spontaneous one and thereby take it as evidence that one is displeased. But what if one's frowning is obviously deliberate? Then it would lack the evidential value of natural frowning. However, one could exploit the common knowledge that frowning is a sign of displeasure and intend one's frowning to be taken as indicating displeasure, provided the other person supposes one intends it to be so taken. Part of what the other person is to take into account in order to infer that one is displeased is that one intends one's frowning as indicating that. This may seem to be circular, to involve a 'reflexive paradox', but Grice does not mean that one's audience has to already know what one's intention is in order to infer it. He means, rather, that the audience has to take into account that one's intention, whatever it is, is intended to be recognized.

In communicating, linguistically or otherwise, one is expressing some propositional attitude or other psychological state. In performing the speech act of asserting, one is expressing a belief; in requesting one is expressing a desire; in making an offer one is expressing a conditional intention; in apologizing one is expressing regret for something one did; and in thanking one is expressing gratitude for something the listener did. In general, different types of speech acts may be classified by the type of psychological state they express (Bach and Harnish, 1979, chapter 3), although expressing such a state does not imply that one is in it – one could be insincere. (*See* **Propositional Attitudes**; **Speech Acts**)

RELEVANCE TO COGNITIVE SCIENCE

Cognitive science touches often on the subject of meaning. Only a few topics will be briefly addressed here. (*See* **Language Acquisition and Language Change**; **Parsing**)

Language Understanding

Normal speakers understand tens of thousands of words of their language. Understanding a word is knowing its meaning, but what does this involve? A natural suggestion is that it involves two things: possessing a certain concept, and associating that concept with the word. Merely possessing the concept is not enough: the concept must be tied to the word somehow. However, it would be implausible to require that the speaker believe that the concept is the meaning of the word, for that would require the speaker to have concepts of both the concept and the word. A less cognitive and more associative account seems more plausible.

In any case, part of what understanding a word involves is knowing how the word can fit into a sentence: for example, whether it is a noun, a verb, or some other part of speech. Many words are compounds, like 'newspaper', 'hotbed', and 'toadstool', or are otherwise composed of meaningful parts, stems with prefixes or endings, such as 'composed', 'meaningful', 'parts', 'prefix', and 'ending'. Also, lexical knowledge, which includes information about the form and meaning of a word and syntactic constraints on its occurrence, must be combined with knowledge of how words are put together to form sentences. Finally, all of this purely linguistic knowledge must be supplemented with knowledge about how what people mean can go beyond what their words mean. Such knowledge, the subject of pragmatics, is not, strictly speaking, linguistic knowledge. (*See* **Lexicon**)

Pragmatic Processing

Although there is ample research on phonological, lexical, syntactic, and semantic processing, there has been little work on pragmatic processing; that is, on how people manage, when uttering a sentence, to make themselves understood, and how, when hearing a sentence, they manage to understand what the speaker means. Grice's (1989, chapter 2) theory of conversational implicature and the associated maxims of conversation provides a broad framework for identifying the factors that contribute to successful communication, from both the speaker's and the hearer's side, but it does not explain in detail how this process works.

One issue pertaining to pragmatic processing has begun to be addressed. Recanati (1995) has distinguished different models of the hearer's processing of an utterance in cases where what the speaker means is an enriched version of what the

sentence means – for example, 'I've had breakfast (today)', or 'Mary has (exactly) three children' – or where the speaker intends to be implying something. On one model, the hearer computes the proposition strictly and literally (the 'minimal' proposition) expressed by the utterance before arriving at a candidate for what the speaker means; on another model, this proposition is computed, but not necessarily first; on a third 'local processing' model, this proposition is not computed at all. Bezuidenhout and Cutting (2002) have tested these models experimentally. Their findings tend to favor the second model over the third and to refute the first model.

Polysemy

It is simplistic to suppose that knowing the meaning of a word consists in associating the 'right' concept with it. One obvious complication is that a great many words are ambiguous, thereby expressing more than one concept, but this shows only that the relation of concepts to words is many-to-one (actually, it is many-to-many, since many words have synonyms). A further complication is that with a great many words it is unclear how many meanings they have. The diverse uses of common words like 'go', 'get', 'keep', 'put', 'on', 'in', 'from', and 'to' might make it seem that their meanings are not fixed from use to use. Ruhl (1989) maintains that each such word does have a core meaning, but that this meaning is too impoverished to comprise what the speaker can mean in using the word. That is, in any particular use the meaning is enriched somehow. (See Ravin and Leacock (2000) for variations on this sort of view, applied to a variety of lexical items.)

Consider the words 'went', 'from', and 'to' as they occur in the following sentences:

Max went from Wilmington to Washington. (1)

The road went from Wilmington to Washington. (2)

The concert went from eight to ten. (3)

Max went from irritated to outraged. (4)

The house went from Max to his wife. (5)

On a simplistic conception of linguistic meaning, it might seem that only in the first sentence, which involves movement from one place to another, are the words 'went', 'from', and 'to' used literally, and that their uses in the other sentences are in various ways 'extended', hence nonliteral, uses. However, it seems plausible to suppose that the words are used literally in all these sentences, despite the fact that they are used differently from one sentence to the next. The existence of those various uses shows that the meanings of these polysemous terms are more abstract than the simplistic 'movement' model would suggest.

A great many seemingly univocal words turn out to have distinct but related forces when applied to things of different sorts. Consider the adjective 'sad' as it modifies these different nouns:

sad person / sad face / sad song / sad episode (6)

A sad face is not sad in the way that a sad person is. Rather, it expresses the person's sadness. A sad song is not sad in the way that a sad person is, and need not express any particular person's sadness, such as the writer's or the performer's (nor need it make the listener feel sad). And a sad episode is not itself sad – it causes sadness. Similarly, consider the variable import of the adjectives 'fast', 'generous', and 'conscious', as they occur in the following phrases:

fast car / fast track / fast race (7)

generous donor / generous gift (8)

conscious being / conscious state (9)

Obviously the most plausible import of each of these adjectives varies with the noun it modifies. Indeed, only in the first phrase in each case does the adjective express a property that directly belongs to what the noun denotes. Such adjectives have counterparts in other languages with the same different but related uses; therefore the variability of their import is due to polysemy, not ambiguity (linguistic coincidence).

Pustejovsky (1995) proposes that such polysemy involves 'co-compositionality': what varies from case to case is not a term's semantic properties but how those properties interact with those of the term it combines with. Although his ambitious theory, intended primarily as a computational model, is an improvement over what he calls 'sense enumeration lexicons', it seems to conflate pragmatic plausibility with semantic possibility. Although a speaker is not likely to use, say, 'sad song' to mean a song experiencing sadness, 'fast track' to mean a track that is moving fast, or 'generous gift' to mean a gift that gives generously, arguably these improbable interpretations of those phrases are nevertheless generated by the grammar. It does not seem to be a semantic fact (a fact about meanings of words)

that songs do not experience sadness, tracks do not move (much less move fast), and gifts are not generous in their giving.

The above examples of adjectival modification raise questions about the nature of compositionality (Partee, 1995). So do the following noun–noun compounds:

child abuse / drug abuse (10)

election nullification / jury nullification (11)

slalom skiing / snow skiing / heliocopter skiing (12)

jellyfish / goldfish / catfish (13)

clipboard / diving board / bread board / game board / headboard (14)

Such examples make it clear that compositionality is not as straightforward as it might seem, for there are different ways in which the meanings of words can combine. (*See* **Lexical Semantics**)

Concepts and Conceptions

Some cognitive scientists, such as prototype theorists and developmental psychologists, often refer to people's conceptions of various types of things as 'concepts'. This usage is misleading, since conceptions are much richer than concepts and play different roles. Conceptions play a role in how people group and categorize things, judge similarities and differences between things, and form theories of things of different types; but concepts are what people associate with words, by virtue of which words mean what they do. The distinction becomes clear if we consider that people can have different conceptions of a given type of thing and yet use the same word to refer to it. For example, they can associate the same concept with the word 'tree' but have different conceptions of trees.

Memory, Philosophical Issues about

Intermediate article

John Sutton, Macquarie University, Sydney, New South Wales, Australia

CONTENTS

Memory is a set of cognitive capacities by which humans and other animals retain information and reconstruct past experiences, usually for present purposes. Philosophical investigation into memory is in part continuous with the development of cognitive scientific theories, but includes related inquiries into metaphysics and personal identity.

INTRODUCTION

Cognitive scientists study an enormous variety of topics under the headings of memory and learning. Events affect humans, other animals, and machines in many ways, and sometimes enduring changes in the respective systems result, altering actual and possible future behavior. Philosophers have been centrally interested in human personal memory for episodes and experiences in the autobiographical past, as manifested in reminiscence, recall, and recognition. This is partly because of a focus on memory as a topic in epistemology, the theory of knowledge, which was in the twentieth century often pursued through methods of linguistic and conceptual analysis that were oddly divorced from psychological inquiry. Recently, however, a naturalistic turn in philosophy of mind has brought theories of memory firmly into productive contact with cognitive science.

This article first sketches central philosophical questions about memory, self, and time. It then focuses on a specific debate which is particularly relevant to cognitive science, about the existence and nature of memory traces, and concludes by outlining recent moves towards a more insistently interdisciplinary approach to memory.

PHILOSOPHICAL ISSUES CONCERNING MEMORY

Memory and Self

Cognitive scientific views of consciousness and self will increasingly influence traditional philosophical discussion about memory and personal identity. To what extent does memory construct and maintain the continuity of personal identity over time? In the history of Western philosophy this question was of pressing concern in religious contexts. In order for it to be truly *me* who is saved or damned at the Day of Judgment, the judged soul has to be numerically identical with the person who committed sinful or praiseworthy acts in this life. For Christian philosophers like John Locke, this meant that we had to retain personal memory in the afterlife.

In our 'materialist' age, the issue remains urgent because many moral and legal practices require a robust notion of continuous responsible agency. Some philosophers argue on conceptual grounds that memory cannot be the basis of personal identity because remembering *presupposes* a self who remembers. But others, notably philosophers who see the self as less unified, stable, and integrated than is acknowledged in traditional philosophical theories of personal identity, urge attention to real case studies of, for example, amnesia and dissociative identity, or to better cognitive theories of the selective and constructive nature of autobiographical memory (Schechtman, 1994).

Memory and Time

What role does memory play in our understanding of time? How is time represented in memory? The philosopher John Campbell (1997) has developed a new picture of the structure of time in autobiographical remembering. For Campbell, the human ability self-consciously to identify personal episodes as having happened at particular past times is bound up with our unique capacities to locate events, and ourselves, in an asymmetric temporal and causal order. Just as our spatial representational skills are not restricted to egocentric models, so our mature temporal orientation

involves an objective conception of time as linear. Drawing on empirical work on the representation of time in humans and other animals, Campbell claims that only humans are genuinely oriented with respect to particular times rather than merely to phase or rhythm. Because we can grasp the temporal relations between temporal cycles or phases, we have a conception of the connectedness of time which gives us the concept of the past. This detached or reflective sense of time is what grounds our understanding of the uniqueness of particular actions.

Campbell's audacious analysis of memory and time suggests, among other things, that there is no true episodic memory in nonhuman animals, and thus offers both empirical and conceptual challenges to his opponents. Comparative ethology and cognitive anthropology are as relevant to the evaluation of his account as is the clinical neuropsychology of amnesia. So this case can serve as a first illustration of the possibility that the immediate future of the cognitive philosophy of memory science will be bewilderingly and excitingly interdisciplinary.

Causation, Representation, and Traces

For me to have a genuine personal episodic memory, my present act of remembering must be causally connected in an appropriate way to the past experience being recollected. Even if it happens to be true that, as a child of four, I got lost in a shopping mall, most of us would deny that I truly personally remember the experience if I had forgotten it, and have only later been told about it by my parents. For this reason, philosophers and psychologists have hypothesized the existence of some kind of 'memory trace' as a continuous physical bridge across the temporal gulf, causally connecting past and present.

When I remember an episode of my personal history, I come into contact with events and experiences which are no longer present. We find it easy to engage in the peculiar sort of 'mental time travel' involved in such autobiographical memory, although we're often aware of significant limits to its reliability. Remembering is an instance of a general, flexible human capacity to think about the absent, so that mental life isn't entirely determined by the current environment and the immediate needs of the organism.

This is one intuitive route to the reliance on mental representations which lies at the foundation of cognitive science. It's natural to think that the physical trace, which is itself the causal result of past experience, somehow 'represents' that experience, or at least carries sufficient information about the past to allow the organism now to reconstruct that experience or something like it. Since we are often able to remember *without* having any such traces in our current external environment (such as photographs or words written in a diary), many philosophers and scientists have postulated memory traces in the brain. There are stronger and weaker versions of this view.

COGNITIVE SCIENCE AND THE PHILOSOPHY OF MEMORY

Localist Models of Memory

Since many historical theorists of memory, from Aristotle to Descartes and on into the twentieth century, explicitly refer to memory traces, it may seem that little progress has been made: 'it is the survival of the memory "trace" concept, some static, permanent, distinct storage form that each experience leaves in the organism, that links together most remarkably the oldest and most modern models' (Colville-Stewart, 1975, p. 402). On this version of the memory trace hypothesis, traces must be independent, 'atomic' items, laid down separately by every experience (or perhaps every part of every experience), and stored at a separate location, until called out again in the reproduction of that experience.

This 'archival' or 'localist' model of information storage has to some extent been physically realized in the design of digital computers since the work of von Neumann in the 1940s. At an abstract level it underlies influential models of human memory in cognitive psychology in which data are clearly separated from processing, or storage system from executive. But it has serious conceptual problems. Followers of the philosopher Ludwig Wittgenstein pursue his point that such static, structural traces are not required by empirical evidence: 'nothing seems more possible to me than that people some day will come to the definite opinion that there is no copy in either the physiological or nervous systems which corresponds to a particular thought, or a particular idea, or memory' (quoted in Stern, 1991, p. 208). Phenomenological and direct realist philosophers, in turn, argue that the view collapses into either incoherence or skepticism. Either, in searching through stored items for the representation of a particular past experience, we must already remember that past experience in checking which is the right representation, in which case the postulation of the trace is redundant; or, if there is

no such independent access to the past, then we are trapped in the present behind a veil of memory ideas, and may not really know the past at all (Wilcox and Katz, 1981).

These anti-representationist criticisms are behind many philosophical doubts about the cognitive science of memory, and sometimes about scientific psychology as a whole. But unfortunately such critics have rarely offered positive alternative approaches, beyond the blunt direct realist claim that memory is an immediate, noninferential awareness of past things themselves. And in fact only strongly localist accounts of fixed and static memory traces are vulnerable to these charges. Alternative, more dynamic conceptions of the memory trace may be more empirically plausible, while yet offering genuinely causal accounts of the mechanisms linking past and present.

Distributed Models of Memory

'Distributed' models of the memory trace build in a degree of plasticity. In connectionist cognitive science, for example, occurrent remembering is the temporary activation of a particular pattern or vector across the units of a neural network. This reconstruction is possible because of the conspiring influences of current input and the history of the network, where this history is sedimented in the particular connection weights between units. Memory traces then are not stored statically between experience and remembering, but are piled together or 'superposed' in the same set of weights (McClelland and Rumelhart, 1986, p. 193):

> We see the traces laid down by the processing of each input as contributing to the composite, superimposed memory representation. Each time a stimulus is processed, it gives rise to a slightly different memory trace – either because the item itself is different or because it occurs in a different context that conditions its representation … the traces are not kept separate. Each trace contributes to the composite, but the characteristics of particular experiences tend nevertheless to be preserved, at least until they are overridden by canceling characteristics of other traces. Also, the traces of one stimulus pattern can coexist with the traces of other stimuli, within the same composite memory trace.

This framework postulates two abstract features: distinct transient patterns of activity, and composite, enduring, but modifiable dispositional states. It is not tied to current computational models, for these two features can be implemented in different physical systems. But how do such distributed models of memory escape the philosophical criticisms of local traces? Firstly, they offer an account of causal continuity which doesn't rely on the permanent storage of independent items, and which thus seems compatible with Wittgenstein's query 'whether the things stored up may not constantly change their nature' (quoted in Stern, 1991, p. 204). Secondly, they suggest a fallibilist realist response to the skeptical worry: while past experience exerts a robust causal influence on the holistic system of traces, veridical recall is not (and need not be) guaranteed. Finally, they can be integrated into a broader consensus in cognitive psychology about the reconstructive nature of memory, to which we now turn.

Constructive Remembering

'A variety of conditions exist', notes the psychologist Daniel Schacter, 'in which subjectively compelling memories are grossly inaccurate' (1995, p. 22). Partly in response to the crisis of the early 1990s over recovered memories and false memories, cognitive psychologists have recently developed a striking consensus about the extent and importance of memory distortions and confusions, assuming that understanding mechanisms of distortion will also elucidate the reliability of memory. Research in a number of areas has focused on the context of retrieval, describing the shaping influences of the remembering situation: many memories are created at the moment they are needed, not simply extracted whole from storage. Related work on source monitoring, interference, and suggestibility has developed fairly independently of connectionist computational modeling. This makes the current state of the sciences of memory a key case study in philosophy of cognitive science.

Because memory is studied in many different disciplines, from neurobiology to narrative theory, there is no obvious unity to either the objects of enquiry or the methods employed. In addition to analyzing evidence for particular psychological classifications of the variety of memory systems, seeking for example the best definition of the notion of episodic memory, a further central task for philosophy is the careful evaluation of relations between different levels of explanation. Memory is thus a test case for the possibility and the pitfalls of genuine interdisciplinarity in cognitive science. The cognitive sciences of memory are as yet immature, yet they harness the vast institutional apparatus of normal science.

Those who value theoretical coevolution across disciplines often optimistically underestimate the difficulty of translating terms and postulated mechanisms; while more skeptical voices doubt

the likelihood of mutually constraining explanations across neighboring levels or disciplines. Yet there are models of interdisciplinarity in the philosophy of science which allow for contact or even local reductive identification between theories at different levels, without unrealistic reliance on the formal unity of science. Valerie Hardcastle, for example, argues (1996, pp. 105–139) that consensus on the existence of dual implicit and explicit memory systems exemplifies a developing 'complicated and cluttered' interdisciplinary theory which relies actively on the methods and underlying assumptions of a number of different research traditions, in this case including developmental psychology, clinical neuropsychology, and experimental cognitive psychology.

The case of autobiographical memory development, to take another example, suggests that this multidisciplinary reach must extend beyond the level of individual psychology to incorporate social and historical factors. Although children talk about the past almost as soon as they start talking, they may first learn some personal narrative forms to organize their explicit, *public* recounting of past experiences, and then use these principles as scaffolding around which to organize their *internal* representations of past experiences. So the development of autobiographical conventions and patterns of coherence is less an automatic unfolding of internal processes than an internalization of cultural schemes (Nelson and Fivush, 2000). The best explanations of the form and content of specific personal memories may often refer not simply to the past episode itself, but (as in the case of failures of source memory) to multiple causes which span internal and external factors. The converse point also applies. This need to bridge the 'personal' level of explanation, the traditional domain of philosophy of mind, and to focus simultaneously on the subpersonal and the social, has implications for the philosophy of the social sciences of memory, in which explanation may need to refer to flexible internal processes of schematization and reconstruction.

Both cognitive anthropologists and philosophers drawing on dynamical and situated approaches to cognition have suggested the need for a general framework for memory science which can make sense of traces both inside and outside the individual. This is not to collapse the distinction between external and internal representational formats: for a connectionist in particular, the kind of 'storage' mechanisms employed by the brain are quite different from those of most external linguistic or digital systems. The point rather is to see brain traces and external traces as parts of temporarily integrated larger systems, used by us so as more successfully to exploit and manipulate information in the environment. As Andy Clark puts it, 'our brains make the world smart so that we can be dumb in peace' (1997, p. 180). This perspective can be given a biological twist, as in Merlin Donald's provocative account (1991) of the crucial changes in cognitive architecture which occurred with the historical development of enduring and transportable external memory hardware or 'exograms'; a psychological twist, as in David Rubin's (1995) ambitious theory of memory for oral traditions; or a metaphysical twist, as in perceptual psychologist Michael Leyton's (1992) general theory of memory as the asymmetric traces left by processes on objects. In each case, the understanding of changing cultural and technological systems becomes an integral part of cognitive science, rather than a humanistic curiosity.

Mental Causation

Intermediate article

Tim Crane, University College London, London, UK

CONTENTS

It is arguably an assumption of both common sense and scientific psychology that mental states and events cause events in the physical world. Yet this fact is problematic for both physicalist and dualist theories of the mind.

INTRODUCTION

Does the mind have effects in the physical world? To believe it does is to believe in mental causation. It can be argued that we are committed to the existence of mental causation when we explain people's actions in terms of their thoughts, beliefs, intentions, desires, and other propositional attitudes. For example, we might say that Jenny drank the whisky because she thought it would calm her nerves. To say that there is mental causation in this case is to say that the 'because' expresses a causal relation between Jenny's thought and her action, just as it does in non-mental cases, as when we say that the bridge collapsed because the bomb exploded beneath it. In other words, the thought, like the explosion of the bomb, is causally efficacious. Understood in this way, mental causation is ubiquitous. Whenever we do something or think something because of something going on in our minds, this is a case of mental causation. But what is the nature of this causation, and why have philosophers found it so problematic?

WHAT IS MENTAL CAUSATION?

Mental causation is when a mental state (like a belief or intention) or a mental event (like an experience) has an effect, either a mental effect (like another thought or experience) or a physical effect, an effect in the physical world. In any case of causation, we can distinguish between the *relata* of causation (what is being related) and the *relation* itself. So, for example, when the explosion caused the bridge to collapse, we can distinguish between the cause (the explosion), the effect (the collapse) and the relation itself (causation) which links these two events. To say that there is mental causation is to say that a cause of some effect is mental; just as to say that there is physical causation is to say that a cause of some effect is physical. It is not necessarily to say that there is a distinctive kind of relation – a distinctive kind of causation – which holds in the cases where a mental entity is a cause. This is a possible position; but it is not required by the idea of mental causation. Hence we should not commit ourselves at the outset to a conception of causation (e.g. that it must involve contact action) that renders mental causation impossible to understand.

What, then, is it that mental and physical causation have in common? What is it that makes them both cases of causation? The answer to this question depends on the correct theory of causation, and it is important to emphasize that few theories of causation entail that causation must be a physical relation. Some theories say that A causes B when there is a law of nature linking A-type and B-type events; others that A causes B when B is counterfactually dependent on A (i.e. if A had not existed, B would not have existed); and others say that A causes B when the probability of B is higher in the presence of A than it would have been otherwise (for all these options, see Sosa and Tooley, 1991). Other theories deny that causation is a relation at all (Mellor, 1995). But however they differ, these analyses can apply equally well to mental as to physical causes and effects.

As well as discussing the nature of the causal relation, theories of causation also discuss what kinds of entity are the relata of causation; that is, what kinds of entity are causes and effects. Some theories say that causes and effects are always events (like the explosion of the bomb or Jenny's drinking the whisky), while others say that they are facts (like the fact that the bomb exploded or the fact that Jenny drank the whisky) or states (the state of Jenny's having drunk the whisky). Others express this distinction as one between events and properties of events (events have many properties,

but only some properties of events are causally efficacious). Theories of 'agent causation', by contrast, claim that the fundamental phenomenon of mental causation is when agents, rather than their states or events involving them, cause things to happen: as when John breaks the window by smashing it. In this article, we will consider only causation by events, or states and properties (where a state is understood as a thing's having a property at a time).

Mental causation is an essential part of some metaphysical theories of mind. So it is with *functionalism*, whose characteristic thesis is that mental states are individuated (distinguished from one another) by the causal roles they play (Block, 1980). A functionalist holds that belief, for example, is the sort of state that is typically caused by perceptions and other beliefs, and is disposed to cause actions in conjunction with desires. Functionalism therefore assumes that mental states are causes and effects – the mind is a causal mechanism – though there are various accounts of what this actually means.

HISTORY

Debates about the causal powers of the mind can be traced back to antiquity; but in their contemporary form they derive from Descartes' influential theory of mind and body. Descartes was a dualist: he thought that mind and body were distinct substances. For Descartes, a substance is a being which is capable of independent existence, one whose existence depends on nothing else. So to say that mind (or soul) and body are distinct substances is to say, among other things, that they are capable of independent existence.

Descartes was criticised in his lifetime for making mental causation hard to understand, most famously by Princess Elisabeth of Bohemia (Descartes, 1985). Princess Elisabeth asked how substances so different as minds and bodies could affect one another; Descartes claimed not to see the difficulty, and the debate between them was left unresolved.

A more effective criticism of Descartes' dualism came from Leibniz. A central thesis of Descartes' physics is that matter is a substance whose characteristic (essential) attribute is extension in space. God has endowed matter with a certain *quantity of motion*, and the total quantity of motion is preserved in all physical interactions: an interaction never diminishes or adds to the total quantity of motion in the world. Thus Descartes believed in the conservation of quantity of motion, but also believed that mental causation was consistent with this law of nature. His reasoning, according to Leibniz, was that the mind causes things to happen in the body by changing the *direction* of motion of the animal spirits (a rarefied form of matter) at the pineal gland in the brain. So the mind can change the direction of motion of matter and not alter the total quantity of motion: mental causation is consistent with the conservation laws, as Descartes understood them.

Leibniz did not challenge the validity of this reasoning, but the correctness of Descartes' conservation laws. According to Leibniz, what is conserved in the physical world of matter is not quantity of motion but quantity of momentum, the product of mass and velocity. Since velocity is a vector of speed and direction, the mind cannot alter the direction of motion of the animal spirits without altering the quantity of momentum in the physical world. Therefore mental causation is inconsistent with the correct conservation law: the conservation of momentum (see Woolhouse, 1993).

Leibniz' alternative to Descartes' dualism was his doctrine of pre-established harmony, sometimes called *parallelism*. This is the view that mind and body do not interact causally, but operate in parallel (in harmony) in accordance with the will of God who initiated (pre-established) the harmony. This doctrine is a form of *epiphenomenalism*: the view that the mind has no effects in the physical world. Another form of epiphenomenalism is the *occasionalism* of Malebranche, which holds that the mind cannot act in the physical world on its own, but needs the help of God's action on each occasion of interaction. Each movement of the body by the mind is, in effect, a miracle. Epiphenomenalism need not deny that there are causal relations between different mental phenomena. But it must deny that there are any causal relations between mental phenomena and matter.

The naturalistic philosophy of the nineteenth and twentieth centuries did not generally see mental causation as a problem. Many naturalists are materialists, and materialists identify the mind with something material, the brain. By identifying the mind with the brain, materialism can allow mental phenomena to cause material phenomena, because mental phenomena are just a species of material phenomenon. In the twentieth century, the term 'physicalism' was sometimes used as a synonym for materialism, while sometimes the term was meant to indicate the special ontological and epistemological authority which physical science has

in telling us about the material world. The supposed difference between materialism and physicalism could then be put like this: materialism holds that everything is matter, whereas physicalism holds that everything is physical, where the physical is the subject matter of physical science. Therefore, if physics talks about various things that are not matter, physicalism can recognise the existence of something that materialism cannot. Since arguably the fields and forces of contemporary physics are not matter in any usual sense, physicalism seems to be the preferable theory. In what follows, therefore, this article will talk of physicalism rather than materialism.

MENTAL CAUSATION AS A PROBLEM FOR DUALISM

The problem of mental causation which originated in the seventeenth century re-emerged in the twentieth century as part of the argument for a specific form of physicalism, the identity theory (Feigl, 1958). Defenders of the identity theory argued that there were no philosophical, *a priori* objections to identifying mental phenomena with states of the brain; the truth of this claim must be established empirically. Identity is here understood literally: the claim is that a mental state is the very same thing as a state of the brain. (The identification of 'pain' with the firing of c-fibres became a common, though empirically false, illustration of the claim.) Later theories went further, and argued that the identity theory could be demonstrated by philosophical argument, rather than simply shown to be coherent (Lewis, 1966; Armstrong, 1968; Davidson, 1970). The general form of their argument is as follows:

1. First premise: mental causes have physical effects.
2. Second premise: the physical world is causally closed; that is, all physical effects have physical causes which are sufficient to bring them about ('the completeness of physics'; see Papineau, 2000).
3. Conclusion: mental causes are physical causes.

Different proponents of the argument elaborate and defend it in different ways, to make it strictly valid. For example, some say that an extra premise denying the existence of mental–physical *causal overdetermination* must be added. (Overdetermination is when an effect has two (or more) causes, each of which is enough to bring the effect about, and each of which would have brought it about if the other (or others) hadn't.) Others say that the second premise must be reformulated to make it compatible with indeterminism, since as it stands it is a deterministic claim. And others say that the first premise must be definitive of the nature of mental states, not just a fact about them (Lewis, 1966). But here we can put to one side these clarifications of detail, and focus on the general form of the argument.

The general form of the argument is that in order to reconcile mental causation with the completeness of physics, we have to identify mental and physical causes. So if all mental phenomena have some physical effects – a widely-held assumption, but an assumption none the less – then all mental phenomena are physical phenomena. The reasoning behind this argument is simple: if there are mental causes of physical effects, then how is this compatible with these effects having adequate physical causes, as the completeness of physics says they must? Either, it seems, the completeness of physics is false or epiphenomenalism is true. In other words, if the completeness of physics is accepted, then mental causation is a deep problem for mind–body dualism. The problem is only resolved, it seems, by identifying the mental and the physical causes.

Can a dualist respond to this problem? Is physicalism the only adequate response? Perhaps the dualist can deny the premises. The first premise of the argument is the existence of mental causation. As we have seen, a dualist could deny this premise by being an epiphenomenalist. But epiphenomenalism is very hard to believe: the view that our minds make our bodies move does not seem to be a theoretical claim, but a datum that theory should account for. Can a dualist deny the completeness of physics? Here matters are more complicated. The completeness of physics is not normally understood as a law of physics (like Newton's laws or the Schrödinger equation) but as a metaphysical speculation based on the laws of physics. A dualist could deny that this speculation is a consequence of the laws of physics. This is widely thought to be contrary to received opinion among philosophers of science; but the issue is still controversial (see Papineau, 2000, and Cartwright, 2000, for opposing perspectives).

The physicalist conclusion is that mental causes are identical with physical causes. So long as all mental phenomena have some physical effect at some point, then physicalists can conclude that each mental phenomenon is identical with some physical phenomenon. This is an *identity theory* of mind and brain. There are two types of identity theory: the 'type identity theory', which identifies mental properties or types, and the 'token identity theory', which identifies mental tokens or particulars.

Which identity theory one accepts might depend on one's views of the relata of causation (see above): if one held that properties or states are causes, for instance, then one would accept the type identity theory (Lewis, 1966), but if one held that events were causes, then one would accept the token identity theory (Davidson, 1970).

MENTAL CAUSATION AS A PROBLEM FOR PHYSICALISM

Since one of the general motivations for a physicalist theory of mind derives from the causal role of the mind, it is surprising to discover that mental causation creates problems for physicalism as well as for dualism. But there is a form of physicalism (called 'nonreductive physicalism') which denies the identity theory. Since the identity theory was what enabled physicalists to solve the problem of mental causation, those physicalists who reject the identity theory encounter that problem in a new form.

Some physicalists deny the identity theory because it entails the thesis that all creatures who are in the same mental state must be in the same physical state too, and this thesis is empirically implausible, given the diversity of organisms. Consider, for example, the variety of creatures who are capable of being in pain, and the variety of their physical constitutions, and then consider how unlikely it is that all these creatures share a physical state or property when they are in the same mental state (Putnam, 1975b). Nonreductive physicalists say that we should not identify mental properties or states with physical properties or states. But they endorse a weaker form of physicalism, to the effect that all particular objects and events are physical, even if not all properties and states are physical. (This is the so-called 'token identity theory'.) The resulting view is called nonreductive because it does not 'reduce' mental states to physical states, as the type identity theory does, by identifying them; but it is still physicalism because it gives an ontological priority to the physical in saying that all particular objects and events are physical. There are no nonphysical objects or events.

How does this affect the question of mental causation? This depends on how nonreductive physicalism regards the relata of causation. If causation is a relation between events, then nonreductive physicalism has no difficulty accounting for mental causation in physicalist terms, since all events are physical, even if not all properties are (Davidson, 1993). But some philosophers argue, for reasons independent of the philosophy of mind, that properties or states are causes, not events. One reason for believing this is from reflection on commonsense examples: if throwing a brick broke a window, then it is not the event of throwing the brick as such that had this effect, but rather the throwing of a brick with certain properties (its weight, its velocity, etc.). If the brick had been made of rubber, or had been thrown with less force, it might not have broken the window. Therefore, it is concluded that strictly speaking, causes are properties or states (i.e. things having properties); or, to put it another way, causes have their effects by virtue of their properties. But if causes are properties or states, then nonreductive physicalists must deny the identity theory of mental and physical causes, and therefore they cannot employ the argument discussed above. If they are not epiphenomenalist, then they must accept the first and second premises and reject the conclusion.

To put it another way: suppose there is mental causation, and the completeness of physics is true. And suppose properties (or states) are causes, and that the identity theory is false. Then it is hard to see how there can be mental causation in the light of the completeness of physics, even if every mental event is a physical event. This is the problem of mental causation for nonreductive physicalists (see Heil and Mele, 1993, for a variety of statements of this problem, and responses to it).

Nonreductive physicalists have tended to respond in one of two ways to this problem: either by developing the notion of causation involved in the debate, or by developing the doctrine of physicalism. Those who wish to develop the notion of causation might say, for example, that mental causes are causally relevant to physical effects, although not causally efficacious. (For similar ideas, see Dretske, 1988, and Jackson and Pettit, 1988.) One difficulty with these approaches is that it is hard to see them as more than ad hoc responses to the problem in hand: it can seem as if a specific notion of mental causation is simply being tailored to solve the problem. Some more ambitious approaches have therefore motivated their solution with detailed independent accounts of causation itself (Yablo, 1992, is a particularly detailed attempt).

The other kind of approach takes causation for granted, but further develops, the idea of nonreductive physicalism (Loewer, 2001). This approach assumes Jackson's definition of physicalism (Jackson, 1998), employing possible worlds: any minimal physical duplicate of our world is a duplicate *simpliciter*. It also assumes that causation is counterfactual dependence between facts or states

of affairs. Jackson's definition yields the metaphysically necessary determination of the mental by the physical: given what the physical facts actually are, the mental facts could not have been otherwise (see also (Lewis, 1993)). It follows that if the mental facts had been different in some way, then the physical facts would have been different, even if the mental and the physical facts are not identical. So, in particular, a mental cause M of a physical effect E causes E even though the completeness of physics guarantees the existence of a physical cause P which is enough for E – because P necessarily determines M, as well as causally sufficing for E. If M had not been the case, then E would not have been the case, since if M had not been the case, P would not have been the case and therefore (arguably) E would not have been the case either. By appealing to this (admittedly problematic) idea of metaphysically necessary determination, physicalists attempt to solve the problem of mental causation without appealing to the identity theory.

MENTAL CAUSATION AND COGNITIVE SCIENCE

In so far as cognitive science is committed to a form of nonreductive physicalism, denies epiphenomenalism, and upholds the completeness of physics, it has to give an account of mental causation. One of the most influential theories of the foundations of cognitive science, Jerry Fodor's 'representational theory of the mind' (RTM), presupposes that mental states involve causally related sequences of mental representations, or symbols in a language of thought. The main argument for RTM is based on the idea that the logical and rational relations between thoughts must have an underlying causal mechanism (Fodor, 1987). The causal mechanism of such thought processes, it is argued, must involve mental representations with a structure that mirrors the logical structure of thoughts; the representations have a semantic and a syntactic (i.e. causal) structure.

Critics have questioned whether RTM renders the content of thought causally idle: since the causal role of mental representations is discharged by the syntactic structure of the representations, what causal role does this leave for the content of thought? And if the content of thought is epiphenomenal, does this make it theoretically dispensable? Defenders of RTM have responded by claiming that the causal efficacy of content is guaranteed by the fact that it *supervenes* on the syntactic structure of the brain, that is, that there is no difference in content without a difference in syntax. But if syntactic structure is an aspect of the local physical structure of the brain, this defence puts RTM in conflict with the widely accepted doctrine of externalism, since according to externalism, the content of our thoughts does not supervene on the local physical structure of our brains (Putnam, 1975a). Fodor (1995) attempts to resolve this apparent contradiction.

Mental Content, Causal Theories of

Intermediate article

Charles Wallis, California State University, Long Beach, California, USA

CONTENTS

Theories of mental content seek to explain how mental states are about the world. Causal theories of mind propose to understand mental content in terms of the causal relationships between brain states and the world.

WHAT ARE CAUSAL THEORIES OF MENTAL CONTENT?

Causal theories of mental content hold that mental states represent the world in virtue of the causal relationships those states have within the mind and/or with the world. Though many theories of mental content are causal theories, not all theories of mental representation are causal in nature. For example, John Locke supposes that ideas of primary qualities (e.g. shapes) represent those qualities in an object because they are similar (share the same properties). Contemporary causal theories have predecessors dating back to Book III of John Locke's *Essay Concerning Human Understanding*, possibly Aristotle's *De Anima*, or even to Plato's *Theatetus*. Locke's notion of secondary qualities (a quality or power of the object which causes particular ideas in us that bear no similarity to the object, e.g. color) looks very much like a contemporary causal theory based upon reliable causally mediated covariation (Cummins, 1989). Aristotle's discussion in Book II of *De Anima* suggests that color in an object, though different from sensations of color, is nevertheless reliably caused by light hitting the object. Plato's analogy of perception as the matching of sensations caused by the world to impressions (knowledge) upon a ball of wax also suggests that Plato entertained the notion that causal connections allowed our minds to represent.

Contemporary causal theories of mental representation have developed in the theoretical context of explanation in cognitive science. Though causal theories can be understood independently, it can be helpful to view these theories in the context of computational explanations in cognitive science.

The computational theory of cognition (CTC) and the representational theory of intentionality (RTI) form the foundation of cognitive science. CTC characterizes cognition as the computation of complex functions on representational states. Computation consists in performing operations defined over representational states. Operations can be rule-based manipulations of syntactic strings as in traditional artificial intelligence, or the weighted passing of activation as in connectionist models. RTI asserts that mental states are about the world (have content) in virtue of a representation relation holding between the world and those states. CTC/RTI portrays cognizers as receiving input through sensory organs and/or memory and generating outputs in the form of memories, inputs to other processes, and/or motor response commands (see Figure 1).

Debate over the concept of computation relevant to the CTC centers around Turing-compatible computation and its development in computer science and mathematics, and dynamically described state transitions (e.g. connectionism). There are several agreed constraints for a theory of representation. First, the representation relation must be consistent with the physicalistic nature of cognitive science. Second, the relation must be present and explanatory in accepted explanations within cognitive science. Nevertheless, a similar dichotomy of theories occurs in the literature on representation. To date, neither theory regarding the representation relation presupposed by the RTI has gained general acceptance.

Varieties of Causal Theories of Mental Content

One theory, nomic covariation, postulates a causal relationship between a mental state and the object

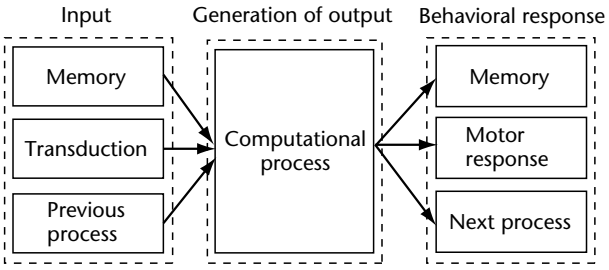

Figure 1. Elements of computational explanations of cognitive capacities in cognitive science.

or property that state represents. The other theory, functional role semantics, hypothesizes that a state has content in virtue of the state occupying a particular position in a complex web of causal relationships characterizing the cognizer's functioning. Candidate content-fixing causal relationships may include causal relationships within the cognizer and/or without. Both functional role and covariation theories satisfy the first, physicalistic constraint, since they suppose a cognizer's states represent the distal environment solely as a result of the specific types of causal connection those states have. The theories diverge in terms of the specific causal relationships each emphasizes.

Nomic Covariation

Nomic covariation theories define content in terms of a causal connection between a given object or property in the world, and the state with which the cognizer represents that object. Contemporary covariance theorists draw their inspiration from information theory as well as work within psychophysics.

> there are circumstances such that red instantiations control 'red' tokenings whenever those circumstances obtain; and it's plausible that 'red' expresses the property red in virtue of the fact that red instantiations cause 'red' tokenings in those circumstances; and the circumstances are nonsemantically, nonteleologically, and nonintentionally specifiable.
>
> In fact, they're psychophysically specifiable.
>
> (Fodor, 1988, p. 112)

Covariation theories seem to satisfy the second constraint upon theories of representation, i.e. that the relation must be present and explanatory in accepted explanations within cognitive science. For example, Hubel and Wiesel (1977) investigated the representational content of cells in the striate (visual) cortex by monitoring the activity of those cells looking for lawlike relationships between the activity of these cells and the presence of properties in the visual field. Covariationists hypothesize that a system's states represent those objects/properties of the distal world with which they covary. More precisely, covariation assigns contents to states via the following definition (Cummins, 1989; Fodor, 1988):

> State, S_b, represents B iff the system tokens S_b when, only when, and because of B.

Advantages of Nomic Covariation

Covariation gains intuitive plausibility in that a cognizer represents an object/property by being causally 'in tune' with that object/property. Covariationists like Jerry Fodor claim their theories assign content to individual states, S_b, independent of the cognizer's potential operations upon those states (inferences it can make) and/or the content of other states with which S_b might interact. Fodor refers to this assignment of content as 'punctate content' or 'atomic content'. Fodor claims that punctate content allows for content identity across individuals having quite different theories regarding the object/property. Similarly, punctate content provides the only theory whereby people can refer to objects even when they have great numbers of false beliefs about them. Fodor and Lepore (1992) note that Aristotle thought and talked about stars even though he falsely believed them to be rotating relatively close around the Earth on glassy spheres.

The systematicity and compositionality arguments suppose that covariation theories are in a better position to explain perceived truths about the combinatorial properties of language and concepts. Compositionality is the theory that the meaning of a complex expression in a language results from the meanings of its constitutive elements. Compositionality plays a central role in many linguistic theories since its supposition for both language and thought provides a fairly straightforward explanation of the human ability to grasp an enormous number of different thoughts of varying complexity and their corresponding linguistic expressions.

Covariation boasts a final perceived advantage in that it provides a clear-cut mechanism through which a system can come to know about an object/property in the world in virtue of its representational capacities. Cognizers represent an object/property insofar as they can reliably detect its presence in the environment.

Problems for Nomic Covariation

Cognitive scientists, particularly philosophers, recognize that covariation theories face a number of standard objections. First, lawful covariation between a state and an object/property cannot straightforwardly explain representation of nonexistent objects/properties. Another objection challenges the ability of covariation to explain the representational capacities of states with regard to objects/properties beyond low-level perceptual properties (e.g. edges), especially very abstract, high-level objects and properties like God or photon. Advocates of covariation suppose that covariation determines content for states representing objects/properties ranging from low-level properties (e.g. edge or blob), to ordinary objects and properties (e.g. dog or chair). Properties/objects associated with thoughts of a higher level of abstraction, like photon, get represented by states in virtue of their being defined in terms of the representational properties of lower level states (Fodor, 1988)

Robert Cummins (1989) complains that covariation of states with objects/properties requires either implicitly or explicitly represented heuristic information in the system. Thus, covariation will explain the representational properties of primitive representational states only. Higher level concepts, e.g. from table to totalitarian, acquire meaning through definition. At first glance, it seems plausible to suppose that states that represent high-level theoretical properties like photon acquire their meaning through definition in terms of lower level properties. After all, such properties and objects often have theoretical definitions. However, the failure of such semantic reductions has shaped the history of Western philosophy and mathematics (Quine, 1953). Worse still, the more ordinary the concept, the less readily one accepts that one knows its meaning because one has an explicit definition. Covariation's critics ask, 'if the state one uses to represent panda acquires meaning from being defined in terms of lower level properties, why does one have difficulty in articulating that definition in any but the most superficial sense?' Psychological research seems to weigh against such semantic reductionism as well. It indicates that object recognition and categorization are strongly influenced by perceptual features, the exact make-up of which is relatively variable.

For Cummins, mental states covary with cats because one already has knowledge about cats (e.g. they are domesticated felines) that one explicitly represents. Further, if covariation is not the simple, unmediated causal relationship between property/object and state, but the result of often complex causal interactions within the system, covariation looks like another instance of its competitor, functional role semantics.

The third, and most widely discussed, problem for covariation is called the 'disjunction problem'. According to covariationists, a state represents an object or property if the system tokens (enters into) that state when confronted with the object or property and only if confronted with that property. Suppose that a cognizer has a state, S_c, that appears to represent cathood. In fact, the cognizer tokens this state in all of its cat interactions. However, one night the cognizer sees a possum in the half light and tokens S_c. The only if clause of the covariationist definition *prima facie* dictates that S_c never really represented cat. Rather, the cognizer has always represented a property one might describe using the disjunction, 'cat or possum'.

The disjunction problem poses difficulties for covariation theories in two ways: first, the theory seems to dictate counterintuitive representational contents for states. If one has beliefs about cats (e.g. cats are domesticated felines having a number of distinct breeds) then covariation would seem to dictate that you in fact have a belief that things having the property of being either a cat *or* a weasel have those qualities. Second, and most widely discussed, the disjunction problem seems to show that covariation cannot account for misrepresentation, since any seeming case of misrepresentation by a cognizer becomes a correct representation of a disjunctive property under nomic covariation. One never mistakenly believes that one sees one's mother at the corner, one always correctly believes that mother/other is at the corner.

Covariationists suggest a number of solutions to the disjunction problem. All of these solutions rely upon some form of idealization. A given solution will separate cases of the tokening (occurrence) of a state into two groups, one in which content is already fixed and representational error can occur, and the second (ideal circumstance) in which content is fixed by perfect covariation. There are several important versions of this solution:

Ideal conditions

Advocates of the ideal conditions solution to the disjunction problem suggest one represents 'mother' and not 'mother/other' despite occasionally mistaking others for mothers, because under ideal perceptual conditions (i.e. in good light, at close distance, etc.) one can always distinguish mothers from others. Difficulties arise for

the ideal conditions solution when one tries to delimit ideal conditions in a precise, nonquestion-begging manner. For instance, in the movie *The Crying Game* an Irishman becomes romantically involved with a woman. However, much to the surprise of the Irishman (and audience) this woman is actually a man. The reaction of the Irishman clearly shows he misrepresented the gender of his romantic partner. Moreover, he saw him in good light, at close distance, etc. The natural suggestion would be that there are conditions under which such a difference would not escape notice. However, in specifying such conditions as ideal conditions for this case, one must be guided in a circular manner by one's knowledge of the property that the state actually represents.

Critics (Wallis 1994a, 1994b) also argue that appealing to idealization to defeat the disjunction problem is strongly and negatively disanalogous with successful scientific uses of idealization.

Learning Periods

Fred Dretske (1981) suggests that a learning period fixes content. In this period, cognizers develop perfect causal connections between states and objects/properties with the help of an instructor who provides examples and corrections. Once the learning period ends, the cognizer's state has a fixed content, and tokenings of the state in cases where the object/property is absent count as misrepresentations.

Fodor (1988) and others criticize this approach on two grounds. First, there seems to be no principled distinction between learning and nonlearning periods. Hence, there seems to be no grounds for calling some tokenings of the state content imbuing and others representing or misrepresenting. Second, even if one could specify a learning period, there seems to be no principled distinction between the univocal and disjunctive causal connections. Critics ask why one ought suppose that causal connections created in the learning period hold between, for example, cats and S_c and not between cat/possum and S_c.

Teleological Accounts

Millikan (1983, 1986) and other advocates of teleological solutions to the disjunction problem suggest that evolutionary history determines content. For example, frogs capture and eat ambient moving dots in their visual field. Consequently, hungry frogs will eat ball bearings rolled in before them. Teleolosemanticists claim frogs misrepresent ball bearings as flies because the frog's visual state has an indicative function in virtue of the state's past co-occurrence with flies. This use of those cells then increases the probability that the frog will propagate its genome.

Fodor (1988) objects that evolutionary selection lacks sufficient precision to account for typical univocal content claims. If frogs represent ambient dots as 'fly or ball bearing' in a fly-rich, ball bearing-poor environment, then that disjunctive content accounts for the frog's ability to propagate its genome. Hence, evolutionary history will not favor fly over fly or ball bearing as the content of frog visual cells.

Furthermore, most artifacts (computers, etc.) were not present during the greater part of human evolution. Teleolosemanticist solutions to the disjunction problem must, therefore, explain a huge percentage of the representational capacities of humans, including the representations of many ordinary objects (e.g. chairs or beer), by definition. Similarly (Cummins, 1989; Davidson, 1987), since teleolosemantics appeals to the evolutionary history of cognizers to explain representational abilities, any seeming representational abilities lacking such a history lack representational content. For example, if a molecule-for-molecule duplicate of, say, Millikan spontaneously appeared, it would seem to have her cognitive/representational abilities. Yet, on Millikan's account, her exact double lacks any representation states. Finally, Cummins argues that one cannot appeal to the adaptational significance of a state to explain its representational content, since in order for the state to have adaptational significance it must play a part in the cognitive capacities of the system, and hence already have representational content.

Asymmetric Dependence

Fodor's (1990) asymmetric dependence theory holds that in addition to a nomic connection between a state, S_c, and an object/property, cathood, representation requires counterfactual connections: if, say, possums cause S_cs, then (1) breaking the possum to S_c connection does not break the cat to S_c connection and (2) breaking the cat to S_c connection does break the possum to S_c connection. As above, a (counterfactual) set of conditions in which subjects can distinguish cats from possums excludes potentially troublesome cases. Critics (Cummins, 1989; Wallis, 1995) argue that asymmetric dependence theories fare no better than other versions of covariation. Since the brain recognizes higher level concepts through the detection of

features, it appears that there is no asymmetric dependence between cases, or worse, it goes the wrong way: from fake to representation. For instance, if I find my car by looking for features x, y, z, I can break the car to S_{car} connection by altering the appearance of my car. But that will not break the look-alike to S_{car} connection (violating 2). If, on the other hand, I break the look-alike to S_{car} connection, then it seems I do break the car to S_{car} connection (violating 1). Similar stories can be told in terms of the normal, albeit somewhat noisy, functioning of cells in the visual system.

Functional Role Semantics

Whereas covariationists focus upon a single causal connection, advocates of functional role semantics (Block, 1986, 1987; Field, 1977, 1978; Harman, 1987) suggest that the overall network of causal relations into which a state can enter fixes its content. Often causal roles are specified functionally/computationally. Versions of functional role semantics include conceptual role semantics, procedural semantics, and inferential role semantics. There are two versions of functional role semantics designated either as (1) 'wide' or 'long-armed' or (2) as 'narrow' or 'short-armed'. Narrow functional role theorists limit content determining causal relations to those occurring between mental states. Wide theorists allow connections to the distal environment and even social contexts as well.

Functional role theories have several attractive features. First, they do not need bifurcated accounts of representational content since all states get their content in the same manner, via their functional role. Hence, functional role theorists avoid explaining the representation of high-level properties via definition in terms of low-level properties. Second, functional role theorists accommodate the observation that changes in beliefs can result in changes in representational content, since changing beliefs will often change the functional roles of states. Finally, functional role theorists can capture the intuition that in trying to understand the representational content of another cognizer's state, one is constrained by the heuristic that the overall set of content ascriptions must 'make sense', i.e. be consistent with the supposition that, overall, the cognizer's interactions with the world are intelligent or rational.

Semantic Holism

Theorists typically raise three distinct but related objections to all versions of functional role semantics. First, identifying particular states in disparate individuals as states having the same representational content *prima facie* requires that the states have identical functional roles. 'Holism', about content (also 'semantic holism') appears to imply, for example, that seemingly both Bill and Bob believe that 'Wallis's article is enlightening'. Each points to the same article, proclaims it enlightening, assigns it to his class, etc. However, the causal roles of their respective states differ in a single respect: Bill believes 'Wallis is a pompous know-it-all', while Bob believes 'Wallis is a precocious windbag'. *Prima facie*, functional role semantics dictates that Bill's belief that 'Wallis's article is enlightening', differs in content from Bob's. Similarly, people with disparate cognitive or perceptual abilities seem to have disparate representational contents. Thus, the theory appears to imply that the concept of traffic light differs in color blind humans and non color blind humans.

Functional role semanticists adopt one of two responses to the above objection. One response prunes the number and/or kind of causal/computational connections necessary for belief/content identity. It thereby allows for belief/content identity across individuals with somewhat different causal/computational roles. Differences in beliefs peripheral to 'Wallis's article is enlightening' would not necessarily constitute the basis for content nonidentity.

While the just-rehearsed response has intuitive appeal, critics (Fodor, 1988) emphasize potential difficulties in distinguishing core (central) beliefs or other causal links from peripheral ones in a manner that is not hopelessly unsystematic and ad hoc. For instance, what causal connections (beliefs, desires, dispositions to take action, etc.) constitute the core of one's belief that the colorless, tasteless, odorless liquid is water? Need one know of the existence of deuterium oxide (heavy water), make appropriate inferences with regard to D_2O, discriminate between D_2O and H_2O, etc.? In the case of beliefs and inferences, one common suggestion includes only analytic beliefs and corresponding inferences in the set of core beliefs and inferences. Analytic truths are conceptual truths, those things that are true solely in virtue of the nature of the concept. Such a suggestion requires a real distinction between analytic beliefs and nonanalytic (synthetic) beliefs. Many philosophers believe that Quine (1953, 1960) has effectively undermined the robustness of such a distinction. Stich (1983) argues that judgments of belief/content identity are more intuitively imprecise than advocates of analyticity predict.

The second response to the *prima facie* difficulty of intuitively identical content across differing functional roles claims that while such beliefs are in fact noncontent identical, they are strongly content similar. The key concept is that belief identity is not a binary notion but ranges from completely nonidentical to completely identical (Cummins, 1989). The strength (or weakness) of this response lies in its ability to accommodate the intuition that Bill's and Bob's beliefs have the same content while simultaneously acknowledging the theoretical constraint that differences in functional roles dictate differences in content.

Critics argue that graded notions of content identity, in addition to being counterintuitive, undermine the formulation of psychological generalizations and subsumption of particular cases under those generalizations. Cognitive science, they claim, would be reduced to the unworkable notion that Bill's and Bob's beliefs are, say, 97 percent content similar to the belief that Wallis's article is enlightening and hence can be, say, 97 percent subsumed under generalizations regarding the belief that Wallis's article is enlightening. Furthermore, Fodor (Fodor and LePore 1992; Fodor 2001) claims that colloquial notions of belief similarity such as, 'His notion of mental representation is similar to mine', as well as their theoretical counterparts, presuppose a notion of belief identity that he claims cannot be provided by holistic theories in any cases where beliefs diverge.

Content Fixing, Error, and Univocal Contents

An objection closely related to holism argues that functional role theories have no nonarbitrary way either of fixing content, distinguishing representational error from veridical representation, and/or they result in nonunivocal content ascriptions or multiple content ascriptions applying simultaneously to a given state. For example, suppose there are two worlds: one, call it $Earth_1$ in which there is no water but in which D_2O (or some chemically different but phenomenally similar substance) is plentiful; and another, call it $Earth_2$, where H_2O is plentiful, but there is no D_2O. Bob grows up on $Earth_1$, where interacting with D_2O results in his forming beliefs, etc. about 'water'. Bill matures on $Earth_2$, developing the exact same set of beliefs, etc. about 'water' based upon interacting with H_2O. Narrow functional role theorists (using only causal connections internal to the cognizer) holds that the two men must have identical belief contents when thinking about 'water'. They either form beliefs, make inferences, etc., using states that represent what we would describe using the disjunction, 'H_2O or D_2O', or their states represent both H_2O and also D_2O (as distinct entities) simultaneously. Most philosophers consider the latter even less intuitively plausible than the former.

Long arm or two factor theories can distinguish Bill's and Bob's beliefs through causal connections to environmental objects/properties. However, suppose that Bob also has the beliefs that 'water is H_2O', that 'I live on $Earth_2$', and '$Earth_2$ has only H_2O on it's surface'. Is Bob representing 'water' as D_2O but forming a false belief about the chemical structure of D_2O? Or, is he representing 'water' as H_2O and forming false beliefs about the D_2O he finds in his environment. Critics assert that functional role semantics lacks the resources to distinguish clearly between such scenarios.

COMPOSITIONALITY AND SYSTEMATIVITY

Finally, Fodor and LePore (1992), Fodor and McLaughlin (1991), as well as Fodor and Plysyhyn (1988), object that functional role semantics seems to violate truths about the structure of language and thought such as compositionality and systemativity. Compositionality is the theory that the meaning of a complex expression in a language results from the meanings of its constitutive elements. Compositionality plays an central role in many linguistic theories, since its supposition for both language and thought provides a fairly straightforward explanation of the human ability to grasp an enormous number of different thoughts of varying complexity and their corresponding linguistic expressions. For instance, because we understand individual notions like 'cup' and 'coffee', we understand the complex expressions 'cup of coffee', etc. We account for our understanding by noting that the meaning of these complex sentences is built up from the meanings of their constitutive elements.

Critics claim that the functional role of a complex, nonidiomatic representation is not always a function of the functional roles of its parts. As a result, functional role theories cannot represent 'cup of coffee' without having the concepts and associated inferences of 'cup' or 'coffee'. This alleged aspect of functional representation schemes results in the possibility that one could represent and think about 'cup of coffee', but could not represent or think about 'iced coffee', 'hot coffee', etc.

CAUSAL THEORIES OF MENTAL CONTENT AND COGNITIVE SCIENCE

Cognitive science progresses in the absence of a resolution of the debate over theories of representation. However, the adoption of either covariance theories or functional role semantics shapes the research of individual cognitive scientists. Many important debates in cognitive science have resulted from allegiance to one or the other causal theory. For example, one aspect of the connectionist versus Turing-compatible approaches is that advocates of connectionist frameworks tend to adopt functional role semantics, while advocates of Turing-compatible frameworks tend to adopt covariation. Similarly, the debate over the nature of mental imagery was drawn along covariance versus functional role lines. It is widely supposed that the adoption of one or the other theory of mental content by the majority of cognitive scientists will have a profound impact on the field.

Mental Content, Nonconceptual

Intermediate article

Jose Luis Bermúdez, University of Stirling, Stirling, UK

CONTENTS

It has long been thought that the ways in which a creature can represent the world are determined by its conceptual capacities. Advocates of nonconceptual content have challenged this by suggesting that some mental states can represent the world even though the bearer of those mental states does not possess the concepts required to specify their content.

INTRODUCTION

Recent work in philosophy, psychology and cognitive science has suggested that there might be various types of cognitive state which possess content without necessarily requiring possession of the concepts needed to specify that content. If there are indeed states with this sort of nonconceptual content, then this suggests that the states involving concepts, which have long been thought to be the only means by which cognition can take place, are not really so distinctive. The familiar propositional attitudes and the cognitive processes defined over them might be part of a larger set of cognitive processes which have representational content by virtue of features that do not require the possession of concepts.

WHAT IS NONCONCEPTUAL CONTENT?

The content of a representational state is, to a first approximation, the state of affairs in the world that has to be the case for that state to be correct or true. The notion of content needs to be approached via the notion of truth, whether the representational states in question are sentences or mental states like beliefs. If, therefore, one wants to specify the content of a sentence or a belief one must specify its truth-condition. But not every way of specifying a state of affairs will provide an appropriate specification of the content of the sentence or belief that is true just if that state of affairs holds. It would be incorrect, for example, to characterize the content of my current belief that my pen is resting on a white piece of paper by describing its truth-condition using the concepts of particle physics. This gives rise to an obvious question: how does one specify a truth-condition in a way that reflects the way in which that truth-condition is apprehended by the utterer of the sentence or the thinker of the belief?

Different theories of content offer different answers to this question, but it is natural to think that no theory of content will be able to answer it unless it satisfies the following constraint:

> ***The conceptual constraint***. Specifications of the content of a sentence or propositional attitude state must not employ concepts that are not possessed by the utterer or thinker. (1)

So, if one specifies the content of a belief in the standard way by employing a sentence following a 'that' clause, the conceptual constraint requires that the specifying sentence should only involve concepts that are possessed by the believer. Of course, the fact that a content specification satisfies the conceptual constraint will not guarantee that it reflects the way in which the thinker apprehended the truth-condition. But it has struck many as plausible that it is not possible to capture what a thinker believes unless one restricts oneself to concepts that the thinker possesses.

Certain theories of content and concepts directly entail the conceptual constraint. It is a trivial consequence, for example, of the broadly Fregean view according to which the objects of belief and the meanings of sentences are propositions that are literally composed of concepts. But the conceptual constraint does not depend on any particular theory of content. Its plausibility stems, rather, from the conjunction of two thoughts. The first is that in specifying what a thinker believes or what a speaker is saying by uttering a certain sentence in a

particular context one has to be as faithful as possible to the way in which that thinker or speaker apprehends the world in having beliefs about it or speaking about it. The second is that the way in which a speaker or thinker apprehends the world in speaking about it or having beliefs about it is a function of the concepts he or she possesses. (*See* **Concepts, Philosophical Issues about**)

The basic idea in the theory of nonconceptual content is that there are certain types of representational state for which the conceptual constraint is not applicable. The proposal is that it can be theoretically legitimate to refer to mental states that represent the world but that do not require the thinker of those mental states to possess the concepts required to specify the way in which they represent the world. Alternatively put, a particular content is nonconceptual if (and only if) it can be attributed to a creature without thereby attributing to that creature mastery of the concepts required to specify that content.

The conceptual constraint can be lifted in two different ways. It can be lifted globally, by simply denying that any content specifications need confine themselves to the concepts possessed by the utterer or thinker. The currently popular identification of propositions with functions from possible worlds to truth values involves a global lifting of the conceptual constraint. Possible world semantics is intended to apply to all propositional attitudes, and it is obvious that few believers who are not also professional philosophers will grasp the theoretical concepts of possible worlds semantics. This article will not consider any such global strategies. The conceptual constraint seems extremely plausible for the contents of propositional attitudes.

Alternatively, the conceptual constraint can be retained for the core cognitive domain of the propositional attitudes but lifted locally by identifying particular representational domains for which the conceptual constraint seems inappropriate. There are three different representational domains for which a local lifting of the conceptual constraint has been proposed: perceptual states; representational states at the sub-personal or sub-doxastic level; and the representational states of non-human animals and human infants who do not seem to be concept possessors. Each of these three domains is a potential field of application of the notion of nonconceptual content.

ARGUMENTS FOR NONCONCEPTUAL CONTENT

The notion of nonconceptual content has been motivated within the context of three different explanatory tasks: the task of explaining the content of perceptual experience; the task of explaining the content of sub-personal representational states; and the task of explaining the behavior of certain non-human animals and of pre-conceptual human infants.

Perceptual Experience and Nonconceptual Content

Although some philosophers have suggested that perceptual states should be analyzed as propositional attitudes, usually by treating them as dispositions to form beliefs (Armstrong, 1968), there seem to be several respects in which the content of perception is drastically different from propositional attitude content obeying the conceptual constraint. (*See* **Perception, Philosophical Issues about**)

First, the content of perception seems to be analog in nature, unlike the conceptual content of propositional attitudes which is more plausibly seen as digital. The distinction between analog and digital representations has (for our purposes) been most perspicuously put by Dretske (1981). Let us take a particular fact or state of affairs, say the fact or state of affairs that some object *s* has property *F*. A representation carries the information that *s* is *F* in digital form if and only if it carries no further information about *s* other than that it is *F* (and whatever further facts about it are entailed by the fact that it is *F*). But whenever a representation carries the information that *s* is *F* in analog form, it carries additional information about *s*. It is clear that perceptual states represent the world in analog form and propositional attitudes in digital form.

Second, the content of perception seems to be 'unit-free' (Peacocke, 1986). If I perceptually represent an object as being a certain distance from me I do not usually represent that distance in terms of a particular unit (in inches, say, as opposed to centimetres), even though what I represent is a determinate distance. I simply represent it as being that distance, where the content of my perception specifies the distance. Propositional attitudes, however, can only represent distances (and other comparable quantities) in terms of specific units.

Third, the content of perception is more fine-grained than the content of propositional attitudes. I can see many more colors than I can name, and discriminate many more shapes than I have concepts for. My belief that the grass is green has a single content; but it would be the appropriate response to an enormous variety of perceptual states.

It seems plausible to conclude from these three features of perceptual experiences that their contents, unlike the contents of the beliefs that might be based upon them, are not circumscribed by the concepts we possess.

Sub-personal Computational States and Nonconceptual Content

It is common in various areas of the cognitive science to postulate the existence of representational states at the sub-personal or sub-doxastic levels (for philosophical discussion see Stich, 1978, and Davies, 1989). A good example comes from the representational states implicated in tacit knowledge of the rules of syntax. It is a fundamental tenet of a broadly Chomskyan approach to syntax that speakers have tacit knowledge of a grammar for their language and that this tacit knowledge is deployed in understanding spoken language. Yet when linguists gives theoretical specifications of the syntactic rules contained within the grammar they frequently employ concepts that are not in the conceptual repertoire of the language user. That is, the language user is ascribed knowledge of rules formulated in terms of concepts that he or she does not possess. A similar point holds for the representational states postulated in computational theories of vision like that put forward by Marr (1980). The contents of such states are formulated in terms of concepts (such as the concept of a zero-crossing) that are not possessed by the typical perceiver (Bermúdez, 1995).

Why should it be thought that the language user does not possess the relevant concepts? How could he grasp the rule if he did not possess the concepts required to spell it out? The reason for denying that the conceptual constraint is operative here is not just that language users are not aware of the beliefs in question. Not all unconscious beliefs are nonconceptual. The point, rather, is that their representations of the linguistic rules are completely inferentially insulated from the rest of their beliefs and propositional attitudes, in a way that is fundamentally incompatible with the 'holistic' nature of conceptual contents. Something like this idea seems to have been at the root of Gareth Evans's pioneering discussion of nonconceptual content (Evans, 1982).

Psychological Explanation and Nonconceptual Content

The final set of arguments for the existence of nonconceptual content comes from the need to give adequate explanations of the behavior of nonlinguistic and prelinguistic creatures. In explaining the behavior of such creatures cognitive ethologists and developmental psychologists often appeal to representational states. Arguably they will not be able to provide adequate explanations at all unless they do this. And yet there are ways of understanding what it is to possess a concept on which it seems inappropriate to attribute mastery of the corresponding concepts to the creatures whose behavior is being explained.

One such argument stresses the relation between possessing concepts and being able to justify certain canonical judgments involving that concept (Peacocke, 1992), going on to argue that providing justifications is a paradigmatically linguistic activity: a matter of identifying and articulating the reasons for a given classification, inference or judgment (McDowell, 1994; Bermúdez, 1998). There is a variety of possible responses to this argument. It might be objected, for example, that possessing a given concept simply requires being able to make justified judgments involving that concept rather than being able to justify judgments involving that concept. Or it might be objected that the ability to justify concepts is not necessarily linguistic, since it is possible to identify the justification for a judgment without engaging in communication.

One might see the issues here as being whether intentional assent requires semantic assent – that is, is it possible to have higher-order thoughts about a given thought (such as, for example, the higher-order thought that it has a certain justification) if that thought is not linguistically formed? The dependence theorist might argue that having a higher-order thought requires holding the target thought 'in mind' in a way that is not possible unless that target thought is linguistically formed. Supporters of the language of thought hypothesis will object that the dependence theorist is equivocating between a thought being formed in a public language and its being formed in a private language of thought.

At any rate, the argument from the need to provide psychological explanations of the behavior of non-human animals and human infants to the existence of nonconceptual content does not stand or fall with the thesis that concepts are necessarily linguistic. It seems plausible that there is a distinction between two types of thinking. Most students of the type of cognition engaged in by animals and infants view it as being domain-specific and modular in important respects, best understood in terms of bodies of 'knowledge' focused on particular

aspects of the natural and social worlds. These domain-specific modules have evolved separately and for specific purposes and are not integrated with each other (Hirschfeld and Gelman, 1994). In contrast, many philosophers have suggested that the type of conceptual thought engaged in by language users is essentially domain-independent, systematic and productive. Concept possessors can generate an indefinite number of new thoughts from the concepts they possess, and their thoughts obey what has been termed the generality constraint (that is, any thought-constituent can at least in principle be combined with any other). (*See* **Modularity**)

If these characteristics of conceptual thought are taken to be essential properties (as it is plausible to do) then it seems to follow that many (if not all) nonlinguistic creatures are not capable of engaging in conceptual thought. So, if they are correctly described as representing the world at all, their representations must be nonconceptual.

PROBLEMS FOR NONCONCEPTUAL CONTENT

Some problems for the notion of nonconceptual content arise whatever field the notion is applied to. Others are specific to particular applications. Some of these specific problems are problems more for the premises on which arguments for nonconceptual content are based than for the notion of nonconceptual content itself – such as, for example, the objection that sub-personal computational states do not have contents at all, and a fortiori not nonconceptual contents. Below we will consider only problems with the notion itself.

Determining a Theory of Content

The characterization we have so far given of the notion of nonconceptual content is incomplete. All we know so far are the formal characteristics of the notion. We do not yet have a substantive account of nonconceptual content to compare with, for example, a Fregean approach to the semantics of conceptual thought. The first problem, therefore, is to provide such a substantive account.

The most developed proposal has come from Christopher Peacocke, who has proposed a radically externalist conception of nonconceptual content aimed explicitly at explaining the nonconceptual content of perceptual states. Peacocke suggests that a given perceptual content should be specified in terms of the ways of filling out the space around the perceiver that are consistent with the content's being correct. For each minimally discriminable point within the perceiver's perceptual field (where these are identified relative to an origin and axes centred in the perceiver's body) we need to start by specifying whether it is occupied by a surface and, if so, what the orientation, solidity, hue, brightness and saturation of that surface are. This specification tells us the way in which the perceiver represents the environment. The content of that representation is given by all the ways of filling out the space around the perceiver in which the minimally discriminable points have the appropriate values. The representation is correct just if the space around the perceiver is occupied in one of those ways.

This proposal provides an attractive way of capturing the distinctive features of the phenomenology of perception highlighted above. Scenario content will be analog and unit-free, and will possess the appropriate fineness of grain. It is not clear, however, how it can be applied beyond the domain of perception. It may well be that certain sub-personal states have scenario contents: those associated with the sub-personal underpinnings of vision are obvious candidates. But the representational states implicated in tacit knowledge of syntactic theory do not fit the scenario model.

The natural conclusion to draw is that different specific accounts of nonconceptual content may be appropriate for different theoretical ends. There is no reason to think that there is a single account of nonconceptual content adequate for all applications.

Distinguishing Nonconceptual Content From Conceptual Content

The notion of nonconceptual notion is, of course, a contrastive notion. It depends for its meaning and interest on the correlative notion of conceptual content, and hence on how concepts are understood. The thinner and less demanding the notion of a concept becomes, the less scope there is for the notion of nonconceptual content to have useful meaning. If, for example, possessing the concept of an *F* simply requires being able to discriminate *F*s from the rest of the perceptual environment, or to act on them in a suitable manner, then it is hard to see how any evidence that animals and young infants represent the world will not also be evidence that they represent the world conceptually.

We have already seen some of the resources available to the theorist of nonconceptual content at this point. Such a theorist might, for example,

stress large-scale properties of types of thinking, distinguishing domain-specific thought at the nonconceptual level from domain-independent thought at the conceptual level. Alternatively, they might try to establish some kind of constitutive link between concept possession and language mastery, perhaps via the claim that intentional assent requires semantic assent. (*See* **Concepts, Philosophical Issues about**)

The Autonomy of Nonconceptual Content

One question that arises is whether a thinker can be in states with (nonconceptual) content despite not possessing any concepts at all. That is, can nonconceptual content be completely independent of conceptual content? Many theorists who wish to employ the notion of nonconceptual content to explain the behavior of nonlinguistic and prelinguistic creatures are committed to giving an affirmative answer to this question (depending, of course, on how demanding their notion of a concept is). So too are those theorists who hold both that sub-personal computational states possess nonconceptual concepts and that the relevant modules can exist in creatures who are not capable of conceptual thought.

Peacocke (1992) has offered an argument against this 'autonomy' thesis. His argument is based on a neo-Kantian understanding of the relation between experience of an objective world and self-consciousness. In essence, he suggests that no creature can be in content-bearing states unless it grasps that the surrounding environment has a minimal degree of objectivity and is able successfully to identify and recognize particular locations within it. This minimal grasp of objectivity requires being able to represent both the spatial configuration of the environment and one's own position within that environment – and, he suggests, this would be impossible for a creature that lacked a concept of the first person.

This argument is powerful, but can be challenged (Bermúdez, 1994). Supporters of the autonomy thesis have suggested that the interrelated capacities to represent the spatial configuration of the environment and to represent one's own location within the environment can be understood at the nonconceptual level, perhaps appealing to the notion of a nonconceptual point of view to explain the interdependence of spatial awareness of the surrounding environment and awareness of one's own location within that environment at the nonconceptual level (Bermúdez, 1998).

NONCONCEPTUAL CONTENT AND COGNITIVE SCIENCE

As we have already seen, one important motivation for the theory of conceptual content is to explain the various types of tacit knowledge that are often postulated at the sub-doxastic and sub-personal levels. The conception of tacit knowledge invoked here is at the heart of cognitive science and enters into such canonical theories as Marr's theory of vision and Chomsky's theory of innate syntactic knowledge. The notion of nonconceptual content therefore has a very clear application within the classical, rule-based conception of cognitive science.

But the notion of nonconceptual content is not applicable only within a classical rule-based approach to cognitive science. Nonconceptual content is a theoretical tool that can also be deployed by supporters of a more distributed and dynamical approach to cognition. As Adrian Cussins (1990) has pointed out, it is natural to interpret the sub-symbolic representational elements of a connectionist architecture in nonconceptual terms.

Moving from the sub-personal level to the personal level, the notion of nonconceptual content is potentially important in interpreting some of the recent experimental research on infant cognition. It is becoming clear that the perceptual experience of even the youngest infants is organized and structured in a way that reflects perceptual sensitivity to certain fundamental physical and dynamical properties of objects, as well as to basic principles of causality and number (Gopnik and Metzoff, 1997). It is arguably misleading to suggest, as many do, that this aspect of infant cognition reflects infant mastery of the concept of an object. Information is being processed nonconceptually and in a domain-specific manner. (*See* **Infant Cognition**)

The obvious practical and adaptive advantage of representing the environment nonconceptually is in the control and initiation of motor behavior. Navigating successfully through the environment often does not require identifying and conceptualizing the objects it contains. It is more important to have perceptual sensitivity to information about a limited range of object properties – position, motion, color, relative size, texture, distance, etc. – and to information, both exteroceptive and proprioceptive, specifying the perceiver's own location and movement. Such perceptual sensitivity can feed into motor behavior without any ability to conceptualize the information picked up. Thus an infant can reach out towards an object that it perceives as being within reach even though it has no concept of distance or reaching. In this sense the

theory of nonconceptual content is a natural ally of approaches to perception (Milner and Goodale, 1995; Jeannerod, 1997) that distinguish two distinct pathways in visual perception. It is a plausible hypothesis that we should understand the outputs of the pragmatic visual stream (the dorsal stream) in terms of nonconceptual content and those of the semantic visual stream (the ventral stream) in terms of conceptual content.

Finally, the theory of nonconceptual content provides a useful theoretical framework for presenting and evaluating research in cognitive ethology. Cognitive ethologists, unlike the older generation of comparative psychologists, tend not to try to explain how an animal behaves in terms of non-representational stimulus–response mechanisms or fixed behavior patterns such as innate releasing mechanisms. They start from the assumption that animals have certain desires and certain beliefs about how the world is organized and act on the basis of those beliefs to try to ensure the satisfaction of their desires. Then they look at the natural behaviors of a species, interpreting them as sophisticated strategies for pursuing the desires that members of that species seem to have. The theory of nonconceptual content provides a way of doing justice to the cognitivist methodology of ethological research while at the same time accommodating the differences between animal thinking and the thinking of language-using and concept-possessing humans.

Mental Content, Teleological Theories of

Intermediate article

Ruth Garrett Millikan, University of Connecticut, Storrs, Connecticut, USA

CONTENTS

Teleological theories of mental content explain how emptiness and falseness can occur in thought. These defects are due to failure of the representation-producing devices to do the jobs they were designed to do. Teleological theories always rest on prior theories of what the jobs of mental representations are and of what their producers are.

INTRODUCTION

To describe the 'mental content' of, say, a belief or desire or intention is to describe what actual or possible state of affairs that thought represents. For example, if you believe that the earth is flat, or if you wish it were, the content of your thought is *that the earth is flat*. According to the nineteenth-century philosopher Franz Brentano, the distinguishing characteristic of mental states that represent or are about other things, is that they can bear real relations to nonexistent things or facts, as when someone believes that the earth is flat or thinks of a golden mountain. Brentano called this peculiar characteristic 'intentionality'. Intentionality poses a paradox for naturalistic theories of mind. How can a natural state of a natural creature bear a natural relation to something nonexistent?

WHAT ARE TELEOLOGICAL THEORIES OF MENTAL CONTENT?

'Telos' means purpose. Naturalistic teleological theories of mental content refer to the biological function or purpose of intentional mental states to explain Brentano's paradoxical relation. These theories generally begin with some more basic theory of the relation between a true thought, taken as embodied in some kind of brain state, and what it represents: for example, with the theory that true mental representations covary with or are lawfully caused by what they represent, or that they are reliable indicators of what they represent, or that they 'picture' or are abstractly isomorphic, in accordance with semantic rules of a certain kind, with what they represent. The teleological part of the theory then adds that the favored relation holds between the mental representation and what it represents when the biological system harboring the mental representation is functioning properly, that is, functioning in accordance with biological design or, perhaps, design through learning; but that when the system fails to perform as designed, false or empty representations may be produced. Then 'what is represented' may indeed be nothing real: to describe 'what is represented' is to describe what would have had to be the case with the represented or the world had the system produced or harbored that same representation when functioning properly.

Teleological theories of content thus sharply separate 'intentional' signs and representations, those capable of displaying Brentano's relation, from natural signs. Even when intentional representations are true, neither the fact that they represent nor what they represent is determined by any current relation they actually bear to what they represent. The representational status and the content of the intentional representation are both determined by reference to its natural purpose or the natural purpose of the biological mechanisms that produced it, and these purposes are determined, it is usually supposed, by history, by what these mechanisms were selected for doing, either during the evolution of the species or through earlier learning by trial and error.

Thus naturalistic teleological theories are 'externalist' theories of mental content. They imply that the content of one's thought is not determined by

anything before one's mind or within one's consciousness or even within one's head. Just as actually remembering something, rather than merely seeming to remember it, does not happen wholly within one's present head but requires that one has previously encountered that thing, thoughts that are about something actual also require the right sort of history. It would be possible for a teleologist to avoid this externalism only with an account of the nature of biological functions that was neither historical nor relative to the environment.

ARGUMENTS FOR TELEOLOGICAL THEORIES OF MENTAL CONTENT

Perhaps the best argument for teleological theories is that no other naturalist theory, taken alone, explains Brentano's relation without sacrificing the determinacy of mental content. For example, causal role theories, picture theories and natural-information theories all map mental content only onto idealizations of actual minds or brains: actual minds can make bad inferences, collect misinformation and fail to correctly identify things perceived. Nor do any of these theories, taken by itself, offer a determinate way to move from an actual mind or brain to just one idealization of it, hence to just one determinate set of contents for its intentional states. But on a teleological theory, if we assume that it is determinate whether a mind or brain is functioning as it was designed to function, the relevant idealization will be determined, no matter which underlying theory of representation turns out to be the correct one.

Nor do teleological theorists need to suppose that the occurrence of false beliefs means there is something wrong with our cognitive systems. Biological systems often fail to perform their more peripheral functions because the environment is wrong rather than because of internal failure. For example, however strong and healthy a bird's wings are, if submerged in water they will not be able to perform their functions properly. Nor does the teleological theory need to imply that most of our beliefs are true or useful. Successful performance of proper functions is often statistically rare. For a mouse, failing to escape from a cat or owl constitutes a failure of its behavioral systems to perform all of the functions for which they were designed. Nevertheless, most mice may eventually be eaten by some predator. If we claim that only states of true belief are biologically proper, this claim has no bearing on the relative statistical frequencies of true and false beliefs.

HISTORY

The teleological theory of mental content arose in the late twentieth century. Dennis Stampe (1977) is usually cited as the first to articulate it. In an effort to explain the possibility of representational 'infidelity' and 'vacuity' (Santa Claus, Macbeth's hallucination of a dagger) in a way that would be consistent with a causal theory of reference, he described the content of a representation as what the representation would probably have been caused by if its producing devices were 'functioning properly'. Gareth Evans (1982, pp. 128–129) described the content of 'information-based thoughts' in a very similar way (though more was required of them), and claimed that their producing mechanisms could 'malfunction', yielding 'informational states' that 'fail to fit their objects' or that are 'of nothing'. Stampe and Evans used the term 'function' without analysis, but David Papineau (1984) and Ruth Millikan (1984) independently proposed teleological theories of mental content which explicitly took 'function' to be defined by reference to natural selection or (for Millikan) learning by trial and error. Fred Dretske (1986, 1988) modified his own purely informational theory of mental content to include a teleological layer to account for 'misinformation', but describing the functions of belief-like states as derived only from a trial-and-error learning history, not from natural selection. At about the same time, Jerry Fodor briefly embraced teleological theory with an essay which he soon repudiated as 'viciously wrong', but was eventually persuaded to publish (Fodor, 1990a). Since then a considerable literature has appeared, criticizing, defending or embellishing teleological theories of content.

VARIETIES OF TELEOLOGICAL THEORIES OF MENTAL CONTENT

It is commonly said that according to teleological theories, the content of a mental state is determined by 'whatever it is the function of the mental state to represent'. This formulation is vacuous, however, unless what it is for one thing to 'represent' another is first specified. Teleological theories all need to rest on more specific underlying theories of the relation between a true representation and what it represents: of the relation that it is the purpose of the perceptual or cognitive systems to produce. We can classify teleological theories accordingly.

Stampe (1977) and Fodor (1990a) took the representing relation to be causal. Fodor claimed that

various kinds of external conditions could in principle be specified under which normal perceptual and cognitive systems would operate optimally in accordance with design, and that what a belief state in the brain represented was whatever would always cause it under these epistemically optimal conditions. Under these conditions, the occurrence of the represented would be sufficient for the occurrence of the representation.

Dretske claimed that the function of a perceptual representation is to 'indicate' or carry 'natural information' about the represented, meaning that if the representation is present, there should be a probability of one, in accordance with natural law, that the represented is also. Occurrence of the representation would thus be sufficient for occurrence of the represented. Theories of this sort might be called 'informational theories', in contrast to 'causal theories' like Stampe's and Fodor's, but the two types have not generally been clearly distinguished in the literature.

Dretske explicitly claims that representations have the 'function' of carrying information because of their situation in some larger system that makes use of the information to guide behavior. Papineau and Millikan claim that it is only the uses to which mental representations are put that are relevant to their content. Millikan claims that a true representation maps onto its represented in accordance with semantic rules determined by the way the systems using the representation are designed to react to it in guiding, perhaps first inference processes, but ultimately behavior. Representations are designed to stand in for aspects of the world outside the organism and, by varying in accordance with these aspects, to control the animal's behavior so as to take account of these aspects. Causal or informational relations between representation and represented play no role in the analysis.

Like Dretske on perceptual representations, Papineau sometimes says that the function of a belief is to be copresent with its represented. But he also says that what a belief represents, its truth condition, is the condition that would guarantee that actions based on that belief and one's other true beliefs will satisfy one's desires, the function of a desire being to produce its satisfaction condition. Again, causal or informational relations are not mentioned. For both Papineau and Millikan, a useful 'correspondence' between representation and represented does indeed occur when the biological system functions properly, but how this correspondence is brought about is not what defines the representing relation.

PROBLEMS FOR TELEOLOGICAL THEORIES OF MENTAL CONTENT

The best-known argument against teleological theories is the 'swampman' argument. Suppose first that teleological theories are right. Then suppose that by some cosmic coincidence, lightning striking a tree near a swamp beside which you are standing destroys you, but at the same time puts a different collection of molecules together out of the swamp to form another creature molecule-for-molecule exactly like you. This creature wouldn't be you, but it would talk like you and behave like you and, presumably, have exactly the experiences you would have had had you survived. But according to the teleological theory, it would have no intentional mental states at all – no beliefs, hopes or desires – because its perceptual and cognitive systems were not designed by evolution or learning. Everyone agrees that this creature wouldn't have memories, but beliefs and desires do not seem, intuitively, to require a history in the way that memories do. They seem to be wholly present-tense occurrences.

Another common objection asks how people's specific beliefs, such as Paul Revere's belief that the British were coming by sea, could each have a selectionist history. It is sometimes suggested that the human mind may not have been designed by natural selection at all, or at least not designed to work as it now works. But even if it has been so designed, surely neither natural selection nor learning by trial and error could have designed, specifically, each belief that each person has. However, the teleologist's position as spelled out by Millikan (1984, 2001) is that the human intellect works in accordance with very general principles of concept formation and belief fixation, applied repeatedly to diverse subject matters: somewhat like a calculator, capable of solving an infinite variety of mathematical problems, but always operating strictly in accordance with the same design. Still, is it plausible that, say, the contemporary theoretical physicist employs no basic principles in thinking except those in use during the evolutionary history of the species?

Other challenges concern whether a history of natural selection yields sufficiently determinate content for representations. Fodor (1990b) has complained that the supposed 'fly detector' that goes off in a frog's optic nerve when it sees a fly also goes off if any other small dark thing crosses its retina, nor has natural selection selected against, say, 'beebees' making it go off. Why then isn't the

detector a 'fly or beebee or …' detector? But it may be countered that what determines the function of a biological mechanism is what caused it to be reproduced more often than competing mechanisms. The fly detector was selected because it caught fies, not because it caught anything small and dark. Neander claims that because biological devices have many functions (the optic nerve fires, causing the tongue to stick out, causing ingestion of the fly, causing … more frogs eggs, and so on) it is not determinate what the function of the 'fly detector' is, hence what it means. But it is only when the fly detector detects a fly that any of these functions gets performed: there is no need to choose among them. Both Neander (1995) and Dretske claim that when the fly detector responds to an irrelevant dark shadow it is not malfunctioning, for there is nothing wrong with it. So detecting, specifically, flies cannot be its function. But this is like saying that opening cans is not the function of my can opener, because if it fails to open cans when I do not use it properly that is not its fault. A suitable environment is often necessary for a device to perform its functions.

TELEOLOGICAL THEORIES OF MENTAL CONTENT AND COGNITIVE SCIENCE

The relevance of the teleological theory to cognitive science is indirect. Cognitive scientists interested in mental representation do, of course, need to understand the relation between a representation and what it represents. But they have mostly been trying to understand and to model systems that are operating properly. Having attempted to model a correctly operating neurological system, they may damage the model in certain ways to see if this simulates certain kinds of damage to real neurological systems, but the point of this exercise is primarily to test the original model. Cognitive scientists are not generally concerned to model systems in environments that these systems are unable to handle. So, for the most part, they have no reason to take an interest in the nature of false representation. Their theories are theories of true representation. Suppose, however, that false beliefs and empty ideas do often derive, not just from faulty processing or from the brain's own inner errors, but from the environment being too uneven and difficult. Suppose that adequate concept formation and true belief fixation are easy or possible only when the environment fits certain common frameworks on which our mental tools are fit to operate. Cognitive systems may turn out to be as deeply embedded in, hence dependent on, their specific environments as are other biological systems. In this case, a strongly ecological cognitive psychology may ultimately be required.

Mental Imagery, Philosophical Issues about

Intermediate article

Nigel JT Thomas, California State University, Los Angeles, California, USA

CONTENTS

Mental imagery, often informally described as 'seeing in the mind's eye', 'visualization', etc., is quasi-perceptual experience: *it significantly resembles perceptual experience, but occurs in the absence of the appropriate perceptual stimuli.*

INTRODUCTION

Imagery is associated not only with fantasy and the imaginary, but also, and perhaps more importantly, with prototypically cognitive functions such as memory, perception, and thought. Although imagery occurs in all sensory modes, most work in philosophy, psychology, and cognitive science has (perhaps regrettably) concentrated upon *visual* imagery. (*See* **Imagery**; **Memory, Philosophical Issues about**; **Memory**; **Perception: Overview**; **Perception, Philosophical Issues about**)

IMAGERY BEFORE COGNITIVE SCIENCE

The Philosophical Tradition

The classical Greek philosophers set the stage for subsequent discussions of imagery. Plato speaks (metaphorically) of an inner artist painting pictures in the soul (*Philebus* 39c), and suggests that memory might be analogous to a block of wax into which our perceptions and thoughts stamp impressions (*Theaetetus* 191c,d). Aristotle endorses this wax impression model of memory, and describes this impression as a sort of picture (*De Memoria* 450a, b). He introduced the notion of a mental faculty of imagination, allied to perception, and responsible for producing and recalling imagery (*De Anima* III. iii). Aristotle was the first systematic cognitive theorist, and he gave imagery a central role in cognition. He asserts that 'The soul never thinks without a mental image' (*De Anima* 431a 15–20), and maintains that the representational power of language is derived from imagery, spoken words being the symbols of the inner images (*De Interpretatione* 16a; *De Anima* 420b). In effect, for Aristotle, images play something very like the role played by the more generic notion of 'mental representation' in modern cognitive science. This was almost universally accepted in the philosophical tradition, even by non-Aristoteleans, up until the twentieth century. With certain qualifications and exceptions (most significantly the 'clear and distinct ideas' of Descartes' epistemology), the 'ideas' that played such a large role in philosophy and cognitive theory from the seventeenth through the nineteenth century are direct descendants of Aristotle's images. Hume, for example, explicitly identifies ideas as images (as does even Descartes in psychophysiological contexts). (*See* **Representation, Philosophical Issues about**; **Descartes, René**; **Hume, David**)

Early Experimental Psychology and 'Imageless Thought'

Imagery played a large role in early experimental psychology (which, especially in Germany where it first flourished, was practiced as a branch of philosophy). Wilhelm Wundt, 'the father of experimental psychology', founded the first psychological research and teaching laboratory in 1876, and imagery played essentially the same pivotal cognitive role in his theories (and those of most of his many students and imitators) that it had played for the philosophers of former ages.

However, from about 1901 Oswald Külpe and his students at the University of Würzburg directly challenged these assumptions. Experimental subjects in Würzburg were asked to provide introspective reports of the contents of their consciousness as they performed specified cognitive tasks. The introspectors (often Külpe himself, or other members of his research team) frequently claimed to experience

not imagery, but rather 'imageless thoughts', conscious contents without any sensory or perceptual quality. In response, Wundt sharply criticized the introspective methodology of the Würzburg experiments, whilst Titchener, Wundt's leading disciple in America, reported that in *his* laboratory, similar introspective experiments *always* evoked imagery (not necessarily visual), producing no evidence whatsoever for conscious imageless thoughts. ('Thinking in words' is plausibly regarded as a form of auditory or vocal-kinaesthetic imagery (Paivio, 1971).) (*See* **Introspection**)

The bitter and irresolvable controversy that arose led to a reaction by which introspective methods became thoroughly discredited amongst the majority of experimental psychologists, and the notion of mental imagery fell out of intellectual favour. J. B. Watson, who inaugurated the very influential Behaviorist movement in psychology, questioned the scientific reality of consciousness in general, and imagery in particular. Between about 1920 and 1960, imagery received minimal scientific attention. The question of the reality of conscious imageless thoughts was left unresolved, and it remains so today (Thomas, 1989; Heil, 1998; Mangan, 2001).

Twentieth-century Philosophy

Amongst philosophers, few questioned the actual occurrence of quasi-perceptual experiences, and imagery continued occasionally to be discussed. However, few twentieth-century philosophers accorded it anything like the theoretically central position it once enjoyed. The analytical philosophy movement (that arose in the early twentieth century, and that still deeply influences most English-speaking philosophers) originated from the hope that philosophical problems could be definitively solved through the analysis of language, using the newly invented tools of formal logic. It thus treated *language* as the fundamental medium of thought, and several of the leading figures of the movement (notably Frege, Wittgenstein, and Schlick) argued strongly against the traditional view that linguistic meaning derives from images in the mind. (For a brief, though critical, summary of the main arguments see Thomas (1997a) and discussion below.) These arguments were widely accepted, and imagery was relegated to the sidelines of philosophy. It no longer seemed to have a vital functional role to play in the workings of the mind. (*See* **Frege, Gottlob**; **Wittgenstein, Ludwig**)

In his seminal *The Concept of Mind* (1949), analytical philosopher Gilbert Ryle set out to refute what he called 'Descartes' Myth': the notion that the mind is somehow a special arena distinct from the physical world, populated by mental (nonphysical) objects. Ryle thus vigorously attacked the notion of a mental image as a 'picture in the mind', and suggested instead that what people call 'imagining', 'picturing in the mind's eye', and so forth, would be better understood as akin to *pretending* (to oneself) to see something. Ryle also questioned whether we really have a coherent, unitary concept of imagination, and it remains controversial whether imagery is really relevant to other notions traditionally associated with imagination, such as creativity (White, 1990; Brann, 1991; Thomas, 1997b, 1999).

Working in the rival phenomenological philosophical tradition, Jean-Paul Sartre (1948) also questioned the cognitive role of imagery and the notion of mental pictures. He argued that an image 'teaches nothing', because any information it contains must have been put there by, and thus have already been in the mind of, the imaginer. Sartre stressed the *intentionality* of imagery, the fact that an image is always an image *of* something (perhaps something nonexistent), but he insisted that an image is not a *thing* in the mind. Although neither Sartre nor Ryle seems to have intended to deny the reality of quasi-perceptual experience, this may not always have been clear to their audience, and their work surely contributed further to the decline of interest in imagery in both analytical and phenomenological traditions. After this, and before the rise of cognitive science, the rare philosopher who wanted to insist on the importance of imagery, perhaps even its very existence, was noticeably on the defensive (Price, 1953; Hannay, 1971; Casey, 1976). (*See* **Phenomenology**; **Intentionality**)

IMAGERY IN COGNITIVE SCIENCE

The Imagery Revival

A revival of research on imagery was an important element of the cognitive revolution of the 1960s and 1970s, contributing greatly to the rising scientific interest in mental representations. Seemingly, this revival initially stemmed largely from applied psychology research on sensory deprivation and on hallucinogenic drugs (Holt, 1964). Another important catalyst was Yates' (1966) seminal historical work on the significance of imagery mnemonics in ancient through Renaissance thought. Once the powerful mnemonic properties of imagery were experimentally confirmed (Paivio, 1971), imagery could no longer be dismissed by psychologists. Interest was only heightened, during the 1970s, by

the stunning 'mental rotation' experiments of Shepard and his students (Shepard and Cooper, 1982), and experiments by Kosslyn (1980) demonstrating 'mental scanning' and related effects. This work was taken to demonstrate that imagery is involved in visuo-spatial reasoning, and has inherently spatial properties. (*See* **Memory Mnemonics**; **Mental Rotation**)

The 'Analog–propositional' Debate

But how could these findings on imagery be reconciled with the functionalist, computational symbol-manipulation approach to cognition that was emerging during the same period? The standard philosophical interpretation of this approach depicts cognition as the computational manipulation of representations expressed in 'mentalese' (the 'Language of Thought') – a hypothetical, essentially language-like, representational system supposedly built into the brain (Fodor, 1975). Two rival approaches arose toward integrating the empirical findings about imagery into computational cognitive science. (*See* **Functionalism**; **Language of Thought**)

Pylyshyn, in a series of influential papers (e.g. 1973, 1981), argued (in effect) that all the genuine phenomena associated with imagery (indeed, *all* truly mental phenomena) can and must be explained entirely in terms of mentalese representations. For Pylyshyn and his allies, the computational paradigm of cognitive science demands that the underlying representational reality of imagery (and of actual perceptual experience) is not picture-like, but rather a detailed mentalese *description* of a scene.

Other cognitive scientists, however, notably Shepard and Kosslyn, argued that the evidence implies that imagery must be a distinct, non-language-like form of representation. Kosslyn, in particular, developed a 'quasi-pictorial' computational theory of visual imagery, based on an analogy with computer graphics (Kosslyn, 1980). Computer graphics files store information in a compressed, non-pictorial form, but when they are displayed they are translated into a mathematical map (bitmap) of the computer monitor screen, that specifies the color at each pixel (tiny dot) on the screen itself. Likewise, suggests Kosslyn, visual information may be *stored* in the brain as compact descriptions, but we experience an image only when this information is used to create a two-dimensional map of visual space in a special, functionally defined memory area he calls the 'visual buffer'. The picture in Kosslyn's theory is merely 'quasi', because there is no equivalent to the monitor screen to display it. What we experience as imagery, and what is available to the cognitive processes that use imagery, is the functional picture, the mathematical map, in the visual buffer. In later work, Kosslyn (1994) identifies this 'visual buffer' with the several retinotopically mapped visual areas of the brain. (*See* **Visual Imagery, Neural Basis of**)

'Description' and 'quasi-pictorial' theorists disagreed sharply over what sorts of computational symbols, or data structures, are acceptable within cognitive theory, and which best capture the empirical properties of imagery. During the 1970s, in particular, this led to a lively and high-profile controversy, commonly, if somewhat misleadingly, known as the 'analog–propositional' debate. ('Picture–description' debate would have been better. 'Proposition' is jargon borrowed from philosophy, where it signifies the underlying *meaning* of a sentence, not, as is intended here, a descriptive 'sentence' of mentalese. Furthermore, the force of 'analog' in this context is hardly clear: Kosslyn, after all, models his quasi-pictures on digitized bitmaps.)

Although the leading combatants in this dispute were psychologists, and experimental evidence was frequently cited, many of the issues raised were conceptual or meta-theoretical in nature – Anderson (1978) questioned whether it was even possible to resolve the debate experimentally – and philosophers soon became involved. The very concept of mental representation seemed to be at stake. Many of the most influential articles from the heyday of this debate, by both psychologists and philosophers, are collected in two volumes edited by Block (1981a, b). Description theory still finds philosophical defenders (e.g. Slezak, 1995), but Tye (1991; see also Rollins, 1989) has undermined much of its appeal with a persuasive defence of the conceptual legitimacy of quasi-pictorial arrays as a distinct form of computational representation. Furthermore, many descriptionist explanations of empirical findings seem worryingly *ad hoc* (Kosslyn and Pomerantz, 1977).

However, Kosslyn's (1994) declaration of victory in 'the imagery debate' may be premature, even though he has certainly developed the venerable picture theory to an unprecedented level of empirical and conceptual sophistication. His (1994) recasting of quasi-pictorialism in neurological terms does little to resolve the significant problems it still faces. Pylyshyn (in press) has now launched a major counter-attack, not only restating his empirically- and conceptual-based objections to

quasi-pictorialism, but arguing forcefully that (despite many claims and some superficial appearances to the contrary) there is no firm evidence whatsoever to support pictorialism. Even the (much disputed) results suggesting that visual imagery experience is correlated with activity in retinotopically-mapped visual cortex (e.g. Kosslyn *et al*., 1995) are quite consistent with non-pictorial theories (Pylyshyn, in press; Thomas, 1999). Furthermore, quasi-pictorial theory does not parsimoniously account for a range of experimental results showing that people have difficulty, in many circumstances, in finding new representational meanings in their imagery, meanings that are relatively easily found in an actual picture (Slezak, 1995; Thomas, 1999). Also, it is unequipped to explain the fact that the experimental effects that it most directly addresses (mental rotation, mental scanning, mnemonic effects, etc.) have since been demonstrated to occur in congenitally blind as well as in sighted subjects. The blind experimental subjects apparently employ haptic (touch) imagery, but any haptic analogue of a quasi-picture would be quite unsuitable to play an equivalent explanatory role (Thomas, 1999). In addition to these empirical shortcomings, quasi-pictorialism fails to address two cardinal characteristics of imagery: its *intentionality* and its *consciousness* (see further below).

Beyond Pictures and Propositions?

Outside the theoretical context of symbolic computationalism, in which the 'analog–propositional debate' first arose, other accounts of imagery, neither pictorial nor descriptional, may become conceivable. Despite a handful of connectionist simulations of versions of quasi-pictorialism, the connectionist movement has had surprisingly little impact on imagery theory. However, more recent alternative approaches to cognition, such as 'dynamical systems theory', and 'situated' or 'embodied' cognition, call into question the basic assumption that mental contents are to be identified with representations in the sense of data structures, embodied as brain states, and manipulated in the cerebral computer. Related work on both robotic and human vision (and perception in general) is converging on the idea that perception is *not* best understood as the processing of sensory input into a detailed inner representation – a description or depiction, of the scene before us – but rather as ongoing, directed exploratory activity (e.g. Landy *et al*., 1996; O'Regan and Noë, 2001). On this view, as our brains direct all the most minute details of our ongoing behavior (including the exploratory perceptual activity itself) they require a constant stream of answers to specific questions about the detailed disposition of the environment, and, instead of seeking this information in a pre-established inner representation, they deploy the sense organs, like measuring instruments, in order to obtain the answers from the environment as and when needed. In order to explain how brains coordinate this activity, we may well need to invoke data structures in the brain. However, they would not encode descriptions or depictions of the environment, but, rather, the procedures that most appropriately direct its exploration. O'Regan and Noë (2001) suggest that perceptual experience is not the experience of having a representation (a percept) in the brain, but, rather, of being engaged in ongoing perceptual exploration. In similar vein, Thomas (1999) proposes that imagery experience (and the empirical data on imagery) is best explained as arising from a sort of abortive, and largely covert, *perceptual activity*: a truncated 'going-through-the-motions' of exploring objects or situations that are not actually there to be explored, under the control of an appropriate procedural representation. (*See* **Connectionism**; **Dynamical Systems Hypothesis in Cognitive Science**; **Dynamical Systems, Philosophical Issues about**; **Situated Cognition**; **Situated Robotics**; **Embodiment**)

Meanwhile, certain philosophers broadly sympathetic to this view of imagery, and with doubts about the 'standard' computational-functionalist view of the mind, have begun to revive the traditional conception of imagery as the vehicle of conscious thought, and the fundamental bearer of mental content, or intentionality (Heil, 1998, chap. 6; Ellis, 1995; Thomas, 1997a). Other recently elaborated approaches to cognition are built around closely related conceptions such as 'image-schemata' (Lakoff and Johnson, 1999) and 'perceptual symbols' (Barsalou, 1999). (*See* **Functionalism**)

KEY PHILOSOPHICAL ISSUES

Meanings of 'Imagery'

Few discussions of imagery draw a clear distinction between the claim that people have quasi-visual experiences and the claim that such experiences are caused by the presence of picture-like objects in the mind. In practice, in the literature, 'mental imagery' (or 'mental images') can mean any or all of at least three things:

(1) quasi-perceptual conscious experience *per se*;
(2) picture-like representations in the mind and/or brain that may be experienced as (1);

(3) any inner representations whatsoever that may be experienced as (1).

Picture theory is so entrenched in our language and our 'folk psychology' that it is only too easy to assume that when people say 'imagery' they mean (2). Far too many confident arguments about what imagery can or cannot do depend on an (often unacknowledged) assumption of pictorialism (Thomas, 1989, 1997a, b).

Block (1981a – Introduction) argues that some confusions could be avoided, without prejudging the 'analog–propositional' issue, if we agreed to define 'imagery' as (3). However, one can perfectly consistently maintain the reality, and perhaps even the cognitive importance, of imagery in sense (1) whilst denying the existence not only of (2) (with description theorists such as Pylyshyn or Slezak), but even of (2) *and* (3) (with Ryle, Sartre, or Thomas: see above). Defining 'imagery' as (1) (as we did initially) seems to beg the fewest questions.

Imagery, Intentionality, and Mental Representation

Nearly all philosophers accept that imagery has *intentionality*: the characteristically mental property of being *of*, *about*, or *directed at* some object (real or imaginary). In this regard, mental imagery proper may be distinguished from superficially similar but nonintentional phenomena such as afterimages and phosphenes. This philosophical concept of intentionality is only distantly related to the notion of doing an action *intentionally* (i.e. on purpose), but it is very closely related to the notion of meaningful representation. To say that an image is *of* a lion is to say that it *represents* a lion. But how is it possible for anything to have this property of intentionality, this power of being able to represent things? This is perhaps the most fundamental problem in the philosophy of cognition, and the answer we give to it will profoundly affect what sorts of cognitive theories we think are workable. (*See* **Intentionality**; **Representation, Philosophical Issues about**)

Most philosophers before the twentieth century held that mental images formed the basis of the mind's power to represent things, and probably assumed that images represent their objects because they *resemble* them: an image of a lion, like a photograph of one, *looks like* a lion. However, consider two photographs of Leo. Each photo resembles the other more than either resembles the lion (both photos are small, rectangular pieces of card, similarly marked, and neither is carnivorous or furry), yet we would normally want to say that they represent Leo, and *not* that they represent each other. Of course, a photograph of Leo does resemble him, when the right aspects of resemblance are considered, but in this regard Leo equally resembles the photograph. We are unlikely, however, to want to say that *he* represents *it*. In order for resemblance to play a role in representation the relevant aspects of resemblance have to be recognized, and the resembling object has to be *used* (or, at least, *taken*) as a representation. But surely, before a cognitive system can recognize or use the relevant aspects of resemblance between a photograph (or an inner quasi-picture) and an object (or a percept), it must already be able to represent the picture and its object, and their various features, to itself. The mind's power to recognize resemblance seemingly depends on its power to represent things, rather than vice versa.

From related arguments, Fodor (1975) concludes (with the analytical philosophy mainstream) that mental images do not possess their intentionality intrinsically. Rather, they derive it from that of another, supposedly more fundamental, form of representation. For Fodor, an image (a quasi-picture, he assumes) of a lion represents a lion not because it resembles a lion, but, in effect, because our minds attach a mentalese caption to it saying 'LION'. It is not that the resemblance is not real, or cognitively useful, but that (contrary to traditional views) mentalese, not imagery, is the fundamental form of representation and the source of intentionality. This line is apparently accepted by Tye (1991) in his philosophical exegesis and defense of quasi-pictorialism. Of course, those like Pylyshyn, who hold that imagery *consists of* mentalese, also ground the intentionality of imagery in that of mentalese.

It is worth noting, however, that, despite strenuous philosophical efforts since the 1970s, no generally acceptable theory of the source of the representational power of mentalese is forthcoming, and, indeed, none may be possible (Cummins, 1997). We might do without the rather extravagant hypothesis of mentalese if the intentionality of imagery could be derived from that of ordinary spoken language (Kaufmann, 1980). However, this would seemingly require an account of the intentionality of ordinary language that avoids reliance upon any appeal to the intentionality of the mental. The prospects for that seem poor. It would also apparently imply that animals and babies have no intentionality: that, in effect, they have no minds.

But just because the resemblance theory of representation fails, it does not necessarily follow that the intentionality of imagery is not intrinsic. After all, resemblance theory was only ever intended to

apply to pictorial theories of imagery. If imagery is conceived of as a form of directed perceptual activity (see 'Beyond Pictures and Propositions?' above), rather than as an inner representation, perhaps its intentionality might be understood as rooted in the inherent goal-directedness of action. Such an approach still awaits detailed articulation, however, and would presumably require an account of the intentionality of action that did not root *that* in the intentionality of representations. (*See* **Action, Philosophical Issues about**)

Imagery and Consciousness

According to most cognitive scientists, mental images are mental representations (pictorial or otherwise) that have their existence as brain states. How could we be conscious of such things (as we clearly can be conscious of imagery)? It seems unlikely to be in virtue of any intrinsic characteristic of the relevant brain state, for brain states are nothing but patterns of excitation of neurons, and excitation of neurons is nothing more than electrochemistry: the movements of certain molecules and ions, polarization and depolarization of membranes, and so on; quite ordinary physical processes that go on outside of brains, and even, quite frequently, within brains, without producing consciousness. (*See* **Consciousness, Philosophical Issues about**; **Neural Correlates of Visual Consciousness**)

Perhaps, then, such representations are conscious not because of any properties they have intrinsically, but, rather, we are conscious of them inasmuch as our minds access and extract information from them. This is a quite traditional idea embodied in the idiom of 'the mind's eye', and it found its clearest philosophical expression in Descartes' (1664) account of imagery, wherein the image is presented as a small physical picture formed deep within the brain (at the pineal gland), from where the immaterial conscious soul is able to apprehend it directly. Nearly all cognitive scientists (and contemporary philosophers) firmly reject such explanatory invocations of the supernatural. Nevertheless, Kosslyn, the leading contemporary quasi-pictorialist, sometimes writes of a 'functional mind's eye' inspecting and interpreting his quasi-pictures. If this is nothing supernatural, however, but just more brain activity, more electrochemistry (as Kosslyn clearly holds), then it is not at all clear that it helps us to understand how we could be *conscious* of a quasi-picture (or, come to that, a mentalese description) in our brain. (Indeed, Kosslyn does not claim that it does.)

Some philosophers do hold that consciousness of mental states arises from their being themselves represented within the brain by 'higher-order thoughts', and a 'mind's eye' account of image consciousness would presumably fit this mold. However, the higher-order thought theory has not gained widespread acceptance for a number of reasons (Lycan, 2000). It probably captures not so much the distinction between conscious and nonconscious states as that between those experiences that flit through consciousness unremarked, and those that *are* remarked, and perhaps thereby become remembered and/or reportable. Furthermore, it relies on the availability of a suitable account of the intentionality of the states in question, which may not be forthcoming. (*See* **Consciousness and Higher-order Thought**)

It might be objected that this is all just a special case of the notorious, unsolved 'hard problem' of consciousness: we just do not know how to explain conscious experience scientifically, so why should it especially concern us that we cannot explain it in the context of imagery? But although we can perhaps legitimately pass over the 'hard problem' in some areas of cognitive theory, we cannot, in good faith, ignore it here. It is of the very nature of imagery to be conscious (or, at the very least, potentially conscious), and, very arguably (Külpe notwithstanding), *all* conscious experiences are imagistic, either perceptual or quasi-perceptual. The apparent intractability of the 'hard problem' just may owe something to entrenched misconceptions about the nature of imagery. (*See* **Consciousness, Philosophical Issues about**)

Metaphysics

Intermediate article

Brie Gertler, University of Wisconsin, Madison, Wisconsin, USA

CONTENTS

Metaphysics aims to determine the basic nature of entities, states, properties, and events. A metaphysics of cognition will specify the logical relationship between mental and physical entities, and will account for the representational power of brain states.

INTRODUCTION

There are several longstanding metaphysical puzzles about the mind. How can a bit of gray matter be conscious? Are sensations and thoughts physical features of humans? What conditions must a physical state meet in order to be a state of a person? How can brain states represent facts and possibilities, as is required for genuine cognition? No account of the mind will be complete without a resolution of abstract questions such as these. Controversies over the basic nature of the mind and mental representation bear on the broader theories of mind to which research in cognitive science contributes.

WHAT IS METAPHYSICS?

The task of metaphysics is to determine the fundamental nature of reality. What is the best analysis of causation? How can we make sense of the difference between what is impossible and what is possible (but non-actual)? Do ordinary objects genuinely persist through time? If so, what are the identity conditions of objects? Of persons?

We can understand the distinctive purpose of metaphysics by contrasting it with another discipline also concerned with the ultimate nature of reality, namely, physics. Because there is no clear, uncontroversial dividing line between metaphysics and physics, the distinction must be somewhat idealized.

Metaphysical issues transcend the domain of physics in two ways. Firstly, while physics is concerned with the physical basis of reality, metaphysics is concerned with its logical basis. This contrast may be illustrated by the account each discipline gives of shape properties. Consider an ordinary cylindrical coffee cup. Physics will tell us how the cup's physical features – such as the arrangement of its component atoms – determine its shape, solidity, and so on. Metaphysics will specify the factors logically responsible for the cup's having these properties. For instance, some metaphysicians claim that to be cylindrical just is to participate in an abstract entity, 'cylindricality'; others deny that such abstract entities exist, and maintain that to be cylindrical just is to stand in a similarity relation to other concrete (cylindrical) objects; still others deny that there is anything truly cylindrical, since what is present isn't a cup but just a collection of atoms in a particular arrangement. (According to this last view, the belief in cups is merely a 'useful fiction'.) Metaphysics aims to explain what instantiating a property consists in, regardless of the particular physical laws that causally determine property instantiations. For instance, the basic metaphysical account of shape properties will not depend on particular physical laws. In this way, metaphysical claims transcend descriptive claims about the actual state of the universe.

The second way in which metaphysics transcends disputes within physics derives from the first. Since metaphysics is concerned with the logical basis of reality, its methodology is *a priori*. By contrast, the methodology of even theoretical physics is partially empirical or *a posteriori*. (Obviously, physics and other sciences also use nonempirical methods of inquiry, including mathematical reasoning.)

Some philosophers are suspicious of the metaphysical enterprise. Linguistically-minded philosophers maintain that there are no facts of the sort metaphysics seeks, independent of human conventions or conceptual schemes. These philosophers deride putative metaphysical questions as 'pseudo-questions'. Empirically-minded philosophers have questioned the legitimacy of *a priori*

methods of inquiry, and have claimed that genuine knowledge can be gained only through empirical research. Nevertheless, metaphysics continues to be a central and thriving philosophical discipline.

ISSUES IN THE METAPHYSICS OF MIND

Debates in the metaphysics of mind center on three topics: ontology, intentionality, and personhood.

Ontology concerns what sorts of things, properties, states, events, and relations exist or are instantiated, which of these are reducible to others, and which, if any, are irreducible and, hence, basic. Mental ontology thus concerns the mental's fundamental nature and its relation to other ontological categories, most saliently the physical. The famous 'mind–body problem', the problem of specifying the relation between the mental and the physical, is the main problem in mental ontology. (*See* **Mind–Body Problem**)

Theories of intentionality will explain how states have representational power. Since representational power is possessed by a wide variety of items (paintings, thermometers, the dances of bees) this problem does not exclusively concern the mental. A theory of mental intentionality will explain what relation obtains between my current belief that there are nine planets in our solar system, and that actual solar system, by virtue of which the belief is about the solar system; it will explain what relation obtains between my current desire to drink coffee, and the possible event of my drinking coffee, by virtue of which that event satisfies the desire; and so on.

The main questions about personhood are the following. What features of a state renders it the state of a person, as opposed to, say, the state of a mere machine? What features of a process render it something a person does, like making inferences, rather than something that merely occurs within a person, like digestion? Because persons and their actions are usually taken to be morally significant, answers to these questions have consequences for moral theories.

These three topics are interconnected; but for simplicity we will address them separately.

Mental Ontology

The main ontological dispute about the mind is whether mental states and properties are physical, or whether instead the mental constitutes an ontological category distinct from the physical. The first view is called 'physicalism' (or 'materialism'); the second view is called 'dualism', since it is usually further assumed that the physical and the mental are the only basic ontological types. Within each of these views, there are disputes about the precise nature of the mental, and about the relation between particular mental states or properties and particular physical states or properties.

Materialism is often construed as a negative thesis: the denial that there are souls or what one author has dubbed 'spooky mind-stuff'. This denial is not adequate to distinguish materialism from contemporary, naturalistic forms of dualism, which need not rely on a religious conception of the self and which typically deny the existence of 'spooky' things or properties, immune to scientific explanation.

Materialism is an ontological view, not a methodological one. But it is hard to formulate a good definition of physicalism, one which is neither too restrictive nor too liberal. Defining physical entities as those which are similar to entities currently posited by empirical science is too restrictive, as it illegitimately constrains future scientific discoveries. And defining physical entities as those discovered through scientific methods is too liberal as it begs the question against scientific naturalist forms of dualism. This difficulty besets dualism as well. Dualism is the view that there are mental things or properties that are not physical, so dualism can be defined only by reference to a clear notion of the physical. The dispute about materialism and dualism continues to generate lively discussion, and it certainly seems as if there is something at issue here, if only the question of whether the mental is fundamentally, and importantly, dissimilar from the physical. (*See* **Materialism**; **Dualism**)

Another basic ontological dispute about the mind concerns the reducibility of mental states or properties to non-mental states or properties. According to physicalist reductionism, mental states are identical to physical states. While dualists will deny reducibility, not all materialists believe that particular mental properties are reducible to particular physical properties. For example, consider the relation between biological properties, such as having a heart, and physiochemical properties. Is a biological feature identical to a particular collection of physiochemical features? If not, is the latter causally sufficient for the former? Are there interesting explanatory relations between biological and physiochemical features, or are these correlations basic and inexplicable? Reductionism is often advanced on grounds of parsimony. But it also has epistemic advantages, for reductionist

programs seek to understand one class of properties (e.g. thoughts) by another class which is purportedly better understood (e.g. neurobiological properties). It is hoped that a reduction of theories will follow a reduction of properties. For instance, neurobiological theory (or, perhaps, basic physics) may explain the predictive power of psychological theory. (*See* **Reduction**)

Mental Intentionality

The power to represent a variety of things – from particular items, such as a coffee cup, to abstract claims, such as 'justice is blind' – is a remarkable characteristic of the mental. Brentano (1838–1917) went so far as to consider intentionality the mark of the mental, claiming that all genuinely mental states are intentional and all genuinely intentional states are mental. Some present-day philosophers accept one or other of these claims, though few accept both. Still, the persistence of each of these claims, and the fact that their conjunction was once widely accepted, attest to the importance of a theory of mental intentionality in a larger account of the mind.

Most philosophers now believe that mental representation is continuous with other phenomena in the natural world. According to this naturalist viewpoint, the sorts of facts and laws that will explain intentionality will be the same as, or similar to, those that explain non-intentional phenomena. Current theories of intentionality are largely attempts to vindicate this claim by 'naturalizing' intentionality.

The nature of mental representation is highly controversial in several respects. The first of these has to do with the standard distinction between phenomenal and intentional features of states. A state's phenomenal features consist in 'what it's like' to instantiate that state. Pains and tickles are examples of states with phenomenal features: the painfulness or ticklish quality is the state's phenomenal 'content'. A state's intentional features are its representational properties. Beliefs, desires, and perceptual states are examples of states with intentional features. The intentional content of such a state is what it represents. For example, the intentional content of a belief that justice is blind is *that justice is blind*; the intentional content of a desire to bicycle is the activity of bicycling. (*See* **Qualia**)

Historically, some philosophers have treated intentional content as a species of phenomenal content, but this view is now out of favor. A more popular view, 'representationalism', is that phenomenal content is reducible to intentional content. Another view is that these are distinct but that all (nonderivatively) intentional states have phenomenal content, or that all phenomenal states have intentional content. Yet another view is that states with phenomenal content overlap with intentional states only partially, if at all.

The second dispute about the nature of content is more ontologically oriented. Suppose I am wondering whether my coffee cup is in the sink. Is the content of this mental state a (possible or actual) concrete state of affairs (that is, the cup's being in the sink)? Is it an abstract proposition, 'the cup is in the sink', perhaps on a par with 'justice is blind'? Is it a relation between me and a state of affairs? Between me and an abstract proposition? Or is it a hybrid of these – for example, do I represent the concrete state of affairs partially in virtue of standing in an intentional relation to an abstract proposition?

There is currently active debate over a third question concerning the nature of content, namely, whether content logically depends on one's external environment, including social and linguistic facts, or whether external factors are at most causally influential. Content externalism is the view that, holding fixed my 'internal' state, the content of my thought 'Is my coffee cup in the sink?' can vary with variations in physical facts (about the cup or sink), or with variations in social or linguistic facts (e.g. about how my linguistic community uses 'cup'). While content internalists agree that external facts causally influence my thought content, they deny that having a thought with a certain content consists in any such facts. Instead, they hold that all mental content is narrow content; that is, states internal to the subject fix the subject's mental contents. The externalism–internalism dispute is closely tied to the dispute over 'methodological solipsism' (Fodor, 1980), the view that we need make no reference to anything outside the subject's head in order to explain the subject's behavior. (*See* **Narrow Content**)

These disputes take place within a realist view of mental content. But some philosophers deny that mental states are genuinely intentional, and contend that talk of mental content is at best a useful fiction. Among antirealists, 'eliminativists' (e.g. Churchland, 1981) think that talk of beliefs and desires, and their associated contents, is a residue of a naive and mistaken folk theory, and that scientific (specifically, neuroscientific) advances will warrant abandoning intentional notions, just as scientific advances warranted abandoning the notion of phlogiston. By contrast, 'instrumentalists'

(e.g. Dennett, 1987) deny the existence of intentional states but regard intentional notions as pragmatically indispensable. (*See* **Eliminativism**; **Intentional Stance**)

Because of the plurality of views about the nature of mental content, theories of mental content differ in their explanatory aims. Generally speaking, however, the chief task of a theory of content is to explain what having a state with a certain content consists in. Providing a causal etiology of mental content is at most a secondary concern of such theories. (*See* **Intentionality**)

Personhood

Issues about personhood are closely tied to ontology and intentionality. But while ontology concerns the mental and intentionality concerns the representational, the notion of a person is an ethical notion. To be a person is to warrant ethical consideration and to be a possible bearer of moral responsibility. Since moral responsibility is generally taken to apply to free actions, theories of personhood relate to theories of action and free will. (*See* **Action, Philosophical Issues about**; **Free Will**)

What makes a mental state the state of a *person*? There are two aspects to this question. The first concerns how we distinguish persons from non-persons. Is the capacity for thought the essence of personhood? Must one also be capable of free agency? The second aspect concerns the intuitive contrast between what a person does and what processes occur within him or her. For instance, we ordinarily say that persons wonder, or engage in inference, while digestion is something that occurs within them (or their bodies). The former sorts of processes are said to occur at the personal level, while the latter are at the sub-personal level. Which sorts of processes occur at the personal level, and how can we best analyze the difference between the personal and sub-personal levels?

VIEWS ON THE METAPHYSICS OF MIND

Views on Mental Ontology

Materialism is the dominant view among philosophers and cognitive scientists; and it may appear that materialism is the only reasonable position consistent with a scientific outlook. But strong naturalistically-oriented arguments have been made in favor of dualism, and dualism is still taken seriously in the philosophy of mind.

The simplest forms of materialism are 'type identity' theories. These theories identify a type of mental state – say, the type 'coffee desire' – with a type of physical state – say, the release of a certain neurotransmitter *N*. This is a strong claim. The claim is not just that the release of *N* causes coffee desires, or that coffee desires accompany the release of *N*: these are claims of causation or correlation. Type identity theories state that the release of *N* simply *is* the coffee desire: the mental type and the physical type are one and the same.

While identity claims are not merely claims of correlation, they are committed to the necessary, complete overlap of their relata. They are therefore undermined by the possibility that one relatum could be present in the absence of the other. The 'multiple realizability' objection to type identity theories claims that mental state types such as 'coffee desire' can be realized in different physical types. Even if the release of *N* is essential to coffee desires in humans, it is conceivable that organically different beings that lack neurotransmitter *N* (e.g., silicon-based creatures) could desire coffee. (*See* **Multiple Realizability**)

In light of this objection, many philosophers have rejected type identity theories in favor of 'token identity' theories. These theories identify a particular ('token') mental state, such as the coffee desire I have now, with a particular physical state, such as the current release of *N* in my brain. A silicon-based creature's token coffee desire may similarly be identical to a state of her silicon brain.

One influential token identity theory construes mental tokens as states which play a particular functional role in the larger cognitive system. On this view, called 'metaphysical functionalism', my coffee desire and the robot's coffee desire qualify as the same mental type because they share typical causes (e.g. a background fondness for coffee, a sluggish feeling) and effects (coffee-seeking behavior). (*See* **Functionalism**)

Some arguments for dualism make use of the idea that our epistemic access to certain mental states is irreconcilable with a physicalist account of those states. For instance, Nagel (1974) argues that even if we understand the physical workings of a bat's echo-location system, we still do not know the phenomenal aspect of the bat's experiences; that is, we do not know 'what it's like' to be a bat. Other dualist arguments are based directly on the conceivability of certain scenarios. For example, Chalmers (1996) argues that we can conceive of a 'zombie', a creature that shares all of our physical states but is entirely devoid of phenomenal experience. These arguments support the idea that there

is what Levine (1983) has dubbed an 'explanatory gap' between physical and phenomenal features. According to this idea, even a complete account of the world in physical terms will fail to explain the presence of phenomenal features. Most present-day dualists accept a dualism about properties rather than about substances. Property dualism holds that some mental properties – usually, phenomenal properties – are irreducible to any physical properties. (*See* **Knowledge Argument, The**; **Explanatory Gap**)

The deepest difficulty facing dualism concerns mental causation. Mental states obviously causally interact with physical states: a desire for coffee causally contributes to my heading for the kitchen; drinking coffee causes a pleasurable sensation; and so on. But (as Princess Elizabeth of Bohemia complained to Descartes in 1643) it is not clear how the nonphysical could causally interact with the physical (Wilson, 1969, p. 373). Various solutions to this problem have been proposed. Some dualists whose dualism is limited to phenomenality avoid the problem by denying that phenomenal states enter into causal relations. (*See* **Epiphenomenalism**)

Among physicalist views, representationalism is especially relevant to intentionality. Representationalism claims that representational content is what is crucial to a state's identity. Representationalism is most significant as a theory about phenomenal content: it entails that the felt quality of a pain, say, is exhausted by what the pain represents. In general, materialism seems to have more difficulty accommodating phenomenal content than intentional content; by assimilating phenomenal content into intentional content, representationalism seeks to reduce problems about the ontology of qualia to more tractable problems about the ontology of representational content, or intentionality.

Finally, accounts of mental ontology encompass a range of positions with regard to reductionism. Some presume that mental properties are reducible to neurobiological processes; some add that neurobiological processes are themselves ultimately reducible to physical properties. But there are several objections to the claim that the mental is reducible to the physical. (*See* **Anomalous Monism**; **Multiple Realizability**; **Emergence**)

Views on Mental Intentionality

Most currently accepted theories of intentional content are causal theories. One causal theory of intentionality is the 'structural isomorphism' view. On this view, a thinker represents a set of objects if and only if the causal patterns between the thinker's states are structurally isomorphic to the causal patterns among the objects (Cummins, 1996).

The view of content that is most salient for cognitive science is also the most currently influential. This view, 'content functionalism', individuates mental state types by their causal roles *vis-à-vis* other mental states, stimuli, and behavior. For instance, the belief that there is coffee nearby is that state typically caused by an olfactory experience of freshly brewed coffee, or seeing a sign reading 'café open' (and so on), and which – when accompanied by a coffee desire – typically causes one to engage in coffee-seeking behavior. Functionalism is promising for computational models of mind, which construe cognition as information processing and individuate cognitive states by their roles as causal mediators between input (stimuli, other states) and output (other states, behavior). (*See* **Functionalism**)

Views on Personhood

The central question about personhood is: what distinguishes a person from a non-person? Some philosophers believe that this distinction is sharp, while others allow that there may be degrees of personhood. For instance, some causal views of cognition associate personhood with complexity of the causal (cognitive) network, and thus allow that more complex networks have a higher degree of personhood than less complex ones.

Some of the factors that are thought to be essential to personhood are: the ability to think; the capacity for self-consciousness and belief revision; and the capacity for phenomenal states. Each of these is, of course, subject to further scrutiny. The issue of what constitutes thinking is itself difficult. Some humans suffer impairments which arguably leave them incapable of self-reflection, but they are considered morally significant beings nonetheless. And lower animals seem to experience sensations, but are not ordinarily treated as persons.

There is a similar range of views concerning the distinction between personal and sub-personal processes. Some maintain that it is intrinsic to thinking, or to pain, that these occur at the personal level. Others contend that this is a relational feature of these processes: for example, a matter of one's being aware of them, or of their occurring above a certain threshold of consciousness, or of our being free to determine their outcomes. As with the requirements for personhood, the distinction between the personal and the sub-personal levels may be sharp, or it may admit of degrees.

THE METAPHYSICS OF COGNITIVE SCIENCE

Broadly speaking, cognitive science is the attempt to understand the human mind as an information processing system. Cognitive scientists use computational models of cognition to explain how humans acquire, store, and manipulate information, and how this information guides their behavior. The basic assumption of computational models is that humans process information by cognitive operations on representations. For this reason, philosophical accounts of intentionality are particularly important to cognitive science. Ontological concerns are also important, as background motivation for the enterprise of cognitive science. Since artificial computers are physical systems, a computational account of human cognition could solve one aspect of the mind–body problem by showing how thought can be accomplished in a purely physical system.

Cognitive Science and Ontology

One ontological problem about cognition is the difficulty of conceiving how a small bit of gray matter can be responsible for human activities (navigating one's way through unfamiliar terrain, predicting others' actions, carrying out long-range plans, etc.) and human thought (from reflecting on the nature of beauty to speculating about future stock market behavior). Cognitive science approaches this difficulty with a 'divide and conquer' strategy. It seeks to divide complex tasks into simpler ones, and conquer these simpler ones by showing that they are analogous (or, perhaps, identical) to computational processes.

Dividing complex cognitive operations into simpler ones seems to resolve the complexity issue, but it is less clear that an analogy to computational processes resolves the basic ontological issue. Even supposing that cognitive science breaks complex cognitive operations into smaller processes that are relevantly analogous to computational processes, there remains the question: how does this physical and computational process realize a mental process?

Cognitive science is not explicitly concerned with the question of materialism: most cognitive scientists assume materialism from the outset. But ontological issues, including the objections to materialism that focus on qualia, are nonetheless important. There are several positions cognitive scientists can take regarding qualia. Firstly, they might simply deny that qualia are the concern of cognitive science. But since some representational states, like perceptual states, clearly have qualitative properties, this response commits them to the contentious claim that the representational features of such a state can be fully explained independently of its phenomenal features. A second option is to adopt representationalism, that is, to claim that the phenomenality of a state is exhausted by its representational content; representational content would then be explained computationally. This response has the advantage of comprehensiveness, but it also opens the account of qualia to arguments against representationalism, including the anti-materialist arguments described above. A third option is to hold that phenomenal content is irreducible to representational content, and to offer an explanation of how phenomenal content contributes to representational content. This third strategy, perhaps the most ambitious, is especially challenging given that many philosophers take phenomenal content to be an intrinsic property of a state, while computationalist explanations of representational content exploit the relational nature of representational properties.

Cognitive Science and Intentionality

Cognitive scientists generally account for the intentionality of a cognitive process by finding a computational analogue for the process. As with the ontological issue, the method is to resolve questions about how human cognition operates by analogy with the better-understood intentional features of computational processes.

A common objection to this approach to understanding cognitive intentionality is expressed in John Searle's famous 'Chinese room' argument (Searle, 1980), which aims to show that what computational features provide is not sufficient for semantics (meaningfulness). Searle concludes that the central project of cognitive science – understanding cognitive intentionality by analogy with well-understood computational processes – is misguided. (*See* **Chinese Room Argument, The**)

Objections to the computationalist approach to intentionality also arise from connectionism. Computationalism assumes that the entities (symbols) that have intentional content are also the entities involved in the computation. That is, it assumes that intentional content occurs at the computational level. Connectionism denies this, claiming that computation occurs at a subsymbolic level and that intentional content is a higher-order property

of patterns of lower-order computations. One purported advantage of connectionism is that it allows us to treat intentional processes as higher-level algorithms while exploiting lower-level, neuroscientific data in accounts of computational processes. (*See* **Connectionism**)

But this purported advantage is also a potential problem for connectionism. If the causal, computational relations occur at a lower level than the intentional processes, then it seems wrong to say that I conclude that there is coffee in the kitchen *because* I smell coffee; that is, because my cognitive system contains an olfactory representation of coffee. Computationalism uses the meanings of symbols upon which computations operate to partially explain why the system engages in those computations. On the connectionist model, the emergence of higher-order meaningful symbols from lower-order non-intentional computations appears to be inexplicable.

Cognitive Science and Personhood

Cognitive science is strictly neutral about the requirements for ethical personhood. Still, since most believe that ethical status is closely tied to mentality, the cognitive science approach to the mind is likely to encourage a causal view of personhood. Computationalism may lend itself to a straightforward causal view, according to which a particular state's causal role determines whether it is a state of a person. Connectionism may lend itself to a more complicated causal view, according to which personhood is a higher-order (perhaps emergent) property of a larger causal network of states. For parallel reasons, those sympathetic to Searle's objection to computationalism may embrace an intrinsic view of personhood.

Cognitive science's general methodology, of breaking cognitive tasks into progressively simpler tasks, may help to distinguish between processes at the personal level and those at the sub-personal level. For it may be that the level of complexity correlates with the personhood distinction, so that (conscious) thought occurs at the personal level, while each subtask that contributes to thought occurs at a sub-personal level.

Mind–Body Problem

Introductory article

Robert Van Gulick, Syracuse University, Syracuse, New York, USA
Jason Clark, Syracuse University, Syracuse, New York, USA

CONTENTS

The mind–body problem is the problem of explaining the relation between the mental and the physical, especially the question of whether the mind is something over and above the physical or just a special part of it.

INTRODUCTION

Dualism divides reality into mutually exclusive mental and physical domains. This may involve a duality of substances, as in traditional Cartesian dualism, or one of properties, a more modern perspective. Substance dualists treat minds as thinking things that are distinct from material objects, including the animal bodies with which they may be causally linked; it is an intuitive notion that finds expression in the ancient belief of self as soul. Property dualists regard minds as physical substances (perhaps embodied brains) that none the less have mental properties over and above their physical properties. If the fiery taste of which I am aware when I bite into a chili is not identical with any physical property of my brain, then reality would seem to extend beyond the physical.

Physicalists hold that the physical exhausts reality. They claim that everything real is in some fundamental sense physical, though they differ about just what that sense might be. Thus if minds are real they must exist as parts of the physical world, and they can have no real properties other than those that are physical in the relevant sense. The physicalist must thus address two sets of questions. First, do minds really have such features as consciousness, meaningfulness or free will? Some physicalists would deny the reality of certain of these, just as modern science denies the existence of ghosts and phlogiston and feels no need to fit them within the physical. Second, if some mental feature is accepted as real, how could it be physical (in whatever sense the theory requires, whether that be a matter of identity, material composition or dependence)?

EVOLUTION OF THE PROBLEM

Questions about the place of mind in nature go back to our earliest records of human thought, but the specific problem of the relation between mind and matter came to the fore with the rise of modern physical science in the seventeenth century. The newly-found ability to model quantitative physical relations gave rise to the so called mechanical philosophy with its grand explanatory ambitions. Inevitably the question arose of whether minds could be mechanically explained. This question found its sharpest formulation in the philosophy of René Descartes. Although he was a major contributor to the mathematical and physical theories of his day, he argued that mind and matter are distinct kinds of substance, each with its own essence: minds as thinking things and matter as spatially extended. Despite their different natures, he accepted their mutual causal interaction: what happens in the mind affects the body and vice versa.

Descartes' view quickly attracted criticism. The early materialist Thomas Hobbes argued for a surprisingly computer-like view of minds as physical systems for manipulating symbols. Other critics accepted Descartes' dualism but denied that mind and body interact, despite appearing to do so. Gottfried Leibniz, the German philosopher and co-inventor of the differential calculus, believed in a divinely pre-established harmony that made minds and bodies run in parallel, like the many clocks in a shop striking the hour together.

For the next three centuries the dualists held their own against the materialists, and even at the beginning of the twentieth century the majority of thinkers still had a basically dualist outlook. However, in the twentieth century, physicalism became the dominant viewpoint among scientists and philosophers, in part following advances in neuroscience, computing and biochemistry. If life and reproduction are biochemical and ultimately

physical in nature, should we not expect the same of mind and thought?

CONTEMPORARY POSITIONS

While serious arguments for and about dualism are still heard, contemporary discussion more often concerns how best to formulate physicalism. Physicalists disagree as strongly among themselves as they do with their dualist opponents. Any physicalist theory needs to answer two related but distinct questions: what counts as physical in the strict or primary sense; and how must something be related to the strictly physical to be counted as physical in the extended sense which is supposed to apply to minds? Both questions have received diverse answers.

Regarding the first question, the physicists' inventory of fundamental features has changed again and again over the centuries. Beginning with a simple mechanical view of matter in motion, Newton's gravity was added, and then electromagnetic forces and fields. Physicists have since introduced the strong and weak forces, gluons, and more recently strings in high-dimensional space. Features regarded as 'fundamental' may be added or dropped. Given this theoretical flux, most physicalists leave the exact nature of the strictly physical as an open variable. They claim simply that whatever minimum of basic features suffices to account for nonmental physical reality will account also for minds.

The second question is more controversial. Physicists don't include earthquakes, rockets or cockroaches in their list of basic physical features, yet few would deny that they fall within the physical realm. The physicalist must first explain what relation to the strictly physical makes them count as physical, and then show that minds meet that same criterion.

Contemporary physicalism was first formulated in the 1950s as a claim of strict identity between mental and physical properties. Analogies were drawn with familiar cases of scientifically discovered theoretical identities: lightning is just an atmospheric discharge of static electricity; water is just a collection of H_2O molecules. Similarly, it was proposed, consciousness, beliefs and pains might be just certain sorts of neural processes in the brain. This view is called the type identity theory, since it aims to identify mental properties or types with specific physical counterparts. It does not assert merely that, for example, pains are correlated with certain brains states, or that the latter cause the former, but that the two are one and the same thing viewed from different theoretical perspectives, just as water and H_2O are identical.

A relation of property identity would certainly validate physicalism; but it seems too strong to be true, as one can see from the 'multiple realization' objection. The identity theorist identifies being in pain with some specific neural property, for example, increased activity in the anterior cingulate cortex. But that links the mental property too specifically with the particular neural correlate of pain in humans. If we were to find no such neural processes in birds, monkeys or extraterrestials, it would not follow that they don't feel pain, especially if they respond in pain-like ways to injury. The type identity theory seems even less plausible for more abstract states such as believing, perceiving or wanting. Indeed, it is hard to see why even an electronic robot without neurons might not qualify for having such states.

Thus most physicalists moved away from the type identity theory towards a view of mental properties as higher-level systemic properties based on an underlying physical substrate, more like functional categories such as being an amplifier or being a recessive gene for light eye colour. According to this functionalist view, what makes some state a pain, a belief or a desire is the functional role it plays within the system or organism of which it is a part. Pains, for example, typically indicate bodily damage, cause avoidance of the source of the pain, and interfere with concentration. To validate physicalism one would need to show that the things playing those roles were physical and filled the relevant roles by virtue of their physical causal profiles. To draw a biological analogy, there are many different structures that count as stomachs, but they all perform certain functions and do so because of their physical configuration. In that respect, according to the functionalist, minds are no different from stomachs, and thought no different from digestion.

If mental properties are higher-level functional properties of organized systems, then they are not identical with underlying strictly physical structural properties. The physicalist must find a relation between the two that is weaker than identity but still strong enough to validate the claim that everything real is ultimately physical. Consider again the biological analogy. Many of the things or properties to which biologists refer (e.g. organisms, reproductive fitness, or cellular immunity) are not strictly physical, in the sense that physicists do not refer to them in their theories or models. Yet given our current view of life, we accept such biological features as complex aspects of physical

reality. Can the physicalist specify a relation between mental and physical properties that would support the claim that minds are also just complex aspects of the physical? Various candidate relations have been offered, of which the three most prominent have been physical composition, supervenience and realization.

According to the 'composition' proposal, a thing counts as physical if it is entirely composed of physical parts or constituents. Being a grasshopper may not be a property studied by physicists, but if grasshoppers are composed entirely of parts that have strictly physical properties then grasshoppers would count as physical, as would all their higher-level properties. Being alive or ready to mate might not be strictly physical properties, but they would count as physical in the extended sense that they are properties of physically composed systems.

However, being physical in that sense may be too weak a condition. The fact that all the parts of a system are physical does not guarantee that all its properties are physical. Its parts might have nonphysical (perhaps protopsychic) properties as well as physical properties such as mass and charge: that is, they might be dual in nature. Indeed, some dualists, called panpsychists, believe just that. They claim that reality has both physical and mental aspects down to its lowest level. The view was proposed at the beginning of the dualism–physicalism debate by the Dutch philosopher Baruch Spinoza. Early in the twentieth century, the British philosopher and logician Bertrand Russell and the American philosopher and psychologist William James both proposed similar dual-aspect theories. More recent theorists have cited quantum mechanics as supporting their view that reality embodies a mental–physical duality at its most fundamental level; they appeal especially to those versions of the theory that accord a role to the consciousness of the observer in quantum-mechanical measurements, in which an indeterminate quantum state is collapsed to a determinate value, apparently by the measurement process itself. Although panpsychism and dual-aspect theories remain controversial minority views, they do show one way in which the composition relation might fail to validate physicalism. The requirement might be strengthened to avoid the problem by counting as physical only things that are composed entirely of parts that can be fully described in terms of their strictly physical properties. Such an addition would exclude the panpsychic possibility; but for that reason dual-aspect theorists would deny that everything is physically composed in that sense. They would demand that the physicalist prove any such claim and not merely assume it.

Moreover, even the strengthened requirement might fail to validate physicalism for a second reason. Perhaps a system as a whole could have properties that were emergent in the radical sense: that is, it could be more than the sum of its parts and their modes of combination. 'Emergent' dualists claim just that: they view mental properties as radically emergent nonphysical features of complex systems. Thus, even if all of a system's parts were physical in the strengthened sense, the system itself might still have nonphysical properties.

It is important to be clear about the various senses in which a system's properties might be termed 'emergent'. Some are quite modest and pose no problem for physicalism, while other more radical senses would entail dualism. Modest emergence is just the view that wholes can have properties quite unlike those of their proper parts. Thus a collection of H_2O molecules at room temperature is liquid even though none of the molecules themselves have that property. None the less, the liquidity of the collection is a necessary and understandable consequence of the physical properties of its molecular parts. The higher-level property of liquidity is not identical with any lower-level properties of its parts, but it depends upon them so intimately and necessarily that one can regard it as physical in a very strong sense.

Physicalism would conflict with a more radical form of emergence in which a system had properties that were not only distinct from those of its parts but that could not be explained by appeal to those properties or their modes of combination. In this case, the dualist might well regard the properties of the whole as something over and above the physical. Even if there were law-like connections between the two sets of properties, it would not follow that the system-level properties were themselves purely physical.

Physicalists and emergent dualists disagree about whether there are any cases of radical emergence. The matter can be settled only by the evidence, which is as yet incomplete. If the radical emergence of the mental remains a possibility, however remote, then physical composition, even in the strengthened sense, would not guarantee physicality. A system all of whose parts were physical might still have emergent nonphysical mental properties.

As an alternative to physical composition, some physicalists appeal to a supervenience relation between the mental and its physical substrate. Supervenience is the idea that a set of properties cannot

change without a corresponding change in another set of properties, even if the two are distinct and quite different in nature. Supervenience was first proposed as a way to think about evaluative properties such as moral and aesthetic ones. The beauty of a painting is not identical with any set of its physical properties, such as the distribution of different colored regions of paint on its canvas. None the less, if a second painting had exactly the same physical properties (including the same paint distribution), then the two paintings would have the same aesthetic properties. If the first were beautiful, so would be the second. Supervenience might be summed up in the slogan 'no difference without a physical difference': in particular, no two systems that are the same in all physical respects can differ mentally. The supervenience of the mental on the physical thus seemed to offer a way in which mental properties might be nonidentical with physical properties but still dependent upon them enough to qualify as physical as well.

However, like physical composition, supervenience runs into objections and seems too weak to validate physicalism. In particular, supervenience does not rule out various dualist possibilities. For example, it is consistent with dual-aspect theory as long as the properties of the two domains are reliably and invariably correlated, as they are in Spinoza's version of panpsychic dualism, in which mental and physical properties correspond as a matter of metaphysical necessity. Even if the connection were only a matter of natural law, it would guarantee that there could be no actual mental difference without a physical difference. Moreover, supervenience does not itself entail the sort of one-way dependence needed to support the claim that everything real is ultimately physical. In Spinoza's theory, for example, there is dependence in both directions: neither the physical nor the mental can vary without a corresponding change in the other. Given that supervenience is compatible with such interdependence, it cannot by itself sustain the claim that the physical is primary or ultimate.

A third relation by which physicalists have tried to link the mental and the physical is that of realization, which perhaps best fits the functional view of mental properties. With a functional property, such as being a 20-amp fuse or being a recessive gene for blonde hair, we can specify the required functional role and then show how an underlying physical structure fills it by means of its physical causal profile. For example, it is not that a given DNA sequence causes the gene; rather, that sequence is the gene in so far as it fills the role that qualifies it as a recessive hair color gene and does so because of its the lower-level physical properties. The relation easily accommodates the sort of multiple realization that refuted the earlier type identity theory. A single role might be filled by different physical structures in different people or different organisms; what makes them all pains, for example, need not be a common structure. Realization may thus provide a sufficiently intimate and necessary form of one-way dependence to validate physicalism, but only if all mental properties are in fact physically realized functional properties. Dualists and physicalists disagree on this point.

DIFFERENT MIND–BODY PROBLEMS

As noted above, the physicalist must accommodate as physical each mental feature acknowledged to be real. If, for example, experience really has felt aspects, like the red of which I seem to be aware when I look at a chili, then the physicalist must show how those aspects might be physical or physically realized. Different mind-body problems arise depending on which mental aspect one considers. In particular, important versions of the problem are generated by the difficulty of explaining consciousness, intentionality, and mental causation in physical terms.

Consciousness makes the mind–body problem deeply puzzling. Those aspects of mind that cluster around it (such as qualia (the felt character of experience) the subjectivity of awareness, and the first-person perspective) seem most difficult to fit within the physical domain. How could the conscious taste of a mango be identical with or realized by any physical process in my brain? The two sides of the psycho-physical equation seem so dissimilar that we are left in bafflement as to how they might fit together. It is not so much like identifying liquid water with H_2O as turning water into wine.

The second major variant concerns what philosophers call the intentionality of mind, the fact that mental states have meaning and refer to things in the world outside themselves. One's thought may be about the Eiffel Tower even when one is sitting in Nebraska, and a medical researcher's desire might be for a cure for Alzheimer disease even though none as yet exists. Minds have certain features that are undeniably representational: there could be no beliefs, desires or perceptions if they had no meaningful content. Thus the physicalist must show how brains as physical systems can have such representational powers and intentional content. What might it be about a brain state or process that makes it be about something, perhaps

something distant, or even nonexistent, like children's beliefs about Santa Claus? Many answers to these questions have been offered, and although no consensus has emerged, there are many promising options and active research continues.

A third variant concerns the problem of mental causation, a problem which itself takes many forms. The basic problem, going back at least to Descartes, is to account for the apparent causal interaction of the mental and the physical. I stub my toe and I feel a pain, or I want a sip of coffee so I reach out my arm and bring the cup to my lips. Cartesian dualists who wish to preserve mental causation must explain how two things so different in nature – spatially extended matter and nonspatial conscious mind – could be causally connected. Moreover, if nonphysical mental factors are able to bring about changes in the physical world, the conservation laws which are among the most empirically well confirmed and basic principles in modern science would be violated. The consequences seem equally drastic and unacceptable if the dualist opts to regard the mental as epiphenomenal and causally inert in the physical domain. Seemingly obvious causal facts, as well as moral responsibility, would be put in doubt if our mental states are not among the causes of our actions.

However, the causal status of the mental also poses a problem for many physicalists, as is shown by the so-called exclusion argument. If all physical events are fully determined by prior physical causes or circumstances, then it would seem impossible for mental properties to affect the course of physical events, unless they were identical with physical properties as the type identity theory claims. My desire for a sip of coffee seems to cause my arm to move, but all the real causal work is being done by brain processes and their physical properties. The fact that those properties, in doing so, might also fill an abstract mental role adds nothing to the causal powers they already had based on their physical nature. Thus the physicalist's current higher-level view of mental properties threatens to make them epiphenomenal.

Although these three variants have loomed largest in recent discussions, there are many other forms the mind–body problem might take, if for example one wished to account for the emotive aspect of mind or the alleged freedom of the will. In each case, the dynamic between the dualist and physicalist would be similar. Each would take a stand about the extent to which the relevant feature was real, and then try to show why and how it could or could not fit within the physical framework.

The mind–body problem is sometimes posed as the question of whether the mental reduces to the physical. However, the notion of reduction is ambiguous about what sorts of things are being reduced. It can be either a relation between objective things in the world, such as events and properties, or a relation between theories or ways of describing and conceptualizing the world. On the first (ontological) reading, it roughly corresponds to the core mind-body problem as discussed above. However, on the second (representational) reading, reduction concerns our ability to derive our mental theories or concepts from our physical ones.

Most contemporary physicalists accept ontological reduction but reject representational reduction, and on the basis of that rejection they are classed as nonreductive physicalists. They deny that the representational or conceptual resources of physical theory will suffice for all our legitimate explanatory and descriptive needs. The point seems obvious if one considers the case of a higher-level science such as economics. No one supposes that there is an ontological dualism of the physical and the economic; there is no metaphysical money-matter problem. But economics gives us a way of describing and explaining patterns in the world that could not be described or explained using only the resources of physics. Every act of paying ten dollars for a book, whether with cash, credit card or cheque, is an ontologically physical event, but what those events share is a higher-level feature that can only be understood relative to the whole organized financial system in which they occur. Some philosophers have criticised nonreductivism as 'physicalism on the cheap'; they argue that nothing short of identities or strict derivation will validate physicalism. The nonreductivist replies that it provides everything a reasonable physicalism requires, and that economists and psychologists can remain physicalists in the ontological sense while being strongly nonreductionist in the representational sense and accepting the validity and autonomy of their special sciences and the valuable ways they offer us of understanding our complex reality. Debate on the issue continues.

Modularity

Intermediate article

Ron McClamrock, University at Albany, State University of New York, Albany, New York, USA

CONTENTS

Various cognitive and perceptual processes may be separated or isolated from one another. Those processes may be understood as relatively independent subsystems, or modules.

WHAT IS MODULARITY?

A cognitive or perceptual process is said to be modular to the extent that it is an independent sub-process of the overall cognitive architecture. A module is a cognitive or perceptual subsystem whose workings are relatively independent from the rest of the cognitive architecture, and whose functioning can be analyzed and understood relatively independently of the overall system in which it is embedded. This idea is based on the more general engineering notion of 'near-decomposability' (Simon, 1981). According to Simon, a system is nearly decomposable if it is made of components whose behavior is, in most respects, not influenced by anything else going on in the system beyond what is given to the components as input.

Although the modularity of subsystems of perception and cognition has been discussed in various forms throughout the history of the philosophical study of mind, the view that psychological systems are to be understood as systems of interacting modules was particularly popular among the 'faculty psychologists' in the nineteenth century. These theorists typically held (apparently with little empirical justification) not only that there were independent modules governing various skills, abilities, and aspects of intelligence (e.g. a musical faculty, and a mathematical faculty), but that these modules had specific physical locations, and that the strength of a psychological faculty was correlated with the size of bumps on the head in the corresponding location.

The modern notion of modularity is expressed in terms of information processing. Here, the central idea is that various subsystems within the overall cognitive and perceptual system are relatively independent in terms of information processing; that is, they have relatively limited informational interaction with other cognitive subsystems. They are thus taken to be 'informationally encapsulated'.

This informational encapsulation has two 'directional' aspects. Firstly, there may be constraints on what information can get into the module and influence its working. This is sometimes called 'cognitive impenetrability'. A process is cognitively impenetrable to the extent that information that is available to other cognitive and perceptual processes is not available to the modular process, even though it may be relevant to the task being done. This is illustrated clearly by phenomena like the persistence of illusion. In the standard Müller–Lyer illusion (Figure 1), the visual system continues to perceive two lines as of different lengths, even when the viewer (after measuring, say) has available the information that they are in fact the same length. The visual system 'won't listen' to that outside information, and so the illusion persists.

Secondly, there may be constraints on the information apparently available to the module but unavailable to the rest of the cognitive system. This is called 'informational opacity'. For example, although a two-dimensional representation of (at least some of) a visual scene is probably computed along the path of visual processing, that two-dimensional representation seems not to be available for making other kinds of judgments. When a subject looks at a table top, the relative lengths and orientations of the two-dimensional projections (from the subject's perspective) of the edges of the table are not easily cognitively available to the subject to make judgments about. It seems that the visual system gives the rest of cognition some 'proprietary' description of visual input – perhaps as three-dimensional shapes – but reveals little of the

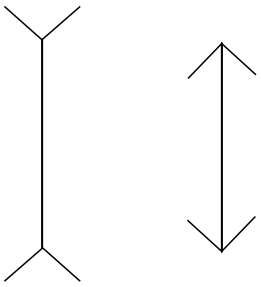

Figure 1. The Müller–Lyer illusion. Even when we know that the vertical lines are the same length, we continue to perceive the line on the left as longer.

methods and assumptions it uses to produce the representation that it gives as output.

Another feature commonly ascribed to modules is 'domain-specificity'. This is the idea that modular processes operate on only very specific domains. It is, however, a difficult notion to define precisely. Firstly, the notion of a 'domain' is not well defined; furthermore, domains, which are concerned with content rather than the form of processing, may change according to how we look at the information processed. A process might be seen as 'domain-specific' by virtue of doing only one particular form of calculation, but those calculations might be applied to representations with different sources and different contents.

Other features commonly ascribed to modules include both information-processing features (such as lack of competition for computational resources with other processes, and speed of operation) and features pertaining to the implementation and ontogeny of modules (that they should be innately specified, neurally specific and localized, hard-wired, and with a characteristic pace and sequencing of development). But there are wide differences of opinion about which of these are critical to the notion, or should even be expected in modules that may be discovered.

VIEWS AND THEORIES OF MODULARITY

The most prominent and influential view on modularity has been that of Fodor (1983). According to Fodor, there is a fundamentally trichotomous architecture to cognition: 'transducers', which just convert stimuli directly into signals to be used in processing; 'input systems', which are informationally encapsulated modules that make inferences about the sources of those inputs; and 'central systems', which are non-modular ('holistic') processors responsible for general inference, reasoning, and the fixation of beliefs. Input modules are constrained and encapsulated subsystems, but, unlike transducers, they engage in real nondemonstrative inference that goes beyond the information given in the stimulus alone: for example, in the case of perception, generating hypotheses about the distant environment.

The linguistic and visual domains were suggested by Fodor as likely to involve significant modularity, and much subsequent research on modularity has focused on these two domains. The views of Marr (1982) and his followers on visual processing have also been influential in encouraging a modular view of the visual system. Marr (for whom the boundary of the visual module is defined by the representation he calls the 'two-and-a-half-dimensional sketch') insists that within the visual module 'the processes can be influenced little or not at all by higher-order considerations' (Marr, 1982, p. 351). Marr further encourages a view of the visual module as largely decomposable into submodules (e.g. for stereopsis, and for constructing the 'raw primal sketch'), each of which is more or less informationally encapsulated even from the rest of the activity in the visual module.

Similarly, in language processing, many theorists have looked for significant modularity. For example, in Jackendoff's analysis, 'syntax … has *no* direct interface with the articulatory–perceptual system; rather, it interfaces with phonological structure, which in turn interfaces with articulation and perception' (Jackendoff, 1997, p. 30).

Much broader and more ambitious accounts of mental modularity have also been proposed. For example, Gardner (1983) suggests that much of higher cognition and intellectual skill is modular. This is in contrast to Fodor's view that higher cognition is generally a holistic and non-modular central system. Other accounts have suggested modules ranging from the perceptually driven (e.g. Lerdahl and Jackendoff's (1983) modular account of musical cognition), to modules in higher cognition specified in much more abstract terms such as the 'theory of mind' module (Scholl and Leslie, 1999), which has been postulated to explain the apparent nonpervasiveness of the cognitive disturbances involved in autism. In the last decade of the twentieth century, some more extreme modularist hypotheses about the mind appeared. Prominent among these is Sperber's (1994) suggestion of 'massive modularity', where a great variety of modules are seen as permeating the structure of the cognitive architecture. Such views have typically been coupled with evolutionary accounts of these allegedly ubiquitous modules (e.g. Cosmides

and Tooby, 1987), and have suggested modules whose 'domains' of operation are much more abstract than domains such as visual processing (e.g. Cosmides and Tooby's suggested 'cheater-detection module').

EMPIRICAL EVIDENCE CONCERNING MODULARITY

There has been significant experimental investigation of the kinds and degrees of informational encapsulation that various cognitive subsystems might exhibit. Much of this work has focused on the cognitive impenetrability of the systems of visual and linguistic perception. But some of the most obvious empirical evidence for at least some degree of modularity in such systems is phenomenological. For example, in the Müller–Lyer illusion, the phenomenological assessment of the stable output of visual processing (roughly, 'how it looks') strongly suggests that the output of visual processing is unaffected by (or cognitively impenetrable by) the information we have about the actual lengths of the lines.

In general, empirical investigation of the possible modularity of these systems has focused on what would appear to be relatively intelligent interpretation of stimuli, and considering whether information for solving such problems is likely to come from generally available (non-encapsulated) cognition about the domain (which would contradict the claim of impenetrability) or from constraints plausibly built into the subsystem itself. Cases in which general background knowledge is actually in conflict with the apparent inference made by the purported module are particularly salient. Thus, with the Müller–Lyer illusion, the background knowledge of a typical subject includes the knowledge that this is a familiar illusion and that the lines are actually the same length. But the apparent lack of penetration of the visual system by this information, combined with the fact that the actual stimuli (both as objects and as retinal stimulations) are lines of the same length, seems to imply that while the visual system is making an inference that goes beyond the stimulus in interpreting the input, it uses only its own limited information in the processing leading to that inference.

Perhaps the best evidence of modularity comes from early processes in vision. Much of this evidence concerns perceptions of illusions, like the Müller–Lyer illusion, and rules and strategies apparently used in visual perception but which are hidden from our notice. Rock (1983) has compiled a catalogue of such data, including facts about non-obvious completions of hidden and illusory visual contours, lightness constancy across illumination changes, and many others. Marr's (1982) analysis of the visual extraction of depth information from stereoscopic images also gives a clear illustration of powerful inferences made within the visual system using rules which the subject would seem to have neither access to nor the ability to override.

Some aspects of language processing also appear to be modular. Competence in learning a language appears to be quite independent of general problem-solving skills – an observation that goes back at least to Descartes, and that has been supported by recent research (e.g. Karmiloff-Smith *et al*., 1997), including brain lesion studies that suggest that localized lesions can affect language skills without significantly affecting other aspects of cognition (e.g. Caramazza *et al*., 1983). And careful chronometric studies of the 'phoneme restoration effect' – one of the most widely-recognized contextual effects on early language processing – have shown it to be plausibly a result of biases introduced by the postperceptual judgments of the subjects, and so perhaps not after all in violation of modularity (Samuel, 1981).

The evidence concerning modularity in other domains is more mixed and controversial; and in all domains, there are some threads of evidence that seem at least to limit the modularity. Farah (1994) has argued that lesion and deficit studies do not support, and sometimes even refute, the suggestion of neurological localization of speech functions. The presence of various sorts of top-down effects on perceptual recognition (e.g. in gestalt shifts) suggests that information flow into perceptual modules is not completely constrained (e.g. McClamrock, 1989). And the 'McGurk effect' (McGurk and MacDonald, 1976) seems to suggest that the process of recognition of even relatively low-level features of language like phonemes is penetrated by information coming from the visual modality, so that the face movements that are seen can influence which phoneme is heard.

ROLE OF MODULARITY IN COGNITIVE SCIENCE

The idea of modularity has had two distinct roles in contemporary cognitive science: one descriptive, the other methodological. In its descriptive role, modularity – and especially its notion of informational encapsulation – is one of many information-processing concepts used for constructing explanatory cognitive models. Empirical results such as those considered above seem to

imply the need for a model of the relative separation of, say, perception of (apparent) length and judgments about the properties of objects. Determining the extent to which such results demand modular models of processing is a difficult but not unusual problem of theory construction and testing.

The methodological role of the notion of modularity is more subtle. Modularity is supposed to provide a kind of 'divide and conquer' strategy for the study of cognition: by defining subsystems whose behavior in relative isolation is similar enough to their behavior in the real, embedded context, we might hope to come gradually to understand the complex working of a system. Conversely, unchecked top-down information flow into perceptual processes would make them difficult to analyze. As Marr puts it, the information-processing approach would be likely to fail with 'systems that are not modular … that is to say, complex interactive systems with many influences that cannot be neglected' (Marr, 1982, p. 356). And as Fodor puts it, 'the limits of modularity are also likely to be the limits of what we are going to be able to understand about the mind … [because] the condition for successful science (in physics, by the way, as well as psychology) is that nature should have joints to carve it at: relatively simple subsystems which can be artificially isolated, and which behave in isolation in something like the way that they behave *in situ*' (Fodor, 1983, pp. 126–128).

As Marr puts it for the case of vision, '[if] we can experimentally isolate a process and show that it can still work well, then it cannot require complex interaction with other parts of vision and can therefore be understood relatively well on its own' (Marr, 1982, p. 101). However, even where this experimental isolation can be achieved, the fact that such an isolable subsystem 'cannot require complex interaction with other parts' does not entail that it can 'be understood relatively well on its own'. The subsystem might still roughly accomplish its task under informationally impoverished conditions, but it might do so in a way that is not a good indication of its normal pattern of working. For example, it might take longer and resort to less efficient means to solve a problem than it would under conditions of normal informational access, where it might work more quickly, with less effort, and with fewer resources. Or it might work as quickly, but with greater error. The case of isolation would then give a misleading view of how the process normally works.

It may be useful to isolate processes in order to study them, but there is a concern that decomposition of the cognitive system has more to do with hopeful simplifying assumptions about cognition than with its actual structure. The accounts of 'massive modularity' mentioned above are perhaps the most optimistic but least empirically grounded of the current modularist views. And Fodor (2000) has recently suggested that assumptions of modularity and related strategies of decomposition have been applied too freely in the cognitive theorizing of the last years of the twentieth century, and are of much more limited applicability than is often suggested.

SUMMARY

Modularity, taken as the decomposability of cognition into components that can be considered in relative isolation from one another, is both a methodological ideal and, sometimes, an assumption that has influenced and guided research in cognitive science. Although there is some evidence to support the idea of modularity, especially in the early stages of processing involved in language and vision, the application of the idea currently exceeds the evidence for it. Modularity is sometimes more an optimistic guess, intended to guide explanation, than a conclusion of experiment and completed theory. Its soundness is a subject of widespread debate, and one of the central metatheoretical issues that cognitive science currently confronts.

Multiple Realizability

Intermediate article

John Bickle, University of Cincinnati, Cincinnati, Ohio, USA

CONTENTS

Multiple realizability, the claim that a type of mental state is implemented in a variety of distinct types of physical states, is the central premise in the most influential criticism of mind-to-brain reductionist programs. But the validity of this argument is under increasing scrutiny, based both on examples from more mature branches of science and on specific developments in the cognitive and brain sciences.

WHAT IS MULTIPLE REALIZABILITY?

Within the philosophy of mind, 'multiple realizability' is the claim that a type of mental state (property, event) is implemented in a variety of distinct types of physical states (properties, events). A philosopher's fantasy illuminates this claim. Suppose that the long-awaited day arrives and friendly aliens land on earth. Their behavior so closely resembles ours in a variety of circumstances that we soon begin explaining and predicting it using our own repertoire of mentalistic terms. For example, we explain alien Fred's consuming large quantities of beer because of his desire for liquid refreshment and his liking for the taste of earth beer.

At some time during their visit, an alien dies. They give us permission to conduct an autopsy. But when we open the alien's head, we find nothing that resembles our brains on the level of gross anatomy (the alien's head is filled with green slime), nor on the level of cellular anatomy and physiology (the slime contains nothing resembling our neurons), nor in its elemental constitution (the slime is silicon-based, not carbon-based). Clearly, the aliens lack brains like ours. Yet they seem to share our mental states. This fantasy suggests that a given type of mental state (desire for liquid refreshment, or a liking for the taste of beer) can be multiply realized in a variety of physical states that have little in common at any level of physical description.

Arguments appealing to multiple realizability, and critical replies to them, have generated a huge literature. Only the landmarks are discussed in this article. For more comprehensive presentations (written at a more technical level, with extensive bibliographies) see Bickle (1998, 1999).

HISTORY

In a series of papers published in the 1960s (most reprinted in Putnam, 1975), Hilary Putnam introduced multiple realizability into the philosophy of mind. He used it as a premise in an argument against early versions of the mind–brain identity theory. Using 'pain' as an example of a type of mental state, Putnam writes:

> Consider what the brain-state [identity] theorist has to do to make good his claims. He has to specify a physical–chemical state such that *any* organism (not just a mammal) is in pain if and only if (a) it possesses a brain of a suitable physical–chemical structure; and (b) its brain is in that physical–chemical state. This means that the physical–chemical state in question must be a possible state of a mammalian brain, a reptilian brain, a mollusc's brain (octopuses are mollusca, and certainly feel pain), etc. (Putnam, 1967)

That physical–chemical state must also be 'a state of the brain of any extraterrestrial life that may be found that will be capable of feeling pain' (ibid.). Furthermore, the identity theory makes a similar claim about every type of mental state. So 'if we can find even one psychological predicate which can clearly be applied to both a mammal and an octopus (say 'hungry'), but whose physical–chemical correlate is different in the two cases, the brain-state theory has collapsed' (ibid.). According to Putnam, it is 'overwhelmingly likely' that at least one such predicate can be found.

Putnam also used multiple realizability to defend the functionalist account of mind he was

developing in the same papers. His functionalism identified mental types with machine table states of a 'probabilistic automaton'. The technical details are not important for our purposes. The important point is Putnam's contention that his functionalism is consistent with the facts of multiple realizability, making it an attractive alternative to early identity theories.

Jerry Fodor (1974) broadened Putnam's multiple realizability argument to challenge all forms of 'reductionism'. In particular, he:

- extended the argument to criticize reductionism built upon existing theories of scientific ('intertheoretic') reduction.
- argued that the 'disjunctive strategy' of identifying a type of mental state with the disjunction of all physical–chemical states realizing it was untenable.
- hinted at an important distinction between two senses of multiple realizability.
- extended the argument against reductionism to include not just psychology but all of the 'special sciences' (other than basic physics).
- developed the concept of 'token physicalism' (a weaker doctrine than reductionism), which is consistent with multiple realizability and 'sufficient for any reasonable purpose'.

Fodor's arguments are still influential in their original form and they stand as monuments in the philosophy of mind.

ARGUMENTS APPEALING TO MULTIPLE REALIZABILITY

The most plausible account of scientific (intertheoretic) reduction available in the early 1970s was that of Ernest Nagel (1961). Nagel construed reduction as deduction of each law of the reduced theory from the laws of the reducing theory. However, reducing theories often do not contain predicates of the reduced theory (e.g., laws of statistical mechanics and microphysics do not contain predicates from classical thermodynamics like 'pressure' and 'temperature'). To obtain valid deductions in such cases, 'bridge laws' must be added to the laws of the reducing theory. Each bridge law relates a predicate of the reduced theory to the appropriate predicate of the reducing theory (e.g., 'temperature' to 'mean kinetic energy of the gas's constituent molecules'). The predicates from the reducing theory occurring in these bridge laws must pick out a kind of property (state, event, process) deemed relevant for explanation and prediction by the reducing theory. To do this, the predicate must occur within the laws of the reducing theory. Obviously, any intertheoretic reduction from psychology to physics will require bridge laws, since no physical science contains mentalistic predicates. But if reduction is to establish physicalism, then these bridge laws must be interpreted as (contingent) identity claims (e.g., 'mental state M is identical to physical state P'). Given the extent and variety of multiple realizability of the mental on the physical, identities require the physical predicate P in psychophysical bridge laws to be 'wildly disjunctive', perhaps infinitely so: M is identical to [P_1 (in humans) or P_2 (in octopuses) or … or P_n (in green slimy extraterrestrials) or …]. And even if the disjunction is finite, it is overwhelmingly likely that the resulting predicate will not be one that appears in any law of any physical science. Hence that disjunctive predicate will not denote a kind recognized as relevant for explanation or prediction in any potentially reducing physical science. As Fodor puts it, it would be 'an accident on a cosmic scale' if this requirement of physicalist reduction turned out to be true.

In a famous pair of examples, Fodor (1974) hints at a distinction between two types of multiple realizability. One is the type that Putnam emphasized: 'multiple realizability across structure types', in which different types of physical structures (human brains, octopus brains, alien green slime) realize the same mental state. The other type is more radical: 'multiple realizability within an individual system across times'. A human brain might realize the same mental state in different physical states at different times (depending upon neural changes brought about by learning or upon whatever other tasks it is carrying out). This more radical sense increases the number of disjuncts in the psychophysical bridge laws. Now there must be a predicate in the disjunction denoting every physical state realizing the given mental state in every instance of every type of cognizant creature at every time. This makes reductionism look extremely unlikely.

Although the functionalism spawned by the multiple realizability argument against reductionism is no longer the 'dominant' account of mind in Anglo-American philosophy, its heir – 'nonreductive physicalism' – also adopts Putnam's and (especially) Fodor's multiple realizability arguments (Horgan, 1993).

PROBLEMS FOR ARGUMENTS APPEALING TO MULTIPLE REALIZABILITY

David Lewis (1969) first offered what has come to be the standard reductionist reply to the multiple

realizability argument. Consider the following three claims:

There is only one winning lottery number. (1)

The winning lottery number is 03. (2)

The winning lottery number is 61. (3)

This triad seems inconsistent for the same reason as the following triad, namely, multiple realizability as expressed in claims 2 and 3 (5 and 6 below):

There is only one physical–chemical realization of pain. (4)

The physical–chemical realization of pain is brain state *B*. (5)

The physical–chemical realization of pain is green slime state *G*. (6)

But there is an easy dissolution of the inconsistency in claims 1 to 3: add 'per week' to claim 1, 'this week' to claim 2, and 'last week' to claim 3. Similarly, add 'per creature type' to claim 4, 'in humans' to claim 5, and 'in the friendly aliens' to claim 6, and the inconsistency disappears there. Lewis's general point is that reduction and identity is specific to a domain of phenomena, and hence is consistent with multiple realizability in the sense Putnam characterized.

Following Lewis's lead, a number of reductionists have pointed out examples of domain-specific reductions throughout the history of science. Temperature, for example, is multiply realized. Temperature in a gas is mean molecular kinetic energy. Temperature in a solid is mean maximal molecular kinetic energy (since the molecules are bound together in lattice structures and are restricted to a range of vibratory motions). Even a vacuum, which lacks molecular constituents, can have a 'black body' temperature, depending upon the electromagnetic waves coursing through it. So this paradigm 'reduced' concept is multiply realized at the level of microphysical and statistical mechanical description. So multiple realizability in itself does not appear to preclude reducibility, in actual scientific cases.

But is Lewis's strategy sufficient to handle the more radical, 'same instance of a system across different times' sense of multiple realizability? Wouldn't this sense require us to relativize reductions to descriptions of individual systems at times? And isn't this much 'domain specificity' inconsistent with the generality of scientific (reducing) theories? Are there examples of this more radical sense of multiple realizability from the history of scientific reductions? In answer to this last question, Enç (1983) hints that the example of 'temperature' is multiply realized at the level of microphysical description in this radical sense. A given instance of a gas can realize the same temperature – the same mean molecular kinetic energy – in an infinite number of distinct 'microcanonical ensembles' in which the kinetic energy of each molecule is specified individually. (This argument is developed explicitly in Bickle, 1998.) So multiple realizability in itself, even in this more radical sense, does not appear to preclude reducibility.

The other questions are more difficult to resolve. They appear to require a new account of intertheoretic reduction. But two considerations support the possibility of developing such an account. Firstly, a close examination of scientific examples reveals that multiple realizability in this more radical sense is common to many 'cross-level' reductions (Hooker, 1981). And the beginnings of a general theory of 'token–token' intertheoretic reduction have been suggested (Hooker, 1981), including a precise formulation of the relation using the resources of mathematical set theory and topology (Bickle, 1998). Secondly, there is reason to wonder whether this more radical sense of multiple realizability about mental kinds is actually so widespread. Kim (1993), Bickle (1998), and Bechtel and Mundale (1999) highlight different methodological practices of (obviously successful) contemporary neuroscience that assume commonalities in how psychological states are realized within and across individuals and species.

MULTIPLE REALIZABILITY AND COGNITIVE SCIENCE

Because of its implications for reductionist programs, multiple realizability remains central to cognitive science. Might cognitivist theories, whose generalizations advert to representations and computations over their contents, reduce to developed neuroscientific theories? Does the recent trend in mainstream neuroscience towards cellular and molecular investigations and explanations potentially tell us anything about cognition and mind? Is reduction, as this relation obtains between theories in physics, chemistry, biochemistry, and molecular biology, the appropriate intertheoretic relation to seek and expect across the disciplines comprising the cognitive and brain sciences? Multiple realizability and its perceived consequences are central to these questions. The historical connection between multiple realizabilility, functionalism in the philosophy of mind, and the scientific project of

artificial intelligence (AI) is also important. Is AI research producing actual examples of alternatively realized cognition?

These fundamental questions in contemporary cognitive science are of more than just 'philosophical' interest. The concept, use, and critical scrutiny of multiple realizability appears to be evolving as philosophical issues are continually reformulated into 'foundational' questions within the cognitive and brain sciences.

Narrow Content

Intermediate article

Gabriel Segal, King's College London, London, UK

CONTENTS

Narrow content is the cognitive content of a psychological state that is conceptually and metaphysically independent of relations between the subject of the state and factors in the external environment.

BACKGROUND

Towards the end of the nineteenth century, the philosopher Gottlob Frege distinguished two kinds of representational content that symbols may have: sense and extension, or reference (Frege, 1892). The extension of a symbol is an object or a set of objects to which the symbol applies. For example, the extension of a proper name is its bearer, and the extension of a predicate is the set of things it is true of. Thus the extension of the name 'Gottlob Frege' is the man Gottlob Frege, and the extension of 'red' is the set of red objects. Frege saw that the notion of extension failed to account for important semantic distinctions, since coextensive symbols can have different meanings. For example, 'The Morning Star' and 'The Evening Star' both refer to the planet Venus, but they differ in meaning. Similarly, 'water' and 'H_2O' both extend over the same substance, but differ in meaning. Frege invoked the notion of sense to account for those aspects of literal meaning that go beyond extension.

According to Frege, the sense of a symbol is a mode of presentation of the symbol's extension, a way in which the extension may be presented in thought. Sense explains extension, in that a symbol has the extension it has because it has the sense it has. To understand an expression is to grasp its sense. And sense determines extension, which means that if two symbols have the same sense, they have the same extension.

Sense also accounts for the cognitive content associated with a symbol. For example, 'Hesperus is Hesperus' has different cognitive content from 'Hesperus is Phosphorus': the former is a tautology, while the latter expresses empirical knowledge. This was explained in terms of the sentences having different senses, or, in Frege's terminology, expressing different thoughts. Thoughts are also the contents of propositional attitudes, such as beliefs and desires. For example, to believe that Hesperus is Phosphorus is to stand in a certain cognitive relation to the thought expressed by the sentence 'Hesperus is Phosphorus'.

Hilary Putnam brought to light what he claimed was a common further assumption among philosophers of language who were sympathetic to the essentials of Frege's theory (Putnam, 1975). The assumption was that knowing the sense of a term is a matter of being in a certain 'narrow' psychological state. A narrow psychological state is one that is intrinsic to the subject of the state. It is one that does not require, as a matter of logical or metaphysical necessity, the existence of anything external to the subject. Being jealous of one's brother, for example, is not a narrow psychological state, because it is logically impossible to be in such a state unless one's brother exists.

Putnam presented an argument against the conjunction of the claims that grasping the sense of a term is being in a narrow psychological state and that sense determines extension. The argument was designed to show that narrow psychological states fail to determine extension, so one of the two claims is false. Putnam suggested it was the first one.

Putnam's argument hinges on a thought experiment. We are asked to compare Earth in 1750 with an imaginary planet called 'Twin Earth'. Earth in 1750 and Twin Earth are extremely similar. But they differ in that where Earth has H_2O, Twin Earth has a liquid that is superficially indistinguishable from H_2O but has a different chemical constitution, which we can call 'XYZ'. Since the chemical constitution of water was not known in 1750, nobody on Earth or Twin Earth would have been able to tell the difference between H_2O and XYZ. We then imagine a typical Earth subject, Oscar, and his Twin Earth counterpart, Twin

Oscar. Oscar and Twin Oscar, unlike real twins, are exact duplicates, molecule-for-molecule replicas of each other. They are identical in respect of all their intrinsic properties. (For the purposes of this experiment it is best to ignore the fact that humans are made out of water.)

Putnam then considered the question of whether the word 'water' meant the same thing in the twins' mouths. He argued that it did not. The argument is as follows. Our word 'water' applies to water, and water only. And water, according to our best scientific theory, is H_2O. XYZ is not H_2O, so it is not water. So 'water' is not true of XYZ. Moreover, 'water' had the same extension in 1750 as it has now. So Oscar's word 'water' extends over H_2O only and not over XYZ. By contrast, Twin Oscar's word 'water' extends over what he calls 'water', which is XYZ.

Since the twins are exact duplicates, their intrinsic properties are the same and so their narrow psychological states are the same. They differ only in their relations to their environments. But such purely relational matters are by definition irrelevant to narrow psychological states. So the twins are in the same narrow psychological state, but the word 'water' has different extensions in their mouths. So narrow psychological states do not determine extension.

Putnam argued further that, intuitively, the term 'water' has different meanings on 1750 Earth and Twin Earth. If Oscar and Twin Oscar had both pointed to a sample of XYZ and said 'that is water', then Oscar would have said something false and Twin Oscar would have said something true. And two sentences must differ in meaning, if one would be true and the other false in exactly the same circumstance.

If sense is to accord with the intuitive notion of meaning, then we should hold that their words have different senses. The conclusion is, then, that grasping the sense of a term is not just a matter of being in a certain narrow psychological state. For Oscar and Twin Oscar grasp different senses, but are in the same narrow psychological state.

Putnam was mainly concerned with the meanings of words and not with the content of psychological states. But many philosophers have extended his arguments to the latter, arguing that the twins' psychological states differ in content. For example, the belief that Oscar expresses when he says 'cold water is good to drink' differs in content from the belief that Twin Oscar expresses when he produces the same sounds. Contents that differ across Putnamian twins, which are not intrinsic to their subjects, are called 'broad'. Hence the claim is that at least some contents of psychological states are broad (e.g. Burge, 1982; McGinn, 1982).

Many (but not all) philosophers have felt that the notion of broad content does not capture the kind of content that appears in psychological explanation, and is deployed in the cognitive sciences. They hold that the kind of content that is or should be deployed in scientific psychology is intrinsic; i.e., narrow.

A spectrum of positions has emerged in the debate. At one end there is pure externalism, which holds that the only kind of content required for psychology is broad, and either is just extension, or, like Fregean sense, determines extension. Pure externalists hold further that at least some psychological states have only broad content and that there is no need to attribute to them an additional narrow content (e.g. Fodor, 1994; Burge, 1986). At the other end of the spectrum, pure internalism holds that the fundamental kind of content, and the only kind that matters for the purposes of scientific psychology, is narrow (e.g. Segal, 2000; Cummins, 1989). In the middle of the spectrum are two-factor theories, which accept a need for both broad and narrow contents, holding that all psychological states have a narrow content, and at least some have broad contents as well (e.g. Block, 1986; Loar, 1988; Fodor, 1987).

Each of these positions comes in a variety of different forms, and some philosophers might be classed as holding a borderline view. But a clear and fundamental point of dispute divides pure externalism from two-factor theories and pure internalism: the question of whether every psychological state has a narrow content.

ARGUMENTS FOR NARROW CONTENT

This section outlines three of the major arguments that all cognitive states have a narrow content.

Causal Explanation in Psychology

The first, and most widely discussed, argument for narrow content was offered by Fodor (1987). The gist of the argument is as follows. Psychology offers causal explanations. (1) A science that offers causal explanation should classify the states it describes by their causal powers. It should not classify states as different if they have identical causal powers. (2) The causal powers of twins' psychological states are identical. So, (3) psychology should count the twins' psychological states as the same. (4) Psychology classifies states in terms of their cognitive contents. So, (5) cognitive content is narrow.

The argument may be questioned at various points. For example, step 1 is questionable since the taxonomy of a science that offers causal explanations might be subject to a variety of different constraints, not all directly relevant to the causal powers of the items it describes. For example, historical evolutionary considerations may be relevant to biological taxonomy, even in branches of biology that offer causal explanations. Step 4 would be questioned by, for example, Stich (1983) and Egan (1995), who argue that at least some parts of cognitive science do not taxonomize by content. And Fodor himself has abandoned the argument, on the grounds that the kinds of twin cases in which classification by broad content would violate good taxonomic principles are either nomologically impossible or have other features that make them irrelevant to taxonomic issues (Fodor, 1994).

Interpretationism

A second argument for narrow content derives from a philosophical theory of the kind of cognitive content deployed in computational theories of cognition. This theory is sometimes called 'interpretationism'. It holds that cognitive content arises in a physical system when transitions among physical states of the system, including those of its components, may be systematically interpreted in a way that makes good sense of the activities both of the system as a whole and of its component parts.

Consider, for example, a conventional pocket calculator. If it receives a pair of numerals and a plus sign as inputs, it will produce a numeral as output. And it does so in such a way that if you were to interpret the numerals in the conventional manner, so that for example '2' represents the number two, the output numeral would always represent the sum of the input numerals. Hence the behavior of the system makes sense under this interpretation. Moreover, the same applies to states of the internal components of the calculator: these can be interpreted as performing calculations the results of which are combined to produce the overall result that the calculator delivers.

According to interpretationism, cognitive content just reduces to this sort of interpretability. Any interpretation that would serve to make sufficient sense of a system, in the manner described, would be valid and would be a correct assignment of cognitive content. Any cognitive state of a system will therefore have many cognitive contents, each one being part of a systematic overall interpretation of a set of cognitive states. (Sometimes certain provisos are added to rule out the assignment of cognitive contents to systems that are too simple.) Interpretationism is articulated by Haugeland (1978) and Cummins (1983, 1989).

Under a certain variety of interpretationism, content is narrow because the actual environment of a system is irrelevant to whether a candidate interpretation makes sense of the system's behavior. For example, an interpretation under which Oscar's 'water' concept was assigned the extension XYZ would be just as good as one that assigned it H_2O. Suppose that Oscar is thirsty and reaches for a glass of water. A conventional explanation might be that he believes the glass contains some water and wants to drink some water. But if we regard Oscar as a computational system, then we might just as well interpret the internal states of the system that cause Oscar's arm to move as representing the glass as containing XYZ and representing the goal of drinking some XYZ. And a better interpretation than either of those would be assign the 'water' concept an extension that included both H_2O and XYZ, since nothing in the cognitive system distinguishes between them.

The main problem with this account is the theory of content on which it rests. In particular, many find the very liberal assignment of cognitive contents implausible. It is commonly thought that each cognitive state has a unique cognitive content rather than a plethora of them.

Empty Extensions

A third argument for narrow content focuses on representations with empty extensions, such as representations of ghosts or phlogiston.

The ideas behind the argument are best understood in the context of a specific example. Take as our first subject someone, Ralph, who has never seen a real anaconda, but who has seen a picture of one in a book and read the accompanying description. We can conceive of a Twin Earth on which there are not and never have been any anacondas, nor any twin anacondas, and on which the term 'anaconda' is empty. Twin Ralph has seen a book just like the one Ralph saw. Twin Ralph's book is fictional but he does not know this.

The argument proceeds as follows. The representation Twin Ralph associates with 'anaconda' has a cognitive content. This cognitive content cannot depend on its relation to members of its extension, because there are none. Moreover, whatever accounts for the representation having its cognitive content is present on Earth as well, and applies to Ralph's corresponding representation. So Ralph's representation has that very cognitive content as

well (Segal, 2000). Assuming that the argument generalizes appropriately, the conclusion is that all mental representations have narrow content.

The last step of the argument may be questioned. For it could be that what accounts for the cognitive content of Twin Ralph's representation on the Twin Earth is not present on Earth as well. For it might be that the full account of how Twin Ralph's representation comes to have its cognitive content would include the fact that there are no snakes or other objects that stand in the right relations to the representation to endow it with a non-empty extension.

THEORIES OF NARROW CONTENT

Ordinary, commonsense psychological explanations typically ascribe content using propositional attitude reports; that is, sentences with forms like '*a* believes that *p*' and '*b* desires that *q*'. The content of the attitude is conveyed by the 'that' clauses. According to common intuitions, the contents so ascribed are broad, not narrow: 'Oscar believes that cold water is good to drink' ascribes to Oscar a belief with the content that cold water is good to drink; Twin Oscar does not have a belief with that content, so the content ascribed is broad. A defender of narrow content thus has to provide an account both of what narrow content is and of how it can be deployed in psychological explanation. We now look at three of the major accounts of narrow content, mentioning some of the problems with them.

Functional Role Accounts

The most popular accounts of narrow content are functional role accounts. The functional role of a mental representation is given by some selected aspects of its causal role, where the latter consists of the totality of potential causal relations that the representation enters into.

The basic idea behind functional role accounts is rather simple. Consider the mental representations of the two Oscars that correspond to their word 'water': their *water* representations. The two *water* representations share certain important causal characteristics. For example, visual presentations of typical samples of either H_2O or XYZ would typically cause either subject's *water* representation to appear in a belief state. If either subject is thirsty and has a representation of the form *there's some water in that glass in front of me* appearing in a belief state, then this representation will combine with others to cause the subject to reach out for the glass. More generally, the pattern of potential causal relations – with stimuli, other mental representations, and behavior – that the two representations enter into is the same. The idea is that causal relations of that sort constitute the representations' cognitive contents.

Functional role accounts face two related problems concerning the individuation of functional roles. Firstly, the account needs to distinguish those aspects of a representation's causal role that are relevant to its cognitive content from those that are not. For example, the causal roles of the representations of two subjects who differ in their short-term memory capacities will differ, since memory imposes constraints on the way representations can interact. A defender of a functional role account needs to decide whether this difference is to count as a difference of content, and then find a way of implementing the decision in the specification of functional roles (Segal, 2000).

Secondly, the account needs to provide a way of individuating functional roles that allows for meaningful comparisons across different subjects. The difficulty is that some causal properties of a psychological state depend upon other states with which it is associated. For example, if Ralph believes that anacondas are dangerous while Thelma believes they are not, then the belief that one is being confronted by an anaconda will tend to cause Ralph, but not Thelma, to retreat. Nevertheless, we might want to use the term 'anaconda' to frame psychological generalizations that apply to both subjects. It might be true to say, for example: 'Ralph and Thelma both believe that anacondas are very large snakes, indigenous to South America, which kill their prey by constriction.' The functionalist thus needs to find a way of classifying functional roles that abstracts away from the difference between Ralph's and Thelma's anaconda concepts and *allows for the generalization*. If this is not possible, then functional roles will not provide an appropriate way of grouping psychological states for the purposes of psychological explanation. See Fodor (1987) and Field (1976) for related discussion.

Character

A second account of narrow content has been offered (Fodor, 1987), which can be understood as a development of a kind of content originally proposed by David Kaplan (e.g. Kaplan, 1978), called 'character'. The idea of character arose in response to a problem for Frege's account of sense and extension that is in some ways similar to that illustrated by Putnam's Twin Earth argument. The

problem concerns indexical expressions, such as 'I', 'today', and 'that'. Indexical expressions have variable extensions: for example, utterances of 'today' on different days refer to different days. Since sense determines extension, utterances of indexicals with different extensions must have different senses. But the meaning of an indexical expression remains constant across different occasions of use: 'today' does not alter in meaning from day to day. Frege's account does not capture this constancy of meaning.

Kaplan proposed to capture the constant meaning of indexicals in terms of character. The character of an indexical can be understood as a function from contexts of utterance to extensions. A context can be thought of as a sequence of relevant items, such as speaker, time, and place. The character of 'today' maps any context *c* onto the day encompassing the time of *c*. The character of 'I' maps any context *c* onto the speaker of *c*.

Kaplan (following Perry, 1977) suggested that character might account for cognitive content. For example, suppose that two different people on different days say: 'It is my birthday today.' The utterances of 'my' and 'today' have different senses and different extensions. However, it is plausible that the two utterances express the same cognitive content. Since the words uttered have the same character, character remains a candidate for cognitive content.

Since 'water' is not an indexical expression, its extension does not vary across contexts of utterance, as these are normally construed. As a speaker moves from place to place and persists through time, the extension of his or her term 'water' does not change. Further, according to most thinkers, if Oscar were suddenly transported to Twin Earth, his term 'water' would still extend over H_2O. That is why, if he were confronted with a Twin Earth ocean and said 'that's water', he would be saying something false. Hence, character as originally conceived by Kaplan does not serve as narrow content. However, Fodor developed a generalization of the notion that was designed to meet the difficulty.

Fodor's idea was that if Oscar had been transported to Twin Earth and then stayed there for a long period, then his word 'water' would have come to extend over XYZ, rather than H_2O. This is because, after a sufficient period, he would have become a member of the Twin-English-speaking community and his use of the term 'water' would have become dominated by his interactions with XYZ. And it is those factors that are usually held to determine the extension of a term. The same ideas extend to Oscar's mental representation, *water*.

Fodor extended the idea of a context of utterance, or thought, to include what might be called a 'home environment'. A subject's home environment is the environment in which the subject has become embedded and which fixes the extensions of the subject's mental representations. Fodor's suggestion was that narrow content is a function from home environments to extensions. Oscar's and Twin Oscar's *water* representations have the same narrow content because they instantiate the same function from home environments to extensions. If Oscar had been in Twin Oscar's home environment, then his *water* representation would have extended over XYZ. If Twin Oscar had been in Oscar's home environment, then his *water* representation would have extended over H_2O. Since the two subjects are twins, the result generalizes: for any home environment *e*, Oscar and Twin Oscar's water representations would have the same extension in *e*.

Fodor's account of narrow content, like functional role accounts, faces the problem that it needs to provide a way of individuating narrow contents that allows for meaningful generalizations across subjects. For while it is reasonable to suppose that twins' representations will instantiate the same function from home environments to extensions, it is not clear whether the same would be true of any non-twinned subjects. Subjects whose conceptions of something differ slightly will probably have representations that would extend over different things in certain home environments, hence would have different narrow contents.

A second problem is that we have as yet no vocabulary for talking about these functions from home environments to extensions. The account needs to provide some such vocabulary as well as some explanation of how it would function in psychological generalizations.

Twin Earth Revisited

A third account of narrow content involves less of a departure from the traditional Fregean theory of content than the previous two accounts. This account rejects the standard intuitions about Twin Earth experiments. It denies that the extensions of twins' representations differ. For example, rather than holding that Oscar's water representation extends just over H_2O and that Twin Oscar's extends just over XYZ, it holds that both representations extend over both H_2O and XYZ. The extension of both representations consists in water-like substances generally. This account therefore allows that the cognitive content of a representation, like Fregean sense, determines its extension.

An advantage of this account over the previous ones is that it does not require any sweeping revisions to the vocabulary of psychology. It does require revision of some people's views about particular ascriptions of content that arise in respect of Twin Earth cases. (For example, rather than saying that Oscar believes that water is good to drink, one might say that Oscar believes that the watery stuff is good to drink.) The account does require a revision of certain aspects of commonsense psychology, but not the development of a new psychological vernacular.

One difficulty with this account of narrow content is that it cannot be applied to indexical representations. For different indexicals with the same narrow content have different extensions: when Oscar and Twin Oscar both think *it's hot here*, their thoughts have the same narrow content, but refer to different places. So the account would have to be combined with a separate theory of narrow content for indexicals. Segal (1989a) has attempted to provide such a theory.

NARROW CONTENT AND COGNITIVE SCIENCE

The arguments for narrow content presented in this article have been pitched at a high level of generality. Some of the debate in the philosophy of psychology has been at a more specific level. One can examine specific theories within cognitive science, and address the question of whether the kind of content deployed in these specific theories is narrow. The theory that has received the most attention is the computational theory of vision, as developed particularly by Marr (1982), and which has been discussed by Burge (1986), Segal (1989b, 1991), Egan (1991), Davies (1991), Butler (1996), and Wilson (1995). An advantage of this kind of debate is that different theories within cognitive science have, to an extent, their own particular methodologies and hence their own constraints on the attribution of content. It may therefore be easier to tell whether a specific theory deploys narrow (or broad) content than whether cognitive science in general does. As the various branches of cognitive science develop, issues about the width of content will become clearer.

Neural Correlates of Visual Consciousness

Intermediate article

Charles A Heywood, University of Durham, Durham, UK
A David Milner, University of Durham, Durham, UK

CONTENTS

The neural correlates of consciousness are those patterns of neural activity that are associated with subjective experience.

INTRODUCTION

The study of consciousness is thwarted both by the lack of an all-embracing definition and, because it is a private experience, its inaccessibility to objective measurement. Nevertheless, useful distinctions have been drawn between different varieties of consciousness (Block, 1995). Access (A)-consciousness refers to the ability to respond to, report or engage in higher-level activities such as reasoning, on the basis of the contents of a representation that resides in a person's brain. In contrast, phenomenal (P)-consciousness refers to the nature of subjective experience – that is, the quality of the bodily sensation, such as the shrillness of pitch or the glare of sunlight. Monitoring (M)-consciousness and self (S)-consciousness, as their names imply, refer to awareness of bodily sensations and awareness of oneself, respectively.

Scientific accounts of consciousness are mainly concerned with A- and P-consciousness, and fall into two broad classes of proposals with regard to their neural basis. The first class emphasizes the way in which information is represented in assemblies of neurons, and is likely to be more relevant to P-consciousness. The second class is more concerned with functional relationships between representations and the processes that they are engaged in, rather than the contents of the representations themselves, and is likely to include accounts that are more appropriate to A-consciousness.

The philosopher David Chalmers distinguishes between 'easy' and 'hard' problems (Chalmers, 1995). 'Easy' problems include questions about how people tell different sensory stimuli apart, attend to and react to them and produce verbal reports. Such questions, although difficult, are tractable because they concern objective mechanisms of the cognitive system that are explicable in terms of neural and computational mechanisms. For example, we have a tolerably good understanding of the mechanisms whereby different wavelengths of light are differentially absorbed by cone pigments in the retina and produce different neural signals for comparison and discrimination. What is absent is any understanding of why an intense long wavelength of light appears vivid red, or indeed why it looks like anything at all. This is the 'hard' problem – the problem of P-consciousness.

WHAT IS A NEURAL CORRELATE OF CONSCIOUSNESS?

Although it is generally accepted that understanding how physical states of the brain may give rise to conscious states presents philosophical and empirical problems whose solution is currently beyond our ability, that does not prevent the undertaking of a first empirical step in approaching this problem. This first step is to investigate what *correlations* may exist between brain states and mental states. The hoary question of causality would then be left for future investigators to grapple with. Although even this correlational question still has a long way to go before it can be answered fully and convincingly, scientists have begun to address it in recent years.

The most promising strategy so far has been to build on our current neuroscientific knowledge. This means that the question has to be focused on particular types of mental processes, rather than addressed broadly with regard to conscious states

in general. A distinction can readily be drawn between the neural events that underpin the *state*, or *level*, of consciousness and those from which the *content* of consciousness arises. Research pertaining to the former involves establishing which brain states correspond to coarse-grained behavioral states such as sleeping, dreaming, wakefulness or, more generally, levels of arousal. In contrast, the search for the neural correlate of consciousness has been chiefly concerned with the *content* of consciousness, namely the phenomenal properties of conscious experience. Phenomenal experience characteristically has modality-specific representational content (e.g., the vividness of colors or the salience of shapes experienced by the observer of a visual scene). The challenge, then, is to find the neural activity that is necessary and sufficient for our conscious perception of, for example, 'redness' or 'roundness'.

This is a different pursuit from identifying the neural events that determine whether we are visually conscious *per se*. The neural correlates of state consciousness are essentially arbitrary. Any pattern of neural activity may be associated with the state of being conscious, but in the case of the neural determinants of subjective visual experience, there is the additional requirement that some characteristic of the neural state must match the content of consciousness. In the latter case the neural state, mediated by the firing patterns of its constituent neurons, represents attributes of the external world. For example, cells in the visual pathways will preferentially respond to a particular orientation or speed of motion of a line segment. With the exception of the special case of visual illusions, such attributes are perceived veridically and are signaled by the neural responses of cells that are tuned to the particular orientation or speed of the visual stimulus falling in their receptive field.

RECENT RESEARCH ON NEURAL CORRELATES OF CONSCIOUSNESS

The above choice of examples from the visual modality is neither idiosyncratic nor merely fortuitous. The past 25 years have seen enormous breakthroughs in our knowledge of the neuroscience of visual processing, mainly through studies of the monkey, but also increasingly now through application and extension of this knowledge to the human brain. Accordingly, the Nobel laureate Francis Crick and his neurobiologist colleague Christof Koch have argued that the domain of visual perception offers the best way forward at the present time for pinning down consciousness (Crick and Koch, 1998). In other words, the question being addressed is 'What is it about the neural systems that mediate visual processing that makes their activity conscious?'. Needless to say, much visual processing goes on that is not accessible to consciousness. For example, we are not aware of what drives our visual reflexes, such as the pupillary reflex to light, nor are we typically aware (until after the event) of what guides automatic actions such as catching an object that we accidentally knock off a tabletop. In the realm of visual awareness, the rapidly alternating presentation of two equiluminant lights results in a stable fused percept, yet neurons in cortical area V1 respond to the fleeting color changes. A closely related question to the one above is therefore 'What is it about the neural systems that mediate visual processing that makes it conscious under some conditions but unconscious under others?'

One means of answering this question is by studying patients with brain damage who show a mismatch between the contents of visual awareness and the efficiency with which a visual stimulus can elicit an appropriate response. The story begins with the famous investigations of so-called 'blindsight' in patients with hemianopia. The neuropsychologist Larry Weiskrantz was the first to undertake systematic studies of this phenomenon, which refers to residual visual processing in individuals who have suffered damage to the primary visual cortex (usually now termed 'V1') on one side of the brain (Weiskrantz, 1986). Since in cases of this type there is a large area of the person's visual field which is subjectively 'blind', by definition any residual 'blindsight' occurs without concomitant visual awareness. We now know that blindsight can be manifested in a wide range of phenomena, ranging from visuomotor acts such as pointing to or reaching to grasp objects, to guesses about the shape or color of two-dimensional images. For example, a patient may be able to reach, or move his eyes, towards spots of light that are not subjectively 'seen', with surprising (although not normal) accuracy. He may prepare to grasp an object in his 'blind' visual field with approximately correct wrist orientation and handgrip size, despite not knowing anything about the object. The upshot of this field of research is that area V1 appears to be a *sine qua non* for visual awareness, but not for the trivial reason that it removes visual processing altogether, since the latter clearly still proceeds to a remarkable degree.

However, this does not of course mean that visual consciousness is *located* in V1. Indeed,

research on a different type of patient demonstrates that it is not. Patients with visual-form agnosia, who have typically suffered brain damage as a result of anoxia or carbon monoxide poisoning, have a profound loss of shape or form perception – that is, they are quite unable to name, describe or discriminate even simple geometric shapes. Yet despite their loss of awareness of shape, they often have a largely intact area V1, as shown both by magnetic resonance imaging (MRI) and by clinical testing of their visual fields. Clearly, therefore, V1 may be *necessary* for visual consciousness, but it is certainly not *sufficient* for it. It is only a part of the necessary circuitry. Furthermore, in one particular patient with visual-form agnosia, D.F., it has been found that her V1 is able to collaborate with other brain areas well enough to allow her to perform a very wide range of visuomotor acts with normal levels of accuracy (Milner, 1998). For example, she can reach out, form her grasp, avoid obstacles, walk around a cluttered environment, catch moving objects and move her eyes, all with apparent normality. This research shows that the areas underlying this processing beyond V1 (which are almost certainly located in the dorsal-stream areas of the parietal cortex) can operate well without their visual processing reaching awareness. Thus the simple formula 'V1 plus higher visual areas' does not add up to a sufficient recipe for visual awareness.

A clue as to where an ingredient in the recipe *may* be located beyond V1 is provided by the damage that is present in D.F.'s brain. It is located in front of V1, and functional MRI scanning shows that it interrupts the neural traffic between V1 and the temporal lobes at the sides of the brain. For some years these areas have been known to be intimately involved in the neural processing of the complex features of objects that allow us to recognize them. In physiological experiments conducted in awake animals, neurons in the inferior temporal cortex (ITC) of the monkey have been found to respond selectively to images such as faces, colored shapes, and the actions of others. They also send information to brain areas concerned with memory and affect. Nikos Logothetis and his colleagues (Leopold and Logothetis, 1996) have now demonstrated that the activity of these neurons is closely linked to the perceptual experience of the monkey. They have achieved this by training the monkey to 'report' manually which of two alternative images it sees on a screen in front of it. When incompatible images (e.g., a face and a house) are presented to the two eyes, a person does not see a fused combination of the two, but rather either a complete face or a complete house, the two percepts alternating at intervals of a few seconds. When the experimental animal faced such 'binocular rivalry', it reported an alternating awareness of the two images just as would be expected from human experience, and the responses of inferior temporal neurons followed these perceptual reports with a high correlation. In other words, despite the fact that the images on the screen remained unchanged, visual consciousness did change repeatedly, and these changes correlated with the firing of neurons in the ITC. Moreover, and importantly, the responses of cells in the primary visual cortex (V1) do not show such a correlation. When the monkey was presented with horizontal and vertical gratings under conditions of binocular rivalry, responses were recorded equally from those cells with horizontal and those with vertical receptive field preferences in area V1, notwithstanding the fact that the monkey reported only seeing, say, vertical gratings. The neuronal response in area V1 thus covaried with the retinal stimulus, not with the visual percept.

Previous research by Charles Gross and his colleagues had shown that neurons in the inferior temporal cortex depend on area V1 for their visual input. In the absence of V1, the neurons lost their visual responses. This would explain why damage to V1 in humans results in subjective blindness – the neurons in the ITC that seem to determine the contents of visual awareness would no longer receive the information that is needed to activate them. Can we then infer from these data that visual experience has its neural correlate in the firing of neurons in the inferior temporal cortex? The answer is not quite. Our visual experience is certainly severely compromised when this part of the brain is damaged or disconnected, as patient D.F. demonstrates. However, our visual experience is impaired when other parts of the brain are damaged as well.

Visuospatial neglect is a condition typically caused by damage (often following a stroke to the middle cerebral artery) to a region of the right hemisphere around the border between the parietal, occipital, and temporal lobes. The result is impoverishment, or even absence, of any awareness of the left side of visual space. However, unlike damage sustained by area V1, neglect is not limited to one side of the retina's view of the world. When patients with hemianopia move their eyes around, their blind half-field moves as well, so they can still manage to see everything that they want to see. However, the neglect patient *still* fails to see things on the left side, even when the eyes are moved to look there. What is lost from the

person's experience is thus not like any type of blindness, but rather something more abstract than that.

The work of the Italian neuropsychologist Edoardo Bisiach has shown just how abstract this loss can be (Bisiach and Luzzati, 1978). He discovered that many neglect patients in his home city of Milan could describe from memory the view across the Cathedral Square, including the cathedral itself and many of the famous buildings around the piazza. Remarkably, however, they would omit to mention buildings located on the left-hand side of their imagined view. Moreover, when asked to imagine standing with their backs to the cathedral, looking the opposite way, they would omit to mention buildings on the *other* side, now on their imagined left. In addition, Bisiach's compatriot, Guido Gainotti, found that many neglect patients may fail to process the left sides of objects even on the right ('good') side of their perceived visual space. These discoveries of 'imaginal' and 'object-based' neglect suggest that neglect is not something that affects the early stages of visual processing, or even the later stages of processing in the ITC where neurons appear to respond selectively to different categories of object. Those neurons may provide the items of furniture for our visual experience, but there must be a higher level of visual representation where this furniture is arranged and can be rearranged. It is at this stage that neglect seems to exert its effects.

Thus the phenomena of neglect suggest that there is a part of the posterior human right hemisphere where conscious scenes and even multi-component objects are constructed. Just as a television image may offer a long-range view of a landscape or a close-up of a single antique teapot, so this representational system in the brain seems to operate at different spatial scales depending on our needs. Consequently, damage to the system can affect whatever we happen to be looking at (or imagining), however large or small it may be. Why is just the left side of these representations affected? The answer may relate to the notable rarity of neglect phenomena after *left* hemisphere damage. It is suggested that there is a similar representational brain area in the posterior left hemisphere, but that it can represent only the right side of our perceptual experience. When its dominant partner in the right hemisphere has been destroyed, it has to do all of the representational work – and it can handle only the right side of space, and even then not all that well. Its efforts are what the neglect patient experiences as a depleted visual world. However, when the left hemisphere area itself is damaged there is no serious impairment of our perceptual experience, as the dominant partner on the right can handle the whole visual scene sufficiently well alone. (Interestingly, however, other types of mental experience may be affected by such left-hemisphere damage, such as our ability to comprehend or plan spoken sentences, perform mental arithmetic, or think using 'inner speech'.)

So is the parietotemporal cortex the seat of our conscious mental life? It certainly seems to play a critical role, but probably not alone. Many theorists (including Crick and Koch) have argued for the centrality of the prefrontal cortex (whose large size is reflected in the uniquely prominent foreheads that we see in the human species) in our conscious life. However, damage to the prefrontal cortex does not deprive people of their conscious experience. Instead, it causes problems in their ability to plan ahead, to foresee the consequences of their actions, and to abide by rules. In other words, damage to that region disrupts our ability to choose between different courses of action according to criteria that depend on abstract mental representations, as opposed to short-term goals.

So could there be a collaboration between that posterior representational system (which is damaged in neglect) and an anterior 'executive' system that is able to manipulate and interrogate those representations? The posterior system may be able to hold the arranged furniture of our mental imagery, but the anterior system might coordinate the arranging and rearranging of it. The anterior system might also play an essential role in the control of verbal processing in the left hemisphere. This general idea would fit well with the theories of cognitive psychologists such as Alan Baddeley and Tim Shallice.

METHODOLOGIES FOR FINDING NEURAL CORRELATES OF CONSCIOUSNESS

Of course, narrowing down the anatomical substrates of visual awareness is only the first step in the task of finding the neural correlates of visual awareness. It may tell us where to look, but not what we shall find there. For that purpose it will be necessary to use the types of refinements of single-neuron recording pioneered by Logothetis and his colleagues, hand in hand with the progressively more refined techniques of human functional neuroimaging that are now available. These may help us to inch further along the road. Indeed, functional magnetic resonance imaging (fMRI) has

been used to confirm the results of Logothetis in human observers, with the added benefit of monitoring whole-brain activity. Changes in frontal and parietal activity were also shown to correlate with changes in perception when subjects were confronted with a binocularly rivalrous display (Lumer *et al.*, 1998).

A further promising approach to distinguishing between brain regions involved in conscious and nonconscious perception is the use of visual masking. The rapid successive presentation of a visual stimulus and a pattern mask can abolish the subjective experience of the former. Yet it is well known that such unseen stimuli can have behavioral consequences. This provides a convenient method for distinguishing between brain regions involved in conscious and nonconscious processing in normal observers. For example, positive variations in blood flow, measured by positron emission tomography (PET), have been shown in the midbrain and amygdala in response to masked (and unseen) facial expressions of anger which had previously been associated with an aversive stimulus (Morris *et al.*, 1999). Subjects were shown angry faces either alone, or accompanied by an aversively loud noise. During scanning, brief presentation of a face was followed by a visual mask composed of a neutral facial expression. Despite failure to detect the emotional facial expression, the aversive stimulus elicited an autonomic response (an increased skin conductance response) and resulted in increased midbrain and amygdala activity. The emotional valence of a face was therefore conveyed in the absence of visual awareness. This suggests that a comparison of regions of activation during presentation of stimuli that straddle the masking threshold (i.e., those that are just above and just below the threshold for eliciting a conscious percept) would provide a promising means of establishing the neural activity related to visual awareness.

However, it may well be that substantial progress will have to await the development of completely new methodologies. One of the questions that will have to be addressed along the way is that of selective attention. It is a commonplace observation that the brain can process visual information to quite a high level without the products of that processing reaching the threshold of consciousness, simply because one's attention is directed elsewhere. Why does a given assembly of neurons achieve awareness on one occasion but not on another? What distinguishes these two neuronal states? At present we have little idea of the answers to these questions, but there have been several suggestions. For example, it could be that the assembly with the highest level of activation inhibits all others and emerges as the dominant one that determines our awareness at that point. Alternatively, it could be that relative neural 'timing' is at the heart of the matter. There is now quite good evidence for synchronous firing among separate neurons that participate together in response to visual patterns. It may be that the greater the degree of synchronous activity, the higher the probability that the percept will reach the level of consciousness. Of course, neither of these suggested correlations offers any explanation for the process whereby we can choose to attend to one rather than another object in the first place.

The search for neural correlates of consciousness is just beginning, but the results are promising. Recent results suggest that correlates can be found in the firing pattern of individual cells in neural assemblies. Future research will have to address the thornier questions not only of how consciousness emerges from such neural activity, but also of the function of consciousness itself.

Other Minds: The Problems

Intermediate article

Alec Hyslop, La Trobe University, Bundoora, Victoria, Australia

CONTENTS

The problem of other minds questions the basis of our knowledge that others have minds, and enquires into how our beliefs about the mental states and inner lives of others can be supported.

INTRODUCTION

Outside of psychopathology, we are all sure that other human beings are very like us. We are sure they think, they reason, they feel pain, feel happy, and so on. But what entitles us to such sureness? Anglo-American philosophy cannot agree on what underpins this most basic of human beliefs. Neither can Continental philosophy.

But this is more than a case of philosophers having some abstractly theoretical, even if deep, disagreement. The different theories affect our view of ourselves and our human situation. Broadly, there is a contest between those who see each individual as initially self-enclosed and needing to reach out to others, somehow, but condemned forever to remain separate; and those who see individuals as essentially social, communal beings, depending on others not merely for their existence, but for their very sense of themselves. Such a difference is fundamental to us as social beings. It has implications for how we live our lives, how we relate to other people, even how we vote.

What Anglo-American philosophy does agree on is what the problem of other minds is concerned with: namely, the basis of our knowledge about the mental states, the inner lives, of other human beings. What is agreed is that it is primarily an epistemological problem, concerned with how our beliefs about those mental states could be supported. Insofar as it is thought that there is a conceptual problem (how is it possible to acquire the concepts we have of mental states other than our own?) that problem is generally raised in the context of solving, or disposing of, the epistemological problem. Even those who, like Wittgenstein (1953), think there is no epistemological problem, agree that the issue is whether or not there is such a problem. This has not been the case within Continental philosophy. There the relevant writings are concerned with our experience of others, our relations with others, how others affect us, are essentially involved in our sense of ourselves, to the extent that often the line between philosophy and psychology seems blurred.

It is remarkable that there is no generally agreed solution to this great human problem. Probably the favored Anglo-American solution takes the form of a (scientific) inference to the best explanation: that other people have experiences is seen as the best explanation of their behavior.

What Generates the Problem?

We have a problem because of the asymmetry that exists between our own case and that of others. We often know directly that we are in a certain mental state. We never have this direct knowledge where others are concerned. The same asymmetry is responsible for the conceptual problem. How can we have the concept of experiences other than our own if our own experiences are the only experiences we know directly to exist?

HISTORY

The remarkable fact about the other minds problem is that it was established as a philosophical problem only as recently as the nineteenth century, when John Stuart Mill (1865) gave us his version of the analogical inference to other minds. Increasing dissatisfaction with the analogical inference culminated within Anglo-American philosophy, strongly influenced by Wittgenstein, in the use of the notion of criterial evidence to deal with the problem. This happened about the middle of the twentieth century. Independently, on the other side of the Channel, Sartre (e.g. 1958) can be seen as engaged in a similar line of thought. Subsequently, and independently again, other elements of Sartre's

thought, stressing the interdependence of the notions of self and other, are mirrored in Anglo-American philosophy, though expressed very differently. More recently, in Anglo-American philosophy, other minds have been regarded as on a par with the theoretical entities of science and supported by means of a scientific inference (Pargetter, 1984). This is probably the currently most favored view in Anglo-American philosophy.

APPROACHES TO THE PROBLEM OF OTHER MINDS

The Analogical Inference to Other Minds

The traditional but now unfashionable solution to the problem of other minds has been an analogical argument. I know that others are very like me in all sorts of ways. I know directly that I have thoughts, feelings, sensations, and the like. So I am enabled to infer that other people also have beliefs, experiences, and emotions. In short, it is with others as it is with me.

This conclusion is, however, impossible to check, not just in fact, but in principle. But where this used to be seen as problematic, it now seems to be regarded as benign, probably because most of the hypotheses so indispensable to science are in practice not such that they can ever be directly verified. However, that my experience is the indispensable centrepiece of this inference, occasions the supposedly fatal objection to this analogical inference, that it is a generalization from one case and therefore unsound, indeed hopeless. This feature is seen as so far from benign that it seems all other responses to the problem of other minds seek to avoid any evidential reliance on our own experience. Approaches to the problem as disparate as applying scientific inference to others, the criterial approach, and virtually all of the responses in Continental philosophy, could be seen as driven by this desideratum.

However, its supporters meet the one-case objection head on, standardly arguing that the requirement for more than one case is to establish a causal link between events. It is claimed that the relevant causal link, involving mental states, can be known to hold from one's own case.

Other Minds as Theoretical Entities

This is most likely, among Anglo-American philosophers, and cognitive scientists, to be the preferred solution to the problem of other minds. A scientific inference is utilized: the best explanation for the way other human beings behave is that they behave as they do because of their mental states. Crucially, no evidence depending on what we know from our own case is used to support this inference.

It has been argued against this approach that the intrinsic content of mental states, how they are experienced, in particular phenomenal properties such as the hurtfulness of pain, cannot be supported by this method. That content can only be filled in by an appeal to one's own case (Hyslop, 1976).

Criteria and Other Minds

Criterialists have attempted to avoid the one-case objection by insisting that the connection between behavior and mental states is neither entailment (as in behaviorism) nor an inductive inference. The connection is claimed to be conceptual and such a connection is characterized as criterial. It has been claimed by some that such a non-inferential connection is required if we are to have any concept of the experiences of others. A claim that itching is conceptually linked to scratching would be an example of such a criterial claim. It is further claimed that scratching is, thereby, known to be evidence of itching, independently of any observed correlations.

Against this conceptual approach it is argued that if there is no entailment directly from the observed behavior to the unobserved inner states to which they are conceptually linked, and there is no appeal to some form of inductive inference, then we are left with the gap. The gap cannot be crossed by *fiat*, as it were.

One way of understanding what has been called the attitudinal approach to other minds is to see it as going beyond other uses of criteria in insisting that our very conception of other human figures is that they have experiences. That is our attitude to them, built in as it were. That is how we perceive them. It is immediate, noninferential, preceding any belief, deeper than mere belief. This view seems, however, not to avoid the criterial gap. Our conceptions might be mistaken. That there are such mistaken attitudes to things and people seems clear (Hyslop, 1995).

PROBLEMS OF OTHER MINDS AND COGNITIVE SCIENCE

Can machines think? What exactly is it to think? Is the Turing test appropriate? Are there significant

differences between different mental states? To what extent, if any, are mental states observable? Are there respects in which, say, emotional states are more inaccessible than beliefs? To what extent is our access to the 'inner' lives of others mediated by their behavior, dependent on what they say, dependent on our capacity to 'read' expressions, dependent on our capacity to understand 'body language', dependent on our imaginative capacities? (*See* **Turing Test**)

These questions are all canvassed inside the other minds problem, to varying degrees. However, some general points can be made. Most discussion is centered on how we are to justify our belief that other human beings have mental lives like our own. Much less attention has been given to whether we have day-to-day practical knowledge about what other people are thinking and feeling in particular cases. Also, the concern is to justify the beliefs we have, not to describe how we acquire them, though this distinction is less honored in Continental philosophy. Continental philosophy differs also in that its focus is on the existence of other human subjects, individuals, persons, rather than (merely) their varied mental states, whereas Anglo-American philosophy confines itself almost entirely to justifying our belief that other human bodies have mental states attaching to them.

A radical response to the problem is to deny, by insisting that we have in some sense direct knowledge of the mental states of others, that the claimed asymmetry between ourselves and others exists. However, some theories of mind have endorsed this, or near enough. Continental philosophy has contested the asymmetry in arguing that awareness of others precedes, or is inseparable from, our having a concept of ourselves.

Even if the asymmetry is accepted, it has been almost universally thought that only a traditional dualist view of the mind has a seriously challenging problem of other minds. Behaviorism is either thought to have no problem at all, or, if it does, nevertheless has no difficulty in solving the problem. Behavior is, after all, observable.

Functionalism is a currently fashionable theory of mind, probably the preferred view of the cognitive scientist, that is thought to have the problem but in a comparatively easy form. Mental states are viewed as internal states differentiated by their various roles, and particularly by the behavior they give rise to, having no other features relevant to their being the mental states they are. It is then comparatively straightforward to infer that such internal states exist, given the appropriate behavioral evidence. Eliminative materialists, denying, heroically, that mental states exist, seem not to have any problem: no minds, no other minds.

However, it has been argued that the other minds problem cannot be so easily evaded or downgraded. Any theory of mind has to be true of one's own mind and other minds, so such a theory cannot, it has been argued, be used to solve the other minds problem. To assume that, say, functionalism is true, in the context of the problem of other minds, is to assume that it holds of minds in general. That would seem to assume there are other minds and the theory fits them. That would seem to ignore the problem, not solve it (Hyslop, 1995).

It has also been insisted that a theory of mind, covering all minds, needs to embrace the theorist's mind as well as other minds. So the evidence (generally implicit) for the theory will include the theorist's experience. That is the only way direct supporting evidence can be obtained.

Pain, Philosophical Issues about

Advanced article

Valerie Gray Hardcastle, Virginia Tech, Blacksburg, Virginia, USA

CONTENTS

There is no consistent philosophical view concerning the nature of pain, how to understand it, or what an understanding of pain might mean for philosophy of mind.

PHILOSOPHICAL VIEWS OF PAIN

Just about every conceivable position concerning the nature of pain is currently held today by some leading thinker or other. Each of these positions has become grist for someone's mill in arguing either that pain is a paradigm instance of a conscious state or that pain is a special case and should not be included in any general theory of consciousness.

Subjective Views

Some philosophers and psychologists hold that pain is completely subjective; it is either essentially private and completely mysterious, or it does not correlate with any biological markers but is completely nonmysterious. The International Association for the Study of Pain (IASP), the formal organization charged with defining pain, has articulated a paradigm subjective view. They write:

> Pain is always subjective … Many people report pain in the absence of tissue damage or any pathophysiological cause; usually this happens for psychological reasons. There is usually no way to distinguish their experience from that due to tissue damage if we take the subjective report … [Pain] … is always a psychological state. (1986)

However, if one holds that pain does not correlate in some way with some sort of bodily twitch, then one becomes a dualist. If pain is merely a private experience, and that experience has no consistent underlying physical cause or correlate, then we lose any interesting connection between the mind and the body over pain.

Philosophers are used to confronting the sorts of issues the IASP comes up against in defining pain. They eschew dualism by retreating to so-called token–token identity theory. Every experience in me is correlated with – identical to – some event or other in my brain. And every experience in you is correlated with – identical to – some event or other in your brain. But, if the subjectivists are right, there is no identifiable neural activity that is the same across all experiences of a migraine, for example. There is no brain correlate for the type 'having a migraine headache'. We can talk about generic headache experiences only from a level of abstraction above brain activity: namely, from the perspective of the mind and its cognitive states.

To uncover the regularities underlying certain brain areas and pain processing, we need repeatable instances of some sort of neural activity being connected to some sort of perceptual experience. However, if we deny type–type identity for larger brain structures across organisms, then at the same time we are denying ourselves any hope of discovering mind–brain connections. For we can generalize to anything from only one instance, and mental event–physical state correlations taken one at a time are all a robust token–token identity theory allows.

At the same time, functionalists of this ilk generally don't want to disconnect the mind entirely from the brain. We believe that there are areas in the brain dedicated largely to pain processing, just as there are other areas dedicated to vision, audition, touch, and so forth. We believe that these areas are basically the same across humans, despite individual variation. Thus, even though a strict type–type identity might fail for particular sensory experiences, it still underlies our views of our sensory systems taken as a whole. Types in science are allowed some play in them. They have to or we would have no mechanism by which to pick out any sort of cognitive processing in the brain at all.

All these lessons are missed by proponents of the subjective view, for they identify pain with the experience of pain and then explicitly deny that that experience has any correlation with any

particular bodily reaction. But since they want to be materialists interested in a scientific understanding of pain, they will have to permit generalizations connecting something in the body with the sensation of pain.

Objective Views

Other philosophers and neurophysiologists argue that pain is completely objective; it is either intrinsic to the injured body part, a functional state, a set of behavioral reactions, or a type of perception. Pain is something we can measure about our bodies or our behavior. As a result, its connection to our mentality, to our sensations of pain, is secondary at best. We might recognize that the pain is there in terms of how it feels to us – the skin burns, for example. For example, according to objective views that take pain as intrinsic to the injured body part, the pain itself is in the tissue. Hence, our beliefs or judgments about the condition of the tissue are derivative. That is, we use the nociceptive or pain information we get from the periphery to infer we are in pain.

Similarly, if pain is understood as a type of perceptual process, then it works no differently than vision or olfaction. We receive some sort of perceptual input on our transducers, manipulate that information in our brains, and then use that manipulated information to alter motor reactions, surrounding mental states, and what have you. Part of the manipulated information might come into conscious awareness, but that sensation would only comprise a subset of what is meant by pain processing. According to this view, our conscious experience of pain, the damaged tissue itself, and our bodily and emotional reactions are fundamental to pain processing. Each is one component in a larger process. Working together, these components take pressure, temperature, and chemical readings of our tissues and use this information to track what is happening in our bodies. They function together as a single complex system to monitor our tissues in order to promote the welfare of our bodies.

In these cases, and most other instances of the objective view, pain is something entirely physical. Prima facie, it appears that the states or processes identified with pain could occur without any awareness of them at all. Most objective views of pain have the unintuitive consequence of divorcing pain from sensations of pain or making the mental events associated with pain processing secondary to and dependent upon the pain processing itself.

Other Views

There are a few objectivist philosophers who hold that pain is not a purely physical event. Instead, it is something like an attitudinal relation. Pain requires both a bodily state and then cognition over that state. Pain itself is the attitude, the belief, we have regarding our bodily condition. This approach gets around the intuitive difficulties of the objective views by identifying pain with the consequent mental state. 'Pain' then just refers to the mental event associated with pain processing. According to this view, we have pain processing and then pain proper.

CENTRAL PHILOSOPHICAL ISSUES ABOUT PAIN

There are three large philosophical difficulties in defending any of the theories about pain processing outlined above: the problem of mental causation, the problem of naturalizing content, and the threat of eliminativism.

The Difficulty with Mental Causation

The difficulty with mental causation is roughly as follows. If I drop a hammer on my foot and subsequently experience pain, that experience is the proximal cause of my writhing, cursing, and gnashing of teeth. Dropping a hammer on my foot leads to pain behavior only if it causes in me the sensation of pain and the belief that I am in pain. If I were unconscious or otherwise oblivious to my surroundings, then I could not sense any pain, nor could I believe that I were in pain. Nor could I manifest any pain behaviors.

On the other hand, if we take a neurophysiological view of the entire hammer-dropping incident, then it seems as though we should be able to explain exactly the same events without appealing to mentality or any sort of psychological entities at all. We might talk about the intense pressure of the hammer head on my foot stimulating various nerve endings which causes action potentials to travel up my leg to my spinal column, where other nerves are then stimulated to fire. These nerves transmit the firing pattern to other nerves, and so it goes until nerves that cause muscles to contract are likewise stimulated and you get the writhing, wincing, and teeth-gnashing behavior. Why doesn't the possibility of this sort of more precise, purely physical explanation rule out the higher level, more general mental account? Or, why doesn't it make the mental account nothing more than a placeholder

until we get the details of our central nervous system figured out? As long as one is persuaded by reductionism, then pain provides an exemplar case for suggesting why psychological explanations appear so tricky.

There is some evidence that depression is related to pain processing. One view is that untreatable chronic pain causes depression, which in turn increases the sensations of pain. This is a (grossly oversimplified) mentalistic explanation of how a mood causally interacts with other psychological states. At the same time, we know that depression is correlated with a decrease in the neurotransmitter serotonin. Persons suffering from chronic pain also show a decrease in their levels of serotonin. But, if depression is (maybe) just an imbalance and a neurotransmitter and sensations of pain are some neural state or other, then why shouldn't we (someday) explain the relation between depression and pain in terms of neurotransmitters affecting neural activity? Why isn't the mentalistic explanation just a stand-in until we have all the more basic neurphysiological details under control?

Mental events causing other mental events seems to be a natural part of our explanatory world. At the same time, accounts of mental causation appear to be nothing over and above a sloppy characterization of more fine-grained and little understood physical details. The difficulty for those who would like to keep the mind intact as an explanatory unit is in explicating how it is that mental causation has a legitimate place in our understanding of the universe, above and beyond being a surrogate for the real causal story. Why shouldn't we claim that our ultimate goal in explaining pain is to redescribe our pain and other related mental states in terms of their neural instantiations, thereby eliminating the former in favor of the latter?

Naturalizing Content

Though most philosophers of mind treat mental causation separately from issues concerning reference, explaining the causal powers of the mind really piggybacks on the problem of naturalizing content. What makes the question of mental causality peculiar is that the content of mental states is relevant to their efficacy. I wince and nurse my foot because my corresponding mental states are about my foot. If they were about something else, then most likely I would be doing something else. To explain exactly how it is that mental events cause other things, we are first going to have to explain how it is that they refer. That is, to justify privileging a mentalistic explanation of sensations and beliefs over a lower-level physicalistic one of neuronal firing patterns or ionic flow in our scientific explanations, we first have to have a clear grasp about what we mean by mental events being contentful, since their content is what is causally relevant to our subsequent behavior.

The matter of the power of the content of beliefs and other mental states is quite important to understanding pain processing. What one is thinking and believing about the world strongly influences how much pain one feels. Athletes intently focusing on their game can break large bones and not even notice. But the same athletes, alone in their living rooms, will writhe on the floor if they stub their toes. Chronic pain patients can be trained to diminish their sensation of pain by changing their focus of attention and their beliefs about death and disease. Those suffering congenital indifference to pain often lead short and unpleasant lives because they can't sense painful stimuli, nor can they form appropriate beliefs about what the vague tinglings that they do feel mean. How pain feels to us depends to a large extent on our current doxastic surround. Hence, understanding pain requires an understanding of what beliefs and desires (and other mental states) are and how they refer.

Eliminativism

One implication of current scientific theories of pain is that our folkways of describing our pains are inadequate and we would be better off eliminating them from our everyday practices. The claim is that our folkways of talking about pain comprise a rough and ready theory of pain. This theory assumes that pains are identical to the sensations of pain and that the word 'pain' can capture the essence of that sensation. From the perspective of some objective views of pain, both assumptions are dubious. Pain processing is enormously complicated and our sensations of pain form only a tiny subset of what these processors do. But even if we focus exclusively on our sensations, since these are most important to our folkways of being, our folk theory is still inadequate. We simply do not have the language to express all the dimensions of our pain experiences. The descriptors we use are either metaphorical or non-existent. Our folk theory of pain needs to be replaced by something commensurate with the phenomenology.

Consider this: not only can we distinguish between the sensory, affective, and cognitive dimensions of pain phenomenologically, we can also

manipulate them independently of one another. We can feel a shooting pain in our leg, but not suffer in the least from it; we can be in agony from pain, without feeling any particular sensation localized to any part of our body. We could simply decide by fiat that 'pain' is going to refer to the localized sensations, or we could just decide that 'pain' is going to refer to the suffering. But either way, we do violence to our folk notion of pain which requires that a single simple sense datum seems to occur in some place and also be unpleasant.

In response to these sorts of claim, some have argued that our folk views of pain do not constitute a theory in any meaningful sense. Some believe that we know certain introspective facts indubitably. Pain is touted as one of those things. Perhaps there are are some sensory states, like pain, about which people have special first-person apprehension. We just know when we are in pain; no inference of judgment is required.

However, it is quite easy to demonstrate that our introspective knowledge of pain can be mistaken. If we burn our hand by touching something hot, we jerk our hand away from the heat source. This is a reflex action; the nociceptive information travels up our arm to the spinal column and then back down again. It takes about 20–40 milliseconds from stimulus to behavior. The information also travels up the spinal column to the brain. We feel the burn as well. Unlike the reflex movement, this processing is more complicated and it takes about 200–500 milliseconds from stimulus to perception, a full order of magnitude longer.

Nevertheless, if we introspectively report on what the incident feels like, we say that we moved our hand away after we felt the pain; feeling pain initiated the motor sequence. For whatever reason, our brains backdate our pain sensations so that they seem causally relevant to our reflex behavior. But clearly we can't cause the effect after it occurs, so our introspective report has to be wrong. We don't have special, first-person knowledge of our pains. Whatever knowledge we do have is embedded and informed by a conceptual framework of our brains' devising. Despite protests to the contrary, our pain experiences have all the earmarks of being at least proto-theoretical in nature.

Other detractors point out that even if a completed science of pain does not use folk terms for pain, that would not entail that those sorts of mental states do not exist; they just would not be referred to in scientific discourse. Our notion of pain would be analogous to our ideas about tables and chairs, germs and gems, and birthday presents and birthday cake. These are perfectly legitimate terms. We just don't use them in science. Being cultural artifacts of one stripe or another, they do not refer to things about which we would have laws. We might not have a mental science or laws about pains, but our folk psychology could still be used as it is now, in our everyday explanations of our behavior.

There is something undoubtedly right about this charge. In many ways, pain experiences are environmentally determined. Puppies raised without ever experiencing pain and without ever seeing any other dog in pain will exhibit no pain behavior. They will repeatedly sniff a lighted match without fear and then show no reaction when burned. Children learn both pain behaviors and the emotional concomitants to pain from the reactions of others around them. Expressions of pain and reports of sensation and experience are significantly different across cultures. Much of our experience of pain and how we react to and express these experiences is socially relative, a cultural artifact of sorts.

However, social relativity is not enough to show that our folkways of understanding pain are adequate. Different cultures have different experiences; they also have different ways of understanding these experiences. Nevertheless, the burden falls on the folk psychologist to demonstrate how our folk theories of pain are actually successful. This work has not yet begun.

THE ETHICS OF PAIN TREATMENT

One of the most hotly debated subjects in pediatric care concerns whether infants are insensitive to pain. The presumption historically has been that because young infants are not conscious, they cannot sense pain. As a result, analgesics and anesthetics are rarely used, even in the most invasive of procedures.

At first, this presumption of insensitivity is curious because infants' reactions to painful stimuli are well documented. Even premature neonates exhibit stress responses, hormonal fluctuations, and slowed recovery to painful interventions. In fact, we know that the afferent nociceptive system is up and running by 29 weeks' gestation, but that pain inhibitory systems don't come into operation until later. If anything, infants should be more sensitive to pain than adults. We can at least say that, by all indications, infants are sensitive to pain in some sense or other.

However, the question for many doctors is whether infants are aware of their pain. Some argue that unless neonates can consciously

apprehend pain, then any sorts of response they give to noxious stimuli are merely reflexes. Hence, we have no reason to treat infants' pain, since the infants can't feel anything.

Suppose they are right, even though there is much that goes on in our brains that is neither conscious nor mere reflex. It is still the case that infants react to pain, both behaviorally and physiologically, that these reactions can be modified with relatively simple treatments, and that treating pain has an impact on recovery. We know that early exposure to pain, whether remembered or not, affects later experiences of and reactions to pain by altering the developmental course of the nervous system. Infants, like other newborn animals, learn to attach particular meanings, or emotions, or importance to particular experiences in virtue of what is associated with those experiences. This sort of behavioral malleability is very important if an organism is going to survive in a complex environment. Consequently, manipulating early experiences can have drastic effects later on, as animal studies show. Merely by changing the smells associated with suckling, scientists can alter adult sexual behavior in male rats, for example. Similar changes occur with pain processing in young infants. Nociceptive stimuli increase the size of the somatic receptive fields for neurons sensitive to pain and help maintain dendritic connections that would otherwise be eliminated over time. Perhaps, as some believe, chronic pain and hypersensitivity can result from early acute pain episodes, in the list of how the neural receptors change. Early pain experiences have been shown to influence later personality and temperament. Something as common as circumcision can have lasting effects on pain sensitivity if done without anesthesia.

We must conclude that given the impact early pain processing can have on later development, we have every reason to prevent infant pain, even if it feels dissimilar to our own, even if it feels like nothing at all to the infant. Whether infants consciously experience pain – and the degree to which they may or may not be aware of some noxious stimulus or their own suffering – is a red herring. Available evidence converges around the idea that infants process pain, though perhaps not in the same way adults do. This processing has an impact on current behavior and later development. Because this influence is generally negative, insofar as we are able to prevent or alleviate some of their pain, we should do so.

Pain

Intermediate article

C Richard Chapman, University of Utah, Salt Lake City, Utah, USA

CONTENTS

Pain is an unpleasant sensory and emotional bodily awareness that normally serves a protective function by informing us of tissue damage.

DEFINITIONS OF PAIN AND RELATED CONCEPTS

Although it is familiar to everyone, pain is difficult to define scientifically. The International Association for the Study of Pain (IASP) offered the following definition in 1979, and it remains the current standard for the field: 'An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.'

In referring to pain as an experience, the IASP definition recognizes the private and individual nature of pain, that pain can occur only in a conscious individual, and that pain exists not at the site of injury but as a complex phenomenon occurring at the level of the brain. It avoids the common error of characterizing pain as a simple or primitive sensation. Moreover, it recognizes that the experience of pain has emotional as well as sensory features. Consensus exists among pain researchers and clinicians that pain has both sensory and emotional dimensions and many would add a cognitive dimension to acknowledge that pain involves attention and interpretation. Normally, pain is associated with tissue damage or potential tissue damage, but the definition wisely leaves open the possibility that pain can exist in the absence of tissue damage. A person may experience pain and describe it in terms of tissue damage, whether or not such damage exists.

The IASP definition has stood the test of time, but it will eventually give way to a revised definition. It does not accommodate neonates, infants, and small children, who perceive and react to tissue damage despite their ability to form a complex perception and describe it. Nor can it account adequately for the pain of a cognitively impaired person, who cannot report the pain but emits behaviors consistent with pain, such as grimacing and guarding.

Related Terminology

Several other terms related to pain merit attention and definition. Nociceptors are sensory end organs that are preferentially sensitive to tissue trauma (Figure 1). They respond to mechanical, thermal, electrical, and chemical stimulation that damages, or threatens to damage, tissue. Chemical changes in their immediate environment, such as those that occur with inflammation, can sensitize nociceptors and lower their thresholds for firing. Their activation occasions nonconscious neural signaling, termed 'nociception', which causes reflexes at the level of the spinal cord along with activation of multiple structures in the brainstem, the limbic (or emotional) brain, and the cortex.

Most pain results from nociception, but pain can also arise from damaged neural structures that generate abnormal neural transmission. Pain arising from damaged nerves or nervous structures is neuropathic pain. Patients with this diagnosis often misidentify the origin of the pain, believing

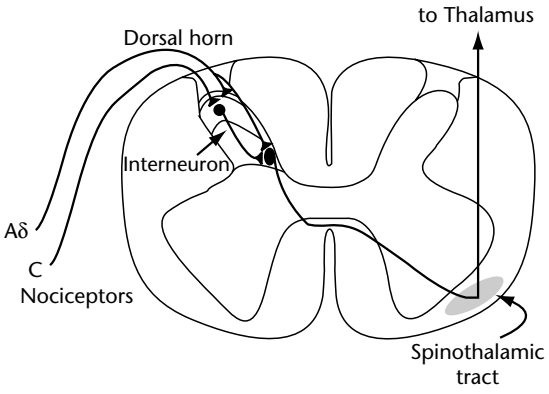

Figure 1. Cross-section of the spinal cord showing nociceptive primary afferents, interneurons, and the spinothalamic tract.

that it comes from a healthy part of the body, although it actually comes from damage to a neural pathway located between a particular body area and the brain. In some cases pain can occur because of damage to the spinal cord or the brain itself. This type of central pain constitutes a central pain state. In the past, physicians sometimes misidentified some central pain states as psychogenic, or arising from psychodynamic origins. True psychogenic pain is extremely rare.

The Relationship of Pain to Nociception

Although nociception is the normal and most common cause of pain, there is a surprisingly poor correspondence in clinical settings between the reported magnitude of pain and observable tissue trauma. This occurs because pain is a complex perception and many factors besides nociception contribute to the quality, expectation, and duration of pain. For example, the correlation between the extent of tissue trauma during surgery and the magnitude of pain that patients report afterwards is weak, and it is difficult to predict pain magnitude well from the depth or area of a burn injury.

When nociceptors become sensitized due to excessive stimulation or chemical irritation, they lower their thresholds for firing and increase their responses to previously painful stimuli. For example, a mild burn injury can cause the affected skin to generate strong pain to mild noxious irritation. This condition, characterized by excessive or exaggerated pain following a painful stimulus is termed 'hyperalgesia'. In some cases, nociceptors and related higher order structures can become so sensitized that they respond to harmless stimuli such as light touch. This is termed 'allodynia'. Hyperalgesia and allodynia distort the relationship between tissue damage itself and the amount of pain that the injured person perceives.

A few persons are born with a congenital absence of the ability to feel pain. Without medical supervision, such people tend to suffer grave injuries without complaint and die prematurely. As children, they may fracture bones to astonish playmates, take significant physical risks, and they may fail to notice and complain of some potentially life threatening disease conditions such as appendicitis. Such cases illustrate the protective function that pain serves in everyday life.

When pain is chronic, or long lasting, the relationship of pain and related disability to a nociceptive origin or neuropathy is often weak or absent. Millions of persons in industrialized countries are partially or wholly disabled by pain that, although vividly real to the patient, has no identifiable cause or is associated with negligible tissue damage. Conversely, various medical diagnostic procedures routinely reveal structural damage or other lesions that should cause nociception in patients who deny suffering pain. These observations indicate that chronic pain is more complex than simple awareness of nociception.

Clearly, pain and nociception are not synonyms. Nociception is nonconscious neural traffic originating with tissue trauma; it may or may not lead to a pain experience. Pain is a complex, unpleasant bodily awareness with sensory and emotional features, to which the person experiencing it ascribes meaning according to immediate context, past history, expectation, and culture. It may, or may not, indicate actual tissue damage, and the magnitude of the pain is rarely a good indicator of the clinical significance of the tissue damage causing the pain.

Analgesia and Pain Relief

Analgesia and pain relief are related but not identical concepts. The term 'analgesia' strictly denotes a complete inability to perceive pain when tissue damage occurs. In common use, however, it typically refers to a reduction in pain. An analgesic drug is one that reduces rather than fully eliminates pain. Pain relief refers to the reduction or elimination of a painful condition. A treatment might cause a person's headache to disappear (pain relief) but fail to cause analgesia for a painful event such as a needle puncture. Conversely, the injection of an analgesic drug might reduce a person's sensitivity to normally painful events like needle puncture but fail to reduce the headache.

ANATOMY AND PHYSIOLOGY OF PAIN

Detection of Tissue Injury

Nociceptors are the free nerve endings of either myelinated, small-diameter (Aδ) or unmyelinated (C) fiber axons (Figure 1). Aδ fibers conduct more rapidly and generate a different quality of sensation than the C fibers. Pinprick at the foot will first produce a fast pain with a bright, sharp quality that lasts no more than 50 milliseconds, followed by a painless interval of approximately one second, and then, a slow pain with a burning quality of roughly one-second duration. Aδ fibers mediate the fast pain and C fibers the slow pain. These nociceptive afferents supply skin, subcutaneous tissue, joints, periosteum, teeth, meninges, viscera, muscles, and blood vessels.

Most nociceptors are polymodal, responding to mechanical stimuli such as crush, extreme thermal changes, and chemical irritation. They encode localization and stimulus intensity. However, visceral nociceptors do not respond to cutting, pinching or burning. Instead, they respond to abnormal distension or contraction of the muscle walls of hollow viscera, the rapid stretching of capsules of solid organs, anoxemia of smooth muscles, traction or compression of vessels or ligaments, and chemical irritation. Pain originating in visceral nociception commonly manifests as a pain on the surface of the body (termed 'referred pain'), and sometimes the location of the pain is distant from the site of pathology. Ischemia in heart muscle, for example, causes pain that patients often experience in the pectoral muscles of the chest or as radiating down the left arm into the little finger and ring fingers.

With repeated noxious stimulation, nociceptors may sensitize, lowering their threshold for firing, decreasing their response latency, and persisting in their firing after a stimulus event terminates. The site of injury itself becomes extraordinarily sensitive, or hyperalgesic, and surrounding, uninjured tissue becomes increasingly sensitive as a result of central nervous system changes. This is called 'peripheral sensitization'.

In most cases of natural injury, inflammation develops at the site of the injury as a protective response. Increased blood flow produces redness and heat, and increased vascular permeability causes local swelling. The production of various mediating substances including bradykinin and certain types of prostaglandins can sensitize, and sometimes directly stimulate, nociceptors. Sensitization of nociceptors is a major factor in many clinical pain states.

The dorsal horn and spinal transmission

At the dorsal horn of the spinal cord, primary nociceptive afferents synapse with the first cells of spinal transmission, that are mainly wide dynamic range (or multireceptive) neurons and nociceptive-specific neurons (Figure 2). The dorsal horn is much more than a relay station. Its complex processing involves selection, modulation, and integration of nociceptive signals. From the dorsal horn, the spinal cord conveys signals to many destinations within the brain: thalamus, hypothalamus, mesencephalon, and reticular formation.

The spinothalamic tract

The thalamus receives and integrates nociceptive and other signals, encoding information about type, temporal pattern, intensity, and localization of tissue trauma (Figure 2). It interacts bidirectionally with both limbic and cortical structures such as the somatosensory cortices. The spinothalamic pathway with its cortical connections makes possible the sensory features of pain.

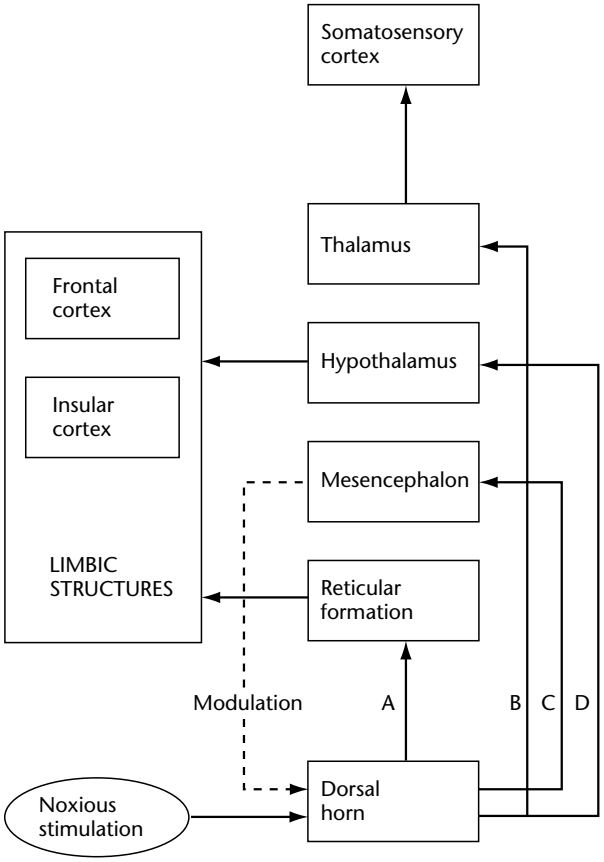

Figure 2. Pathways for the transmission of nociceptive signaling. A, spinoreticular pathway; B, spinothalamic pathway and thalamocortical pathway; C, spinomesencephalic pathway; D, spinohypothalamic pathway. (Based on Willis and Westlund, 1997.)

The spinohypothalamic tract

The spinohypothalamic tract conveys nociceptive messaging to the hypothalamus, which is effectively the control center of the limbic brain (Figure 2). Messages of tissue trauma can provoke the periventricular nucleus of the hypothalamus to initiate a stress response. This is a systematic, adaptive pattern of neural and endocrine activation and behavioral changes orchestrated within the hypothalamic–pituitary–adrenocortical axis. The stress response creates arousal and protective conditions that maximize an individual's ability to respond to threat by flight or fight. A nociceptive stressor can cause the release of multiple hormones that include

adrenocorticotropic hormone, cortisol, the catecholamines (epinephrine, norepinephrine, and dopamine), and renin. The catecholamines produce arousal, cortisol increases blood glucose and decreases inflammation, and the renin-angiotensin system redirects blood flow to the brain and heart during an emergency. In these and other ways, the stress response helps the individual deal with a short-term injurious situation.

Unfortunately, when nociception continues over a long period time, as it can in a patient with a painful cancer, the stress response has numerous negative consequences. Patients develop fatigue and hypersensitive muscles. Sleep is disturbed and rarely restorative. Appetite and interest in sex diminish greatly, as does the ability to sustain mental concentration and attention. Extended exposure to cortisol can damage brain structures and accelerate brain aging. Finally, an extended stress response can suppress immune function and increase vulnerability to adventitious infection. In these respects, prolonged nociceptive signaling exerts an insidious effect.

The spinomesencephalic tract

The mesencephalon contains structures that contribute to descending modulation of nociceptive signaling (Figure 2). These include the nucleus raphe magnus, the periaqueductal gray, and the solitary nucleus. Activation of the pathway descending from these and related structures can result in the attenuation of nociceptive traffic at the dorsal horn of the spinal cord. Direct electrical stimulation of these areas, administration of opioid drugs, and endogenous opioid-like compounds (endorphins) can create analgesia via this pathway. Moreover, increases in blood pressure provoke the carotid baroreceptors, which in turn activate the solitary nucleus, which triggers the descending nociception-inhibiting pathway. The result is reduced nociceptive traffic from the dorsal horn to the brain.

The spinoreticular pathway

The spinoreticular pathway plays a role in the emotional dimension of pain (Figure 2). Nociceptive signals reach multiple structures including the locus coeruleus, which sends extensive noradrenergic projections to diffuse areas of the limbic brain, the hypothalamus, and the cerebellum. One of the projections originating in the locus, the dorsal noradrenergic bundle, extends to many limbic and cortical areas. Activation of this pathway tends to produce hypervigilance, negative emotional arousal, as well as behavior consistent with anxiety and threat.

Pain and Functional Brain Imaging

An extensive literature on functional brain imaging and pain reveals that, during the experience of pain, people show metabolic activity in the thalamus, the lenticular nucleus (a limbic brain capsule surrounding the thalamus), the insular cortex (a cortical area related to emotion), the cingulate cortex, the anterior cingulate cortex, the somatosensory cortex, frontal areas, the vermis of the cerebellum, and other areas related to motor function. Although a few studies have detected activity in hypothalamus, by and large it is difficult for current technology to detect activity in structures at this level and below. Basically, it has become clear that pain emerges from complex, parallel processing in structures that otherwise contribute to emotional arousal, somatosensory awareness, and cognition.

MEASUREMENT OF PAIN

Progress in the scientific study of pain requires sound measurement. However, pain is a private experience, and direct objective measurement is impossible. Moreover, because of the weak correlation between pain and nociception, physiological correlates cannot serve as reliable proxy measures. Researchers and clinicians must rely upon subject or patient introspection for pain measurement. This constraint means that pain measurement is not currently possible in some patient populations.

Simple pain measures treat pain as a single, unidimensional phenomenon and they scale it directly. Subjects rating some feature of pain such as its intensity on a numerical scale ranging from 0 to 10, mark a 10-centimeter line anchored at each end with words such as 'No Pain' and 'Worst Pain Imaginable', or choose one of several descriptive categories that vary in magnitude. Some investigators attempt to scale the sensory and emotional features of pain separately by administering two simple pain measurement tools, one for sensory awareness and the other for emotional awareness.

Many questionnaires exist for measuring pain indirectly and on multiple dimensions. Some approaches ask subjects to choose words describing the qualities of pain from lists that reflect gradations on sensory, emotional, or cognitive dimensions. Others address the ways in which pain interferes with normal function or aspects of daily living. These instruments score pain along several

dimensions and often assess the impact of pain on the activities of daily living.

Pathological Pain

Neuropathic pain

Although nociception has a deleterious impact on health and well-being, it is, in principle, a healthy process if it arises within an intact nervous system. The nervous system is responding as it should to injury. Pain is pathological when it arises from damage to peripheral nerves or central nervous structures, i.e. when it is neuropathic. With rare exceptions, neuropathic pains are chronic, difficult to diagnose, and resistant to most conventional therapies. In many cases, they respond better to drugs otherwise indicated for epilepsy than to conventional analgesic medications such as opioids. Examples of neuropathic pains include postherpetic neuralgia, a pain syndrome that can occur following a shingles attack, and tic douloureux, a facial pain characterized by jolting, painful paroxysms that occur in response to light touch that is normally painless.

Acute and chronic pain

Many clinicians distinguish between acute and chronic pain. Acute pain begins with tissue trauma, diminishes as healing progress, and disappears when healing is complete. Pain after surgery or a broken bone is acute pain. The primary mechanism of most acute pain states is inflammation-induced sensitization of nociceptors.

Chronic pain has two forms. First, when healing never occurs, as in a degenerative disease like arthritis or a progressing disease like cancer, pain becomes chronic because tissue trauma is chronic. Neuropathic pains fall into this category. Second, pain may persist beyond the healing of an injury or disease and continue for an indefinite period, or it may arise from an uncertain or nonspecific origin and continue indefinitely for no apparent reason. Current evidence suggests that pain can become chronic in this sense if persisting nociception brings about long-lasting changes in the function and structure of the central nervous system. This process, called 'neuroplasticity', accounts for the resistance of chronic pain to conventional pain treatments and invasive interventions such as nerve blocks or neurosurgery.

Because persisting pain can alter the neurophysiology of the patient, impose a somatic preoccupation, degrade the patient's lifestyle, and impair general social adjustment, chronic pain requires a different and more thorough clinical evaluation process than acute pain. Many clinics employ multidisciplinary teams that combine psychosocial and medical approaches to evaluation and pain management. The goal of management is not simply to relieve the pain but to restore normal function and reintegrate the patient into a normal lifestyle. Often, it is necessary to include physical rehabilitation and psychological support in the treatment.

SUMMARY

Pain is an unpleasant, subjective, bodily awareness normally experienced as tissue damage or attributed to tissue damage. It serves an important protective function in everyday life. The most common mechanism of pain is nociception, the nonconscious neural signaling of tissue damage, although it may also arise from damage to neural pathways or structures. Various physiological processes can amplify or attenuate nociceptive traffic within the nervous system. In clinical settings, there is a poor relationship between measures of tissue damage and the magnitude of the pain experienced.

Pain is a complex perception with sensory and emotional features, and it depends heavily upon cognitive processes such as attention, expectation, memory, belief, interpretation of the immediate situation, and personal meaning. Functional brain imaging studies of people in pain demonstrate extensive parallel processing in brain areas otherwise associated with somatosensory awareness, negative emotion, and cognition. Measurement of pain is difficult because pain is subjective and highly individual. Because no objective measure of pain exists, introspection is the only window available to researchers and clinicians.

Acute and chronic pain differ, and chronic pain is a costly problem in all industrialized nations because it causes disability. Often chronic pain has a weak or absent relationship to a definable cause and resists invasive treatments that target simple mechanisms. Evidence suggests that persisting nociception can change structure and function within the nervous system to make pain a self-sustaining process.

Panpsychism

Intermediate article

William Seager, University of Toronto, Toronto, Ontario, Canada

CONTENTS

Panpsychism is the doctrine that mind, *in some sense of the term, is everywhere, in some sense of that term. It regards mind as a fundamental and ubiquitous feature of nature.*

BRIEF HISTORY

While panpsychism's origins precede any records of systematic philosophy and probably spring from very early forms of animism, any substantial doctrine of panpsychism had to await the idea that a naturalistic account of the world is possible, for only from the point of view of some such account can the issue of mind's place within the natural world arise. It is possible to trace debate between panpsychist and emergentist views of mind as early as the proto-scientific accounts of the pre-Socratic philosophers, dating from the fifth century BCE.

The problem of mind faded with the demise of this early proto-naturalism, and the debate between panpsychism and emergentism would not arise again until the scientific revolution. In the sixteenth and seventeenth centuries a plethora of mind–body theories suddenly appeared, as the issue of the place of mind within a world governed by natural law became unavoidable and pressing.

Rejecting the infamous Cartesian dualism, Baruch Spinoza (1632–1677) and Gottfried Wilhelm Leibniz (1646–1716) espoused important and quite distinct forms of panpsychism. Spinoza regarded both mind and matter as simply aspects of the eternal, infinite, and unique substance he identified with God, or nature; there is nothing that does not have a mental aspect – the proper appreciation of matter reveals it to be the other side of a mentalistic coin.

Leibniz's view is sometimes caricatured as: Spinoza with infinitely many substances rather than only one. These substances Leibniz called 'monads', which are characterized as spiritual (i.e. mental) automata. What is of special interest is that unlike Spinoza, Leibniz maintained a difference between things with mental attributes and things without by differentiating between a 'mere aggregate' and 'organisms'. Consider a heap of sand. It corresponds to a set of monads, but no monad represents the 'point of view' of the heap. By contrast, your body also corresponds to a set of monads, but one of these monads – the dominant monad, your mind – represents the point of view of this biological system. This idea is retained in modern versions of panpsychism, and undercuts the rather simpleminded objection that stones do not seem to have minds.

The growth of idealism through the eighteenth and nineteenth centuries meant that panpsychism became, in effect, the default philosophy but with a decided bias resulting from positioning the mental as the primary component of reality. Panpsychism was favored by a surprising number of eminent scientists and philosophers of the time, perhaps most curiously by three men now better known as the founders of scientific psychology – Gustav Fechner (1801–1887), Rudolf Lotze (1817–1881), and Wilhelm Wundt (1832–1920). Other prominent panpsychists of the period include William James (1842–1910) and William Clifford (1845–1879).

The richest development of panpsychism in the twentieth century is that of Alfred North Whitehead (1861–1947). Whitehead proposed radically reforming our metaphysical view of the world, replacing things and matter with events and the ongoing processes of their creation. His panpsychism, which has many similarities to that of Leibniz, arises from regarding these elementary events as possessing mentality in some attenuated sense, expressed in terms of creativity, spontaneity, and perception. Perhaps unfortunately, Whitehead's panpsychism stands or falls with his entire metaphysical system, which entails an even more radical revision of our current scientifically based views than does bare panpsychism.

ARGUMENTS FOR PANPSYCHISM

Arguments for panpsychism can be grouped under three broad headings: analogical, genetic, and

intrinsic nature. The basic analogical argument goes like this: if we look closely we see that even the simplest forms of matter exhibit behavior which is akin to that which we associate with mentality in animals and human beings. Therefore we ought to regard these simple forms as possessing mentalistic attributes. Unfortunately the premise seems quite preposterous. Better hope for an analogical defense of panpsychism springs from the overthrow of determinism in physics. Some modern panpsychists, starting with Whitehead, see this indeterminacy as an expression not of blind chance but of free action, in response to a kind of information-based inclination rather than mechanical causation. The question is whether the source and target phenomena are sufficiently analogous to warrant extending attributes from the one domain to the other. This is doubtful here. The indeterminacy of modern physics seems to be pure randomness quite remote from deliberation, decision, and indecision. Another analogical argument which draws upon quantum physics is more promising. This analogy is between between consciousness and information. It is natural to think that a prime function of consciousness is the integration of information and the monitoring of various external and internal states. Thus, if information monitoring is a fundamental and pervasive feature of the world at even the most basic levels, then perhaps this indicates that consciousness also exists at those levels. It is undeniably suggestive that one of the central features of quantum mechanics is the existence of informational but noncausal relations. These relations are noncausal insofar as they are modulated instantaneously over any distance and do not involve the transfer of energy between the parts of the system. But they are informational in the sense that the changes of state of one part of the system seem in some way to be communicated to the other. While these so-called entangled states are normally susceptible to rapid 'decoherence' caused by environmental disturbance, some systems might resist decoherence and it has been conjectured that these are the physical foundations of consciousness (see Hameroff and Penrose, 1996). Furthermore, the decoherence argument evidently collapses for the universe as a whole which by definition cannot be disturbed by any outside force, so presumably the total universe is in one immensely complex, entangled state. Given a link between consciousness, monitoring, and information exchange, this leads to a view highly reminiscent of Leibniz's, with centers of (perhaps rudimentary) consciousness at the foundation of the world.

Turning to the genetic arguments, Darwin's theory of evolution led in the nineteenth century to a popular empirical genetic argument for panpsychism based upon the idea that no novel property could arise by natural selection from systems entirely devoid of it. Clifford puts the argument thus: 'we cannot suppose that so enormous a jump from one creature to another should have occurred at any point in the process of evolution as the introduction of a fact entirely different and absolutely separate from the physical fact' (1874/1886, p. 266). An *a priori* form has been advanced by Thomas Nagel (1979). Nagel links panpsychism to a necessary failure of emergentism: namely, that emergence lacks the status of a true metaphysical relation. Nagel says: 'there are no truly emergent properties of complex systems. All properties of complex systems that are not relations between it and something else derive from the properties of its constituents and their effects on each other when so combined' (p. 182). Thus the only coherent form of emergentism is a merely epistemological doctrine about the limits to our understanding of complex systems. Panpsychism follows from Nagel's denial of reductionism which precludes simply identifying mental properties with complex physical properties. Then, since we can build an enminded system out of 'any matter', mind must be associated with matter in general and in its most fundamental forms.

Another argument depends on the idea that every fundamental kind of thing must have an intrinsic nature. The objects of physics, it is claimed, are described in purely dispositional terms. That is, while an electron, for example, is said to possess 'spin', all this amounts to is that the electron has certain behavioral dispositions. It is arguable that dispositions must be grounded in some intrinsic, nondispositional attributes, but we have no conception whatsoever of what the intrinsic nature of matter might be. In fact, the only intrinsic nature with which we are familiar is consciousness itself. The qualities of conscious experience (the smell of a rose, the taste of a strawberry, etc.) seem not to be reducible to relations among nonexperiential states, nor entirely specifiable without remainder in terms of their causal powers. They seem instead to possess intrinsic and irreducible characteristics. If this is the only idea of intrinsic nature we possess, and matter must be assigned some intrinsic nature, it seems that matter must be granted a mentalistic intrinsic nature. The core idea of this argument can be traced back to Leibniz who felt forced to ascribe mentalistic attributes to his monads as the only possible feature which could

account for the active forces demanded by an adequate physics. In his discussion of this difficulty, Whitehead describes all 'modern cosmologies' as having to admit a 'mysterious reality in the background, intrinsically unknowable' and notes that Leibniz 'explained what it must be like to be an atom'. Although far from demonstrative this is, in the words of Thomas Sprigge (1999), 'a hypothesis worth exploring as the only alternative to saying that matter is unknowable in its inner essence'.

ARGUMENTS AGAINST PANPSYCHISM

None of the above arguments are demonstrative and arguments against panpsychism are not hard to devise. The most obvious is the lack of evidence that fundamental physical things possess any mental attributes. This does not seem particularly compelling since not every attribute is apparent at every scale; gravitation is fundamental and ubiquitous yet individual elementary particles do not appear to gravitate. The presumed causal completeness and closure of the physical world undercuts panpsychism insofar as it renders superfluous the postulation of mentalistic attributes to fundamental physical entities. This objection is closely associated with the more strictly methodological protest that since there is no apparent need to assign any mentalistic attributes to the basic physical features of the world, panpsychism is a purely metaphysical extravagance with no empirical content whatsoever. While compelling for most modern naturalists, in the absence of a successful scientific account of the emergence of mind in terms of a purely physical substrate these points come close to begging the question. To the extent that one worries that consciousness presents an especially difficult and at present intractable problem for physicalism, one cannot legitimately deploy the complete physicality of the world against a panpsychist position. There are also internal difficulties with panpsychism, of which the most serious and interesting is the 'combination problem': even granting that fundamental physical entities have mental properties, there remains the question of how the more complex minds of composite entities (such as ourselves) emerge out of the protominds of their constituents. This problem reveals that some forms of panpsychism require their own doctrine of emergence. If emergence is required even within panpsychism, then one might be excused for preferring mind to emerge from a nonmental substrate rather than the mentalistic base posited by panpsychism. This objection also reveals that any successful panpsychism will have to grant genuine consciousness to the fundamental constituents of the world; otherwise panpsychism will be claiming that consciousness can emerge from the nonconscious, in which case the advantages of a physicalist emergence seem quite clear. And the claim that the fundamental elements of the world are truly, if minimally, conscious further erodes the plausibility of panpsychism itself.

PANPSYCHISM AND COGNITIVE SCIENCE

Panpsychism is a metaphysical doctrine with no very direct relation to any science. There is no test that could decisively confirm or refute it, no more than physicalism can be proven scientifically. Yet metaphysical views form an indispensable background to all science. They integrate our world view and allow us to situate our scientific endeavors within a larger framework. Science has always informed metaphysical speculation, and in return such speculation helps motivate and pave the way for new science. The primary scientific benefit of panpsychism is to leave open certain pathways of speculation that may yet inform future theories of mind and consciousness.

Perception, Direct

Intermediate article

Alva Noë, University of California, Santa Cruz, California, USA

CONTENTS

The theory of direct perception holds that perception, in any sensory modality, is a form of non-inferential awareness of the sorts of things we normally take ourselves to perceive. This view rejects the idea, common to many philosophical and scientific approaches to perception, that our only immediate contact is with sensations, impressions, or mere patterns of stimulation of the sensory receptors.

INTRODUCTION: WHAT IS DIRECT PERCEPTION?

The claim that perception is direct has been advanced by a small but distinguished minority of philosophers and psychologists, including Austin, Gibson, McDowell, Neisser, Putnam, Strawson, and perhaps also Aristotle, James, and Reid. Perception, it is argued, is a form of noninferential awareness of the sorts of things that we normally take ourselves to be aware of when we perceive, such as everyday objects and events. Supporters of direct perception reject the idea that in perception we are aware only of mental intermediaries – sense data, impressions, appearances – and that it is only thanks to our direct awareness of these that we can be said to be aware (indirectly) of the world. They accept that perception is a form of direct access to the world, and, therefore, that the world is very much the way it seems to us in perception. For this reason, defenders of direct perception are sometimes known as naive or direct *realists*.

In fact, there is nothing naive about the theory of direct perception. Although it attempts to defendsomething like 'the standpoint of common sense', it is in fact a sophisticated response to the widely held view that perception could not be, inthe relevant sense, direct. For this reason, the best way to understand direct perception is to examine the family of arguments to which it is a response.

ARGUMENTS AGAINST DIRECT PERCEPTION

We can identify a basic line of argument against direct perception which runs as follows. When you see (say) a round plate held out at an angle, you see that it is round. But its roundness is, strictly speaking, inaccessible to your visual point of view. What is really given to you visually, at least as far as shape is concerned, is a glimpse of an elliptical profile. From the fact that the plate presents you with an elliptical profile, however, it cannot be deduced that the plate is round. From this it would seem to follow that perception is, in the first instance, a form of contact not with things as they are, but rather with mere glimpses, or impressions, or appearances of things. Our perceptual contact with the plate itself, so continues this line of thinking, is mediated by our more direct contact with the plate sense datum (or appearance, impression, etc.). Perceptual judgments, then, must go well beyond what is actually given in experience and must be thought of not so much as immediate records of how things are, but as the results of conjecture or speculation.

Philosophers refer to this general line of argument as the *argument from illusion* (Ayer, 1940). It purports to show that we are, in perceptual experience, immediately aware not of what we think we perceive, but of mental intermediaries that in some way stand for or refer to those things. According to the argument from illusion, when you see a red tomato, for example, you are aware not of the tomato itself, but of a red, tomato-like sense datum. The reasoning is as follows. When you hallucinate a red tomato, you are not aware of a red tomato, but merely of a tomato-like sense datum. After all, it is a hallucination. However, the experience of actually seeing a red tomato and merely hallucinating one are qualitatively indistinguishable. If this were not so, then we would never be deceived by our hallucinations. But if the

experiences are qualitatively indistinguishable, then you are aware of one and the same thing when you see a red tomato and hallucinate a red tomato. Hence, when you see a red tomato, you are aware not of a tomato but of a tomato-like sense datum.

That perception is in this way *in*direct appears to gain support from basic facts about the physics of perception. When you see a tomato you do not make direct contact with it. At best you make contact with the tomato only as mediated by a complicated causal process – the tomato affects the light which gives rise to a pattern of stimulation of the receptors in the eyes which in turn produces activity in the optic nerve and brain. At the terminus of this process there is the visual experience as of a tomato. The tomato, it should be clear, enters the process only as a more or less remote cause of the experience one eventually undergoes. Similar points can be made in the case of other sensory modalities, such as touch, which might seem to be direct in precisely the way that vision is not. For example, when you hold an object (a bottle, say) in your hands, you do make contact with the bottle, but all that is recorded in your immediate experience of the bottle is a pattern of nervous stimulation in your hands (or a pattern of sensation). Just that pattern could be produced by something other than a bottle. That it is produced by the bottle is not something your bottle-experience itself can guarantee. The direct object of your tactile experience is not the bottle, then, but a bottle-like tactile impression.

We have been considering a philosophical line of argument, but it is one that has been entrenched in scientific theories of perception. The central problem for perceptual science has traditionally been that of explaining how it is that we perceive what we do – the three-dimensional world of independent objects, etc. – on the basis of the information available in the form of stimulation of the sensory organs. What makes the problem a difficult one is the fact that, strictly speaking, the data for perception, in the form of the pattern of stimulation of the sensory organ, are highly limited and impoverished. In general it is not possible to infer the character of the environmental layout from the pattern of stimulation of the sensory organ. This comes out, for example, in the fact that a small tomato nearby and a large tomato farther away may project a qualitatively indistinguishable retinal image. The dominant strategy for addressing the traditional problem of perception – what Fodor and Pylyshyn (1981) have called the 'Establishment View' – is to suppose that the brain produces the perceptual experience by engaging in a constructive process of inference or conjecture. A perception, in the phrase of Helmholtz, is an 'unconscious inference' (Helmholtz, 1855). Empirical research on perception focuses on understanding the mechanisms, neural and psychological, that make up the brain's ability to perform this constructive feat. (See, for example, the important work of Marr, 1982.) Much work on perception undertaken in cognitive science since the 1970s is constructive in this way and rests squarely on a conception of perception as *indirect*.

Note, the upshot of these criticisms of direct perception is at once epistemological and also metaphysical. Epistemologically, the argument casts perception as enabling us to have immediate knowledge of how things are with us perceptually, but not with how things are outside of us. This approach to perception is thus at one with the so-called Cartesian conception of mind, according to which the domain of the mental, of consciousness, is that domain within which we have a certain kind of immediate self-knowledge. The metaphysical upshot concerns the nature of perceptual experience itself. Perceptual experiences are internal states whose fundamental character is independent of how things are in the world.

DEFENSES OF DIRECT PERCEPTION

The remainder of this article reviews two main lines of defense of direct perception, one philosophical and one scientific.

Criticisms of the Conception of Experience Implicit in the Argument from Illusion

Several authors have attacked the conception of experience implicit in the Argument from Illusion and in related lines of argument against direct perception. These attacks fall into roughly three groupings.

Austin's criticism

Austin (1962) argued that from the fact that we are sometimes deceived by a hallucinatory experience, it does not follow that the hallucinatory experience and its veridical counterpart are qualitatively indistinguishable. So, for example, one might mistakenly judge a straight stick partially submerged in water to be bent. A straight stick in water, after all, may look bent. But it does not follow from this that there is no qualitative difference between the experience of a genuinely bent stick and that of a

bent-looking stick standing partially submerged in water. In the one case, but not the other, for example, there is the difference owing to the presence of water! But if there is no qualitative identity between the experiences, then there is no reason to suppose that the object of awareness is the same for both experiences, and so the Argument from Illusion collapses. Austin further remarked that the assumption that we are aware of anything, when having an outright hallucination, is itself quite gratuitous. So, for example, in the case of the stick standing partially submerged in water, there is nothing bent of which we are aware.

The highest common factor conception

Snowdon (1980–1981) and McDowell (1982, 1986), developing an idea first proposed by Hinton (1973), propound a line of criticism very similar to that of Austin. Like Austin, they challenge the assumption that there is a single experience common to both a perception and its corresponding hallucination. They reject what McDowell has called 'the highest common factor conception' of perceptual experience. It is true that perceivers may not be able to tell, by mere introspection, whether they are perceiving or merely hallucinating. But from this it does not follow that perceivers and hallucinators are in one and the same experiential state. At best all that follows is that, for all they can tell by introspecting, they might be in the same state. In the veridical case, they undergo an experience of something's looking a certain way to them (let's say). But in the hallucinatory case they are not in that state. Rather they are in the state of its merely seeming to them as if something looks a certain way.

In rejecting the highest common factor conception, McDowell and Snowdon reject, like Austin, the grounds for believing that what we are aware of when we perceive is just what we are aware of when we undergo the corresponding hallucination. This line of criticism of the Argument from Illusion is noteworthy because it breaks with the Cartesian idea that the contents of consciousness, including our experiential states, are immediately and certainly available to our introspection. McDowell and Snowdon break with this enduring epistemological notion by embracing a so-called *externalist* metaphysics of mind according to which perceptual experiences (and other mental states) are constituted by relations between perceivers and their environments.

The intentionality of perception

Sellars (1956) and Strawson (1979) have developed a Kantian line of criticism of the Argument from Illusion based on the observation that perceptual experiences are intentional (in the philosopher's sense). Perceptual experience, they reason, is *always* and *essentially* experience as of things being this way or that, and only a creature in possession of the concepts needed to capture in thought how the experience represent things as being could be said to have full-fledged perceptual experience. We have no acquaintance with our experience, they hold, other than as experience as of things being this way or that. Hence, we can make no sense of the idea that experience, properly described, pertains not to the world but only to our sensory impressions.

This Kantian line of criticism attempts to undercut the Argument from Illusion by depriving its proponents of the needed conception of experience as an awareness of something less than the mind-independent world. The criticism rests, at base, on a phenomenological claim. We *mis*describe what our experience is really like if we attempt to describe it in a merely sense-datum idiom. The line of criticism has an important epistemological upshot. It is only by recognizing the conceptual, articulate, propositional character of perceptual experience that we can appreciate the fact that our experiences give us reasons for judgment and belief.

Gibson's 'Ecological' Approach

Gibson's (1966, 1979) defense of direct perception takes as its start the rejection of the way traditional theorists frame their basic problem. Vision, Gibson argued, is not something that takes place in the eye and brain of a perceiver. We misdescribe vision if we think of it as a process whereby the brain builds up an internal model of the environment on the basis of limited sensory stimulation. Such a conception of the nature of vision, Gibson argued, is pitched at the wrong level. The perceiver is not the brain, but rather the whole animal embedded in an environment. The function of perception is not the production of experiences or representations but rather the enabling of the animal to function appropriately in the environment. The seeing, Gibson argued, takes place in the environment thanks to the engagement of the whole animal with its surroundings. The information available to us in vision, then, is not the pattern of irradiation encoded on the surface of the retina. It is the environment itself – the animal's habitat – that is the repository of information about it. Vision, on this proposal, is a way of acquiring information about the environment by coming into direct

contact with the environment thanks to active exploration.

Gibson's bold claim is that if we reformulate our analysis of the basic visual predicament this way, the puzzling character of how we see disappears. Reconsidering our example of the plate, we can notice that although it is true that the round and the elliptical plates might look the same when contemplated from a certain stationary point of view, their different natures will be readily apparent to the active, moving animal.

In this way Gibson believed that many of the great puzzles of visual science – such as that of how we perceive three dimensions – are in fact artefacts of a misdescription of what vision is.

DIRECT PERCEPTION IN CONTEMPORARY PHILOSOPHY AND COGNITIVE SCIENCE

The debate about direct perception is ongoing. It takes place at the foundations of contemporary thought about perception. For science, as we have seen, what is at stake is our basic analysis of what vision is and our account of the level at which perceptual phenomena are to be studied. For philosophy, what is at stake is our understanding of the nature of experience, and of the role experience can play as a source of knowledge. Beyond technicalities, the basic question of direct perception – what do we perceive, really? – is important because it gives expression to an enduring problem for philosophy: how are we to reconcile what science teaches us with what we know, or seem to know, on the basis of experience?

Perception, Philosophical Issues about

Intermediate article

Austen Clark, University of Connecticut, Storrs, Connecticut, USA

CONTENTS

Three major philosophical issues that have arisen from the scientific study of perceptual processes: the variations and limitations of representational systems, the localization of perceptual function in neural tissue, and the relations to verbal outputs of people introspecting.

CENTRAL PHILOSOPHICAL ISSUES ABOUT PERCEPTION

Broadly speaking, philosophers work on three kinds of task. The first consists of all the work one must do to a question before one can say anything sensible about it. The second is to describe the relations between answers to one set of questions and answers to another. The third, and most difficult, is to reconcile the internal tensions that arise when one tries to complete the second task.

The first and third of these kinds of problem are studied almost exclusively within departments of philosophy. Applied to perception, our first kind of task includes questions such as: Should I believe my senses? Can one prove the existence of the external world? Is it fair to treat the existence of the table in front of me as just a plausible hypothesis? And so on. Such questions of epistemology have been studied within Western philosophy more or less continuously since the ancient Greeks. They are of immense importance, and well worth studying. But one must have already made one's peace with them before even starting the enterprise of 'cognitive science' – or any science, for that matter – so a discussion of them does not belong in this article.

The third kind of task is likewise interior to philosophy. In the attempt to come up with some systematic overview of our intellectual landscape, various schools and traditions have arisen over the centuries. They have approached this project in different ways, and between them there are arguments about how to argue, and questions about the enterprise of raising questions. Within perception, this third category of problem includes such questions as: What sort of logic is required in order to describe the things one seems to see in an illusion (Hintikka, 1969)? Do those things actually exist in some other possible world, or merely seem to? Can they cause things to happen in this world? And so on. These are the sorts of questions that greatly preoccupy analytic philosophers, but will appeal to few cognitive scientists.

So this article will confine itself to questions of the second kind: questions about the relations between different portions of the scientific study of perception. Within cognitive science itself there are problems about perception that are philosophical problems – problems that arise as soon as one steps back from some particular research question, and asks instead: how would the answer to this question cohere, or fail to cohere, with our answers to other questions? One strives for a pleasing and coherent overview of how it all hangs together; but one finds places where the landscape is not at all settled, peaceable, or pleasing. Instead one finds fault lines, where vast tectonic plates grind remorselessly, deep underground, producing earthquakes, lava flows, gaseous effusions, heat, and noise. These are the philosophical regions. I will identify three: three obvious zones of tectonic conflict within contemporary cognitive approaches to perception.

RELEVANCE OF COGNITIVE SCIENCE TO THE PHILOSOPHY OF PERCEPTION

Profits and Perils of Representation

Representation is the wondrous elixir that makes cognitive science possible: a theoretical notion that is powerful, ubiquitous, intoxicating, and dangerous.

Consider arranging the various relations of association between classes of events in a hierarchy of increasing orders of logical complexity. At the bottom we find relations of statistical association, of correlation, and of causation. Claims of the form 'x is correlated with y' are common to all branches of cognitive science and require no special theoretical tools. The relation is fully extensional, in the sense that if x is correlated with y and $y = z$ then x is correlated with z. Causal links are one step up the hierarchy, with some additional content. Another step up takes us to information. Like correlation, talk of information describes a kind of association between ensembles of classes of events, but it is a more complicated kind. It requires a rather robust structure of relations of conditional and *a priori* probabilities between ensembles of input events and output events. These relations can help one make discriminations that mere causal or correlational talk cannot. They may, for example, help us to decide which object is the one perceived among all of the causal antecedents of a given perception. Causally, those antecedents are of a piece, but the perceptual state carries much more information about some of them than about others. Talk of information can relate classes of events in ways that causal talk cannot.

The notion of 'representation' adds another order of complexity to our talk. Event x represents y, is about y, says something concerning y, and is more or less accurate or inaccurate in what it says about y. What makes this relation complicated is that it proceeds through a semantics: one must provide a semantic interpretation for events at the 'representing' end of the relation. That is, what it means to say that x is a representation is that it has some content 'about' some putative object y, and that such content can be assessed for correctness or incorrectness, accuracy or inaccuracy, truth or falsehood. In order to understand that content one must understand exactly what x is representing, and in order to understand that one must understand the semantics of the system of which x is a part. Extensionality fails: even though x represents y and $y = z$, x may fail to represent z. It all depends on the semantics, on how x represents y. It might represent its object as y but not as z – for example, as water, but not as H_2O, even though in fact water equals H_2O. The system in question has yet to learn this piece of chemistry.

The notion is intoxicating because it is so powerful. Once we endorse the claim that the objects under investigation themselves employ a system of representation, then suitable adjustments of the details of those systems can explain any behavior one might encounter, or any behavior one pleases. And indeed the cognitive revolution is (arguably) founded on the claim that all mental states are representational; within our theories the elixir can be employed anywhere, at any time, in liberal quantities.

Perception provides a particularly interesting test for this view. Is all perceptual content representational? Is any? What makes perception so interesting in this regard is that its scientific study started at least a century before the cognitive revolution; competitive research traditions, confined to simpler and less powerful relations of association, were already well established by the middle of the twentieth century. Members of the *ancien régime* had accomplished much with the older tools of correlation, causation, and information, and some resisted the claims that were made for the hegemony of representation.

Even today, there is a full range of opinions concerning whether all or any perceptual content is representational. Clearly there are aspects of perceptual experience that do not seem to represent anything. Whatever a sensation of green signals could it seems, just as well have been signaled by a sensation of blue. So the difference between green and blue is not a difference in what the experience represents. Other qualitative variations likewise lack representational content. A penny on the table presents different ellipses at different times, from different perspectives; yet one would never judge the penny to be anything other than circular. All the aspects of object constancy – size, shape, color, and so on – provide similar examples. The variations in the character of perceptual experience that are discounted when one achieves object constancy do not represent variations in the object. They are variations in what philosophers call 'qualitative' content, and they seem not to represent anything.

The most prominent of the researchers who deny that perception has representational content are ecological psychologists and perception–action theorists. Ecological psychologists prefer to cast their theories using relations of association that stop at the level of information pick-up. After all, perception is found in creatures so simple that one hesitates to ascribe them any other cognitive state at all, and perhaps their commerce with the environment can be accurately described without invoking the complexities of semantic interpretation. Such is the promise of perception–action theory.

There is, however, the problem of perceptual illusion. The conventional view about illusions is that they are a kind of misrepresentation: an error of the senses, a case in which the senses deceive.

But error and deception are impossible unless correctness conditions apply. These states have a content, which in such cases is misleading. Other varieties of perception that are less than fully accurate, such as the perception of pictures, of mirror images, or of movies, raise similar issues. All provide cases of 'mere appearance' (intentional inexistence), in which someone perceives something that seems to be *P*, or seems to perceive something that is *P*, though in fact there is nothing in the vicinity – nothing within the optic array – that is *P*. The representational gambit is particularly hard to resist in such cases. The alternative is either to posit some new metaphysical entity – one which is *P* and is somehow directly perceived – or to deny the existence of illusions altogether. Whereas the representational account is straight-forward: the subject in such episodes is representing something to be *P*, but that representation is (for one reason or another) a misrepresentation. What is real is the existence of the representation. What is unreal is the thing represented. We have a real representation of something unreal. This neatly disposes of the ontological problems of mere appearance.

At least, it does if we accept the hegemony of representation, and allow its governance to extend all the way to the earliest stages of the sensory processes of the simplest creatures. This still needs to be empirically substantiated, and doing so is not easy. What are the elementary terms, the morphemes and syntax, of these systems of representation? One needs to specify the primitive elements, the rules by which they are combined, how they refer, what predicates they employ, and what their truth conditions are. Are they simple, isolated 'features' that might be registered in cortical feature maps? Or must even the primitive terms have the relational character of gestalts (or of affordances)? Is the primeval form of sensory reference allocentric or egocentric? Are all the predicates innate? Is comprehension of them modular? And so on. The representation relation adds another degree of freedom and another layer of complexity to one's theory. While this makes the theory more powerful, it also obliges one to determine the empirical details of how representational systems are constituted. There are reasons to doubt our ability to do this: to have warrant for ascribing one system of representation to a creature rather than another, extensionally equivalent, one.

Psychology Versus Physiology

Another region of tension is found in the relations between the top-down, high-level, boss, chief executive psychologists, and the bottom-up, low-level, worker, underling, physiologists. This description is deliberately tendentious, but it reflects the temper of early broadsides in the revolution. The boss executives were supposed to run the show, tell us what jobs needed to be done, and give broad functional specifications of the different subsystems of the mechanism they master. The neurophysiologists, biophysicists, and neuroscientists gratefully receive these job specifications, get to work, and eventually pass upwards the implementation details of how the lowly neurons cooperate so flawlessly, yet mindlessly, to produce the wonders of representation, The 'autonomy' of levels of explanation guaranteed that the offices of the executives would never be invaded by the grubby workers.

This view has been seriously challenged by empirical discoveries. What are we to make of 'feature detectors' in the primary visual cortex, or of the subsequent 'feature maps' in secondary areas (Treisman, 1993)? How are we to understand the distinction between 'what' and 'where' channels in visual processing, or the importance of synchronized 40-hertz oscillations (Crick and Koch, 1990)? Suddenly the physiological underlings seem to be providing job specifications for the psychologists, instead of the other way round. Such developments oblige us to reconsider the relations between sensory contents and physiological implementation.

We need a clearer view of those relations: of relations between perceptual states and neural states. For example, might we someday find a 'color perception center' where perceptions of color are localized? The question poses a dilemma. It remains incredible that we might someday point to a region of Joe's neuroanatomy and say, truthfully, 'process *x*, going on in there, is identical to Joe's sensation of red'. How do processes in that region get promoted to the status of 'Joe's sensation'? And how could we explain the connection between those processes and the fact that the sensation is a sensation of red, and not of green? This is one version of the 'explanatory gap' (Levine, 1983), and it has yet to be bridged. But alternatives to localization are equally hard to fathom. How could the experience of seeing a red patch be distributed across chunks of neural tissue? How are the chunks coordinated? What binds them into one experience, or into an experience of one patch and not two (Crick and Koch, 1990)?

Other questions are equally in need of recalibration. The connected claims for the 'autonomy' of 'levels of explanation', and for psychology as a 'special science', increasingly seem irrelevant to

the scientific study of perception. Can one consistently hold such views while maintaining that all properties are physical properties?

Theories Versus Common Sense

A third area of stress for contemporary cognitive approaches to perception lies on the tense border between it and the legions of ordinary language and common sense. Many of the processes described in scientific theories or perception seem also to be open to direct observation and immediate access by the ordinary Joe. After all, Joe sees, touches, tastes, smells, and hears; is often aware of doing such; can say when he does such; and can describe something of what it's like when he does. What are those processes but the very ones described by theories of perception? Because the theories seem to encroach upon the territory of common sense, theorists are forced to stipulate relations between what they say and what common sense says. This is quite literally a job of public relations, and like any public relations job it is delicate, essential, and potentially explosive.

It is under this heading that one must place all the philosophical arguments relying on ordinary intuitions about what it's like to see red, about the 'qualitative character' or 'qualia' of seeing red, and about the possibility that what it's like for me to see red is qualitatively identical to what it's like for your to see green (see Block, 1980). All such arguments can be entirely dismissed – claims based on common sense might occasionally be true – but simply that the task of figuring out a response to them is similar to the task of negotiating with a public whose intuitions may differ from one's own.

Possible responses range from ignoring ordinary Joe altogether (either denying that perceptual experience has any contact at all with the states and processes hypothesized by these theories, or admitting that there is some contact, but despairing of any useful information arising from introspective methods) to embracing his verbal outputs as constituting the canon for 'heterophenomenology' (Dennett, 1991). At one end of the spectrum we have the public relations triumph of scientific vindication of all the intuitions of dear old Auntie (Fodor, 1985) – the customer is always right! – while at the other end the corporate PR man announces, gleefully, that Auntie and all the other putative customers have no thoughts, no desires, no beliefs, and no existence (Churchland, 1979).

The problem can emerge in the laboratory, for example, in experiments on the cognitive unconscious. What are we to make of the appearances (or lack of appearances!) of first-person introspective access to the states and processes hypothesized by theories of perception? For example, blindsight is problematic largely because one relies on the truthfulness of the subject's testimony that he or she does not see the *X*, is not aware of the *X*, even though pointing (and other behavioral measures) would normally be taken to contradict this (Weiskrantz, 1997). Why should we believe the subject who says, sincerely, that he or she does not see? And why should one adopt the commonsense assumption that seeing something implies consciousness of it, or, alternatively, consciousness of seeing it? These questions lead us back to the old problem of the scope and limits of introspective methods.

Some useful distinctions have gradually become clear in the philosophical literature. For example, the notion of qualia – the paradigm of entities whose essence is fully revealed by introspective consciousness – is ambiguous. In one sense, qualia are the qualities attributed to appearances – the qualities of color, taste, smell, etc., that things seem to have – and in another sense, qualia are the properties of sensations – the properties of sensory states in virtue of which things appear as they do. Neither notion should be confused with 'what it is like' to have a given sensory state. The latter phrase, made popular by Nagel (1979), was meant to pick out all and only the conscious mental states, and if one admits the possibility of sensory states of which one is not conscious, then the qualia of a sensory state may sometimes differ from 'what it is like' to have that state. The term 'conscious' is itself ambiguous. In one sense, it applies to any creature that is awake and sentient; in another sense, it applies only to mental states of which one is introspectively aware. In any case, it is clear that consciousness and sentience are not the same thing. One can study sensory processes and the qualitative character of sensory states without necessarily committing oneself to some verdict about what it is like to have those states.

The logical endpoint of such continuing Balkanization is a continuum of states, starting at some that are clearly unconscious and insentient, and ending with some that are, in the fullest sense, conscious sensory states. In between would be a vast series of intermediate states, of varying orders of organization, encompassing all the transition zones between unconscious and partially conscious states, and capturing all the pathological states and paradoxes. Once that order is empirically described, and all the relations between neighboring points within it are made clear, it becomes a matter

of indifference where one draws the line between cases in which some ordinary language term applies and cases in which it does not. All the facts upon which such a verdict rests would be laid upon the table, and the only remaining questions would be verbal.

RELEVANCE OF THE PHILOSOPHY OF PERCEPTION TO COGNITIVE SCIENCE

The three philosophical issues about perception outlined above are rarely found in 'pure' forms – as isolated and distinct dilemmas about representation, about neural implementation, or about common-sense introspective access. More typically, and more potently, in the outstanding controversies of the day, all three themes are found intermingled, in maximally confounding combination. For example, the puzzles over temporal anomalies of perception and the phi phenomenon (Dennett and Kinsbourne, 1992) involve all three. We need assumptions about how time is represented, how those representations are instantiated in the nervous system, and how ordinary subjects access those representations when they see a moving light. 'Filling in' likewise gains the critical mass of a dilemma only when one imports assumptions from all three of our philosophical regions: assumptions about spatial representations, about their neural implementation, and about introspective access to them (Pessoa, Thompson and Noë, 1998). Blindsight (Weiskrantz, 1997) and the various 'binding problems' (Crick and Koch, 1990; Treisman, 1993) may seem to be almost pure neurophysiological issues, but on closer examination what makes them controversial, what generates all of the heat, is some combination of assumptions crossing our philosophical faultlines. Lots of energy builds up at such places, and when it is let go, the results can be exciting.

CONTENTS

Unconscious perception involves the processing of sensory information by the brain in the absence of subjective awareness. The physical properties of sensory stimuli, their meaning, and their emotional significance, may all be perceived unconsciously.

INTRODUCTION

Many psychological experiments suggest that much of our perception occurs in the absence of conscious experience. In this article we explore the phenomenon of unconscious perception, beginning with a historical account of the concepts of perception and consciousness. We examine the methods adopted by experimental psychologists to try and distinguish between perception with and without consciousness in normal observers. There are different measures of unconscious perception, and different ways to define the boundary between conscious and unconscious processing. Many aspects of unconscious perception are evident in patients with focal brain injury caused by stroke or tumor. These neuropsychological cases provide important clues to the neural substrates of unconscious perception, as do recent brain imaging results. We conclude that considerable perceptual processing can occur in the absence of conscious experience, and that specific brain regions may have a special role in supporting conscious perception.

WHAT IS UNCONSCIOUS PERCEPTION?

'Perception' refers to the automatic and relatively effortless process implemented by the central nervous system to extract information about physical objects and events in the world. Much of what we perceive of the world occurs without us being directly aware or conscious of it, i.e., without any direct or immediate subjective experience. The idea that perception might occur without conscious experience has generated a great deal of interest, because it challenges the conventional idea that perception is an ontologically conscious phenomenon. In this article we focus on unconscious visual perception. Roughly half the primate brain is devoted to processing visual information. Due to the large body of experimental work conducted in the visual domain, we now know more about unconscious perception in vision than in any other modality.

Numerous terms have been used to refer to the phenomenon of perception in the absence of awareness: most commonly 'unconscious' or 'implicit' perception, and sometimes 'automatic', 'covert' or 'tacit' perception. Unconscious perception has proven difficult to define, but it may be broadly characterized as perception that is not accompanied by subjective experience or the ability to act upon relevant information in an intentional fashion. Unconscious perception is generally understood to occur without effort (automatically) and in parallel (simultaneously) across different sensory modalities, and to have a large processing capacity. Unconscious perception can be contrasted with conscious perception, which carries with it a characteristic, though often indefinable, subjective experience of 'what it is like': for example, the smell of coffee, the color of a rose, or the sound of a familiar voice. Conscious perception involves processing of sensory inputs in such a way that we can act upon them in a voluntary, intentional and novel manner. (*See* **Qualia**)

The idea that perception might occur in the absence of consciousness raises an important question: should consciousness be regarded as an 'all or nothing' phenomenon? Or should it be characterized as a graded phenomenon, in which there are varying degrees of conscious perception. Note that the term 'consciousness' is used in many contexts that are not directly related to perception (e.g. consciousness as the waking

state, self-consciousness). In this article we restrict our discussion to the conscious–unconscious dichotomy as it pertains to perceptual awareness. (*See* **Self-consciousness**)

HISTORY AND EPISTEMOLOGY

The question of whether perception occurs in the absence of consciousness has a long history in experimental psychology and philosophy. Nineteenth-century psychologists such as Wilhelm Wundt, William James and Sigmund Freud used introspective measures of awareness (i.e., systematic reporting of conscious perceptual experiences from a personal perspective) to demonstrate the existence of unconscious perceptual processes. Introspectionist techniques fell out of favor with the advent of behaviorism in the first half of the twentieth century. The behaviorist view maintains that only directly and objectively observable behavior is appropriate subject matter for experimental psychology. This led to a rejection of the concept of consciousness, and a denial of mental constructs as explanations of behavior. (*See* **Introspection**; **Behaviorism, Philosophical**)

The failure of behaviorist accounts to adequately characterize cognitive processes that are not overtly observable, such as attention and memory, led many researchers to advocate a cognitive approach instead. The cognitive approach emphasizes the importance of mental representations and computations in providing explanations for behavior. It allows a broader conceptualization of the causation of behavior, thereby again admitting the study of unconscious perception into the domain of scientific investigation.

The study of unconscious perception was advanced in the 1980s through pioneering methods for dissociating conscious from unconscious perception in normal observers. This research was paralleled by studies of unconscious perception in neurological patients with discrete brain lesions. Recent advances in functional brain imaging techniques, such as scalp-recorded event-related potentials (ERPs) and functional magnetic resonance imaging (fMRI), have significantly increased our understanding of the brain areas that mediate conscious and unconscious perception. (*See* **Event-related Potentials and Mental Chronometry**; **Neuroimaging**)

HOW MUCH INFORMATION IS PERCEIVED UNCONSCIOUSLY?

At every moment, our various sensory systems are receiving a vast amount of information about the environment. Receptors sensitive to particular sorts of stimuli encode incoming information according to physical properties, location, intensity, duration, and so forth. This information is carried within distinct neural systems belonging to the relevant sensory pathways, and is ultimately transmitted to specialized regions within the cerebral hemispheres. The information thus conveyed is used to create a representation of the external environment. In the case of vision, it is important to note that perception is not embodied in an exact representation of the world (a 'picture in the head'), but rather reflects a reconstruction based upon the distributed activity of structurally and functionally diverse regions within the brain.

Despite the vast amount of sensory information that is received by the brain, there appear to be limits to the amount of information we are able to consciously process at once. Due to this limit in conscious processing capacity, incoming sensory information must be filtered for importance: relevant stimuli must be given high priority for further processing, while irrelevant information must be filtered out. This filtering is largely achieved by mechanisms of selective attention, which have been likened to an 'attenuator' or 'bottleneck' in information processing. (*See* **Attention, Models of**)

Mechanisms of selective attention form a crucial bridge between unconscious perception and what reaches consciousness. We are able to modulate the content of our conscious perception by choosing what we will attend to. Perception may be influenced by top-down (endogenous) strategies, so that awareness is actively, and with effort, controlled by one's intentions. Because of limited capacity, this necessarily involves the filtering of concurrent sensory events, preventing these from reaching awareness. Conversely, perception may be affected in a bottom-up (exogenous) fashion, by stimuli that automatically grab attention due to their sudden appearance or salience. For example, we can direct our attention to oncoming traffic when waiting to cross the road (top-down control), yet salient stimulus information, such as a car horn, can rapidly modify the current content of our perception (bottom-up control), independently of current goals and intentions. The coexistence of stimulusdriven and goal-driven filtering of information in the control of attention, awareness and behavior has obvious evolutionary advantages: it allows us to act purposefully and intentionally without being oblivious to potentially harmful situations. (*See* **Selective Attention**)

METHODS USED TO ASSESS UNCONSCIOUS PERCEPTION

There are many ways in which awareness of stimulus information can be assessed. There is a continuing debate concerning the best methodology to reveal unconscious perception, how to define a threshold of awareness, and how to establish an unambiguous criterion for awareness. Consequently, many tasks have been employed to demonstrate unconscious perception. It is useful to consider these different methodologies within a framework that illustrates the similarities and differences between them.

Dissociations Between Measures

The most common approach to examining perception without awareness has been to demonstrate a dissociation, or difference in performance, between two measures of perception; one measure is designed to be sensitive to perception with awareness, while the other is assumed to reflect perception in the absence of awareness. The aim of the dissociation technique is to demonstrate that stimuli perceived without awareness (as assessed by the measure of conscious perception) are none the less able to influence performance (as assessed by the measure of unconscious perception). If perception can occur without awareness, then a dissociation between the two measures of perception should be observed.

Manipulating stimulus properties

One approach to detecting and measuring unconscious perception of stimulus information is to systematically reduce the quality of the critical stimulus. This reduces the availability of the critical stimulus to conscious perception (as judged by self-report or forced-choice recognition tasks). The typical approach is to initially ascertain an individual's threshold for awareness of experimental stimuli. These stimuli are then presented under conditions in which they appear below the defined threshold, with the aim of determining whether stimuli that fail to reach awareness are none the less able to influence performance on some task.

Many examples of unconscious perception come from studies using 'priming' paradigms. In a typical word-priming experiment, a single letter string (a 'prime') is presented briefly, followed by another letter string (a 'target') in the same location, to which the participant must make some kind of response. The rationale behind this paradigm is that the priming stimulus can change the efficiency of processes involved in generating the target response, depending upon the physical or semantic relationship between prime and target stimuli. Semantic priming is a phenomenon whereby the time taken to respond to a target (e.g. to classify a letter string as a word or a non-word) is affected by the meaning of the prime. For example, if participants are presented with a prime word such as *BREAD*, followed by a semantically related target word such as *BUTTER*, responses to the target word are facilitated: they are faster than when it is preceded by a semantically unrelated word such as *NURSE*. Presentation of the prime may have either facilitatory or inhibitory effects on a subsequent response to the target, depending on whether the prime makes access to the target response more or less efficient. (*See* **Priming**)

'Masked priming' techniques are designed to limit the accessibility of a prime to awareness. The aim of masked priming is to determine whether prime stimuli are able to influence responses to a subsequent target indirectly, even when presented below an objectively defined threshold of awareness. Several techniques have been used to manipulate awareness of the prime. In 'visual masking', visibility of a prime is reduced by presenting another stimulus (a 'mask') in close temporal or spatial proximity (see Figure 1(a)). (*See* **Masking**)

The sorts of stimuli used in these experiments (as either target or prime) range from numbers, letters and color patches to words, pictures and faces. Results suggest that basic stimulus properties such as shape and orientation are perceived unconsciously, as are more complex stimulus attributes. These include categorical associations (e.g. that 'mouse' and 'horse' both belong to the animal category, whereas 'apple' and 'donkey' belong to different categories); semantic associations (e.g. that 'king' and 'queen' are related in meaning); and emotional valence (e.g. face stimuli with happy or fearful expressions).

Manipulating the distribution or focus of attention

Rather than limit conscious perception using techniques such as visual masking, an alternative approach is to manipulate where, or on what, attention is focused. The aim of this approach is to determine whether there is a dissociation between conscious and unconscious perception of unattended stimuli. In these experiments, stimuli are presented under suprathreshold (readily detectable) conditions, so that when observers are asked to focus attention on the critical stimulus it can be perceived consciously. Arguably, manipulations of

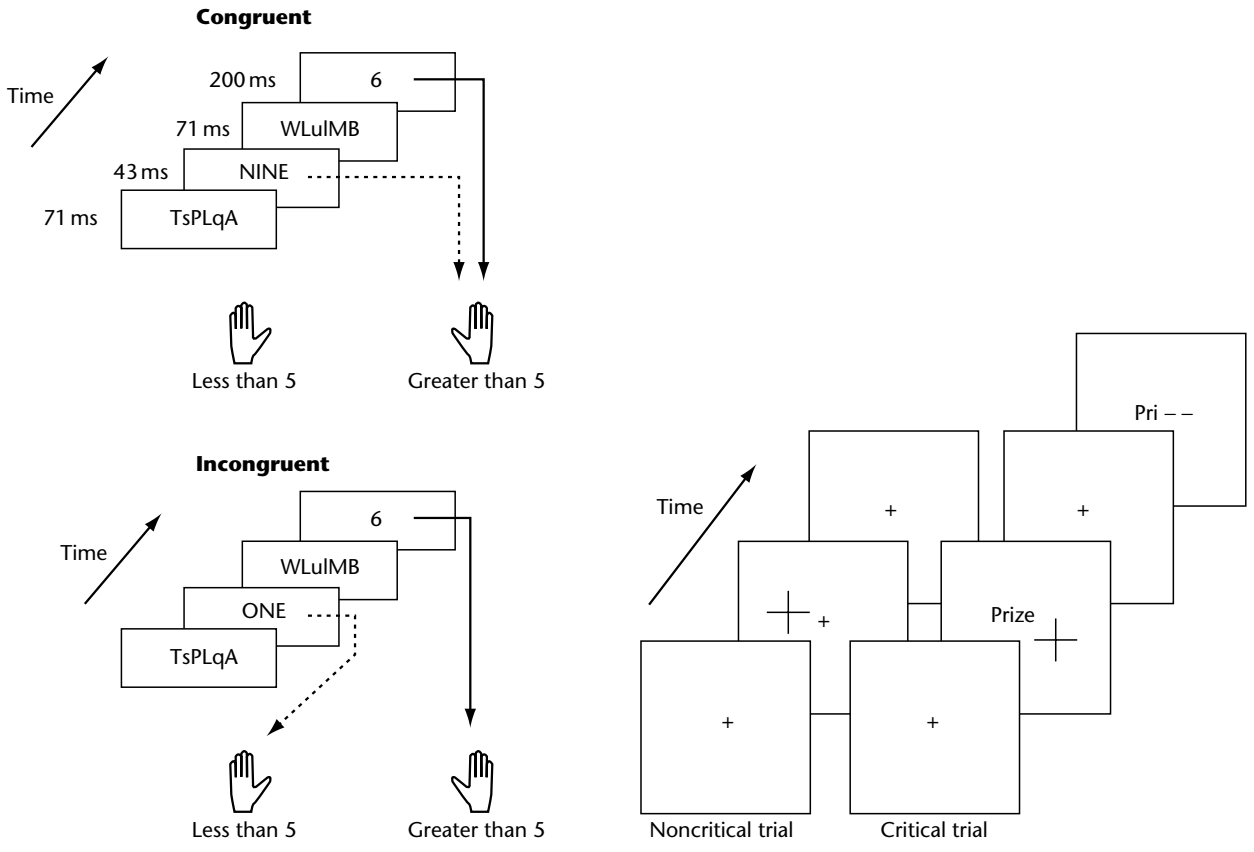

Figure 1. (a) Unconscious perception of a masked prime. Dehaene *et al*. (1998) used a masked priming paradigm, in combination with brain imaging techniques, to demonstrate unconscious perception of masked stimuli. On each trial a number between 1 and 9 (the prime) was presented for a very short duration (43 ms). The prime was forward and backward masked by random letter strings (the first and third displays), and followed by another number (the target). The subject's task was to indicate via a key-press whether the target was greater than or less than 5. The prime could either be 'congruent' with the target (i.e. yielding the same answer), or 'incongruent'. Although subjects were unable to detect the prime, they responded to congruent prime–target pairs faster than to incongruent pairs. Unconscious perception of the masked primes was accompanied by changes in electrical brain activity (as measured by ERPs) and cerebral blood flow (using fMRI) in brain areas responsible for controlling motor responses. (Adapted from Dehaene *et al*., 1998.) (b) Example of displays used in a study of unconscious perception during inattentional blindness (Mack and Rock, 1998). Subjects' awareness of word stimuli was manipulated by having them attend to a distractor task in which they compared the lengths of the vertical and horizontal limbs of a cross, while fixating a central spot. On unexpected 'critical inattention trials', a word (the prime) appeared in the centre of the screen at the same time as the cross. A large proportion of subjects failed to report the word on the critical inattention trial, thus demonstrating inattentional blindness. Unconscious perception of the prime word was subsequently examined using a stem completion task (i.e. making a word from the first three letters presented). Subjects offered the unseen prime as a stem completion on a significantly greater number of trials than would be expected by chance, indicating that the primes had been perceived unconsciously.

attention provide a more realistic simulation of the way in which information is perceived without awareness in everyday life than do manipulations of stimulus quality.

There are numerous cases in which attentional mechanisms influence conscious visual perception. For example, in normal observers the second of two briefly presented visual targets often goes undetected when it occurs within half a second of the first: an effect known as the attentional blink. Failure to detect the second target is due to attentional rather than sensory limits in processing, since it is only observed when the task involves detection of both targets; there is no such deficit when participants are only required to detect the second target. Similarly, in the phenomenon of

change blindness, observers fail to notice salient changes between two visual scenes flashed successively with a blank interval between them. In this case the blank interval removes the visual transient associated with the change, so that attention is not automatically drawn to it. A closely related phenomenon is that of inattentional blindness (Mack and Rock, 1998). When observers have their attention directed to one aspect of a visual display, they frequently miss suprathreshold stimuli presented elsewhere. Note that in this case the failure of conscious perception occurs without a blank interval or mask. Again, the effect is due to having attention devoted to a concurrent task, since if observers are directed to focus their attention on such stimuli, they are capable of consciously perceiving them. (*See* **Change Blindness**; **Change Blindness, Psychology of**)

These examples from experimental psychology have parallels in real-world situations. For instance, Haines (1989) examined experienced pilots as they attempted to land a plane in a flight simulator. As they were landing, the pilots monitored a display of critical flight information that was projected onto the windscreen. While their attention was directed to the flight information, many pilots failed to notice that another aircraft had moved across the runway into their field of view.

What happens to visual information that escapes our awareness due to inattention? Electrophysiological evidence suggests that the meaning of a word stimulus presented during the attentional blink may be accessed unconsciously. In change blindness, above-chance performance in detecting visual changes (e.g. on a forced-choice task) has been observed even though participants are not able to perceive the changes consciously. Similarly, Mack and Rock (1998) found that participants who were inattentionally blind to a prime word tended to offer this word more often in a stem completion task than would be expected by chance (Figure 1(b)). Taken together, these findings provide evidence that engaging attention on a secondary task can limit conscious reports of stimulus events, but leave unconscious perception of them relatively unaffected.

Theoretical Considerations

Subjective versus objective measures of perception

Two general approaches have been used to demonstrate dissociations between measures of perception with and without awareness: 'subjective' and 'objective'. Studies employing subjective measures of awareness consider an observer's direct report to be a valid index of whether or not a given stimulus has been perceived consciously. However, it has long been known that subjective reports can be influenced by factors other than an observer's perceptual sensitivity. Such factors may include confidence, expectations, or simply an affinity for one or another response. For instance, participants may be more or less willing to guess under conditions of uncertainty. This can lead to differences in the measured extent of conscious perception without any differences in sensitivity. It therefore becomes difficult to determine whether subjective measures of awareness actually represent an exhaustive probe of conscious influences on behavior.

Objective measures do not rely on self-report as an indicator of awareness. Rather, conscious perception is inferred using a measurable index of performance (such as forced-choice recognition), and compared with performance on a task designed to reveal any unconscious perception. Objective measures provide a more conservative estimate of the sorts of conditions under which stimuli might be perceived without awareness. However, the objective approach may underestimate the extent of unconscious perception. In contrast, subjective techniques allow a less stringent measure of unconscious perception and thereby increase the likelihood of detecting unconscious influences on performance. Because of the subjective nature of conscious perception, many argue that introspective reports of perceptual experience should be considered valid. In any case, whether assessed by subjective or objective measures, numerous studies have provided unequivocal demonstrations of unconscious perception.

Direct versus indirect tests

The distinction between direct and indirect measures of perception concerns the kind of stimulus information required to complete a task. In direct tests, participants respond to the critical stimulus under investigation. For example, consider a typical priming paradigm in which the word *QUEEN* is presented and masked. A direct test of perceptual awareness might require participants to indicate the identity of the prime via a forced choice. An indirect test might require participants to make a decision as to whether a subsequent letter string (e.g. *KING*) is a word or not. Any difference in the speed of response to the target as a function of prime identity is taken as evidence for unconscious perception of the prime.

Unconscious Perception in Neuropsychological Patients

The phenomenon of unconscious perception in normal individuals may be closely related to the residual abilities exhibited by neuropsychological patients with impaired conscious perception. Understanding the nature of preserved unconscious perception in neuropsychological cases provides important insights into the structural and functional mechanisms subserving conscious perception in the human brain.

Blindsight

Patients with lesions to the primary visual cortex (also known as area V1, or striate cortex) are subjectively blind (i.e. they lack visual experience) for a region of the visual field represented by the lesioned cortex. Despite their subjective visual loss, however, there is evidence to suggest that these patients can perceive aspects of visual stimuli unconsciously. This phenomenon is known as blindsight. Individuals with blindsight may be able to make eye movements towards, or point in the direction of, briefly presented lights flashed in the blind field. Some such patients are also able to discriminate different attributes of visual stimuli, such as color, shape, orientation or direction of movement. Importantly, this residual perception occurs in the absence of the subjective experience of seeing, and so provides a compelling example of unconscious perception. By considering the neural pathways that remain intact in such patients, it is possible to determine the neural basis for these unconscious visual abilities (see Figure 2). (*See* **Blindsight**; **Blindsight, Neural Basis of**)

Visual information from V1 is directed along two anatomically and functionally distinct pathways, or 'streams' (Milner and Goodale, 1995). A dorsal stream, projecting from the occipital cortex to the superior parietal lobe, is involved in the spatial coding of attention and movement; while a ventral stream, projecting to the inferior temporal cortex, is involved in processes of object recognition. The ventral stream relies almost entirely on geniculostriate pathways for visual input. In the dorsal stream, however, retinal information is projected directly to various subcortical sites, including the superior colliculus, inferior pulvinar and suprachiasmatic nucleus, without passing through V1. (*See* **Parietal Cortex**; **Temporal Cortex**)

In cases of blindsight, damage to area V1 disrupts the flow of visual information within the geniculostriate pathway, thereby depriving the ventral stream of visual input. Subcortical structures and their connections to sites within the dorsal stream, however, remain intact. It is these pathways that are likely to underlie the blindsight patient's residual visual abilities in the affected field.

Unilateral neglect and extinction

Unilateral neglect is most commonly observed after damage to the parietal lobe, particularly of the right hemisphere. Neglect patients are typically unaware of stimuli located towards the contralesional side (i.e., the left side after right hemisphere damage), with profound consequences for normal activities of daily living. Patients with left neglect may fail to eat food on the left side of their plate, may have difficulties in dressing the left side of their body, and may collide with objects on the left. Some neglect patients are able to detect isolated stimuli on the contralesional side, but have problems detecting the same stimuli when a simultaneous event is presented on the opposite (ipsilesional) side. Such patients are said to have 'extinction', because the stimulus on the affected side is extinguished from awareness. (*See* **Neglect**)

Conscious perception is lost in neglect and extinction patients even though the primary visual cortex usually remains intact. But, like blindsight patients, these patients demonstrate unconscious perception of visual information in the neglected or extinguished field. For example, although neglect patients are often unaware of left-sided details of objects, they are able to perceive whether such objects are symmetrical in shape – a judgment that requires perception of both sides of the object (Driver *et al*., 1992). This demonstrates that unconscious figure–ground segmentation processes remain intact for neglected information. Other unconscious visual processes, such as perceptual grouping, allow separate stimuli to be bound together to form coherent objects. Contralesional stimuli that would usually be extinguished upon bilateral presentation may suddenly be perceived consciously due to the operation of such perceptual grouping processes (Mattingley *et al*. (1997); see Figure 3(a)). (*See* **Vision: Occlusion, Illusory Contours and 'Filling-in'**)

Unconscious perception in neglect may extend to more complex visual attributes. Visual priming studies have shown that neglected words and pictures may be perceived unconsciously, and in some cases may even activate semantic and emotional associations (McGlinchey-Berroth *et al*. (1993); see Figure 3(b)). Such preserved semantic processing is reminiscent of that observed under conditions of inattentional blindness in normals.

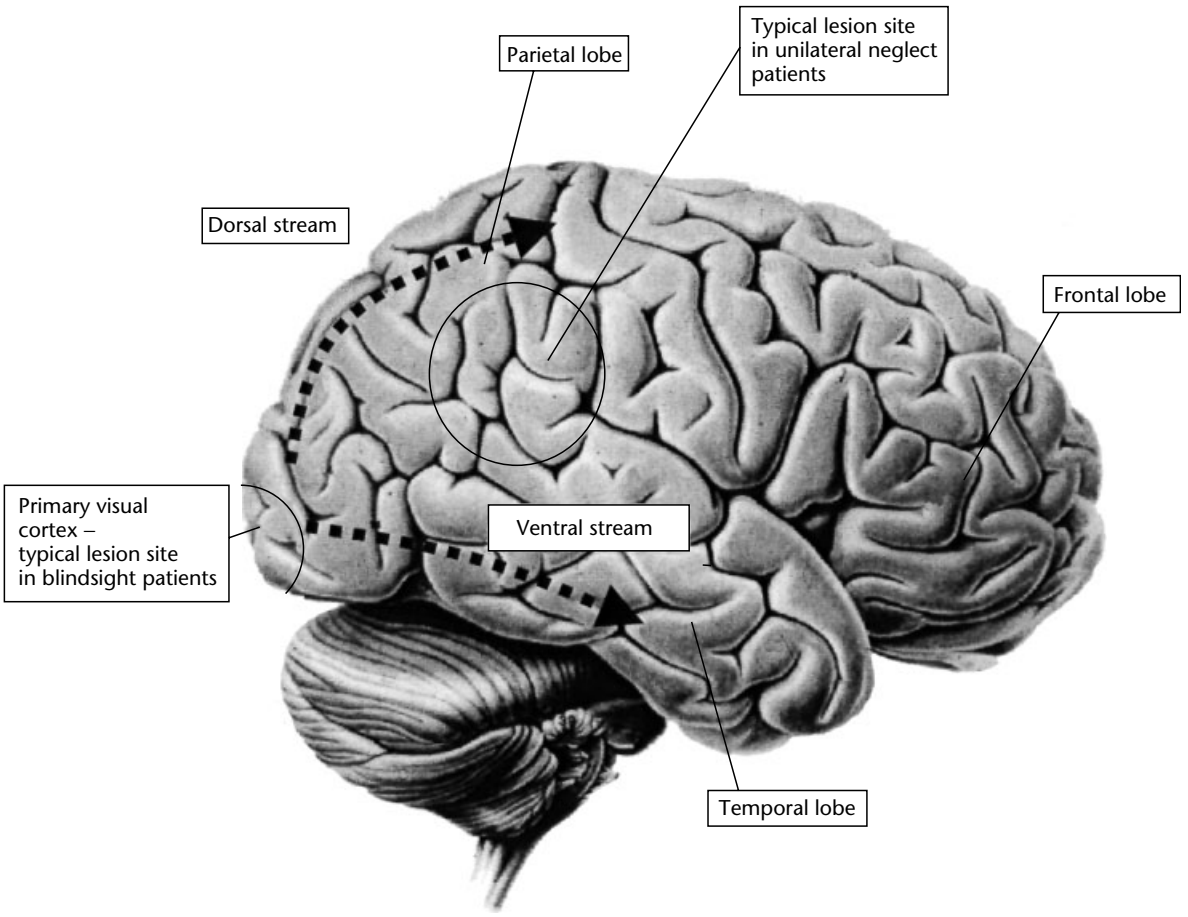

Figure 2. Lateral view of the right hemisphere of the human brain. Temporal, parietal and frontal lobes are shown, as well as the site of primary visual cortex (area V1, or striate cortex). Dorsal and ventral visual pathways are indicated by arrows. Outlined areas indicate typical lesion sites associated with blindsight and unilateral neglect.

Behavioral observations of unconscious perception for neglected stimuli are consistent with the locus of brain damage in these patients (see Figure 2). Although neglect can arise after damage to several different brain areas, it is most severe and persistent following lesions of the inferior parietal lobule, which is located at the interface between the dorsal and ventral visual pathways. Preservation of some contralesional inputs to the ventral pathway following such damage may underlie unconscious perception of object identity and meaning. This hypothesis is supported by recent fMRI and ERP studies with extinction patients (see Figure 4). These studies have shown that extinguished visual stimuli that escape conscious perception still activate early striate and extrastriate areas, as well as subsequent processing stages within the ventral stream, such as face-specific regions in the fusiform gyrus (Rees *et al*., 2000).

The failure of conscious perception for contralesional stimuli in neglect and extinction patients resembles the loss of visual awareness in normals when their attention is engaged elsewhere (as in inattentional blindness), or when it is limited by the rapid succession of target events (as in the attentional blink). Neglect and extinction reflect a pathological bias of spatial attention towards the unaffected field. When patients are cued to attend to stimuli on their neglected side they suddenly perceive them consciously, only to lapse back into their neglectful state shortly afterwards. The modulatory role of attention in conscious perception may be especially relevant in the case of extinction, in which contralesional events are only missed when an ipsilesional stimulus competes for attention. Indeed, extinction patients appear to suffer from an exaggerated form of the normal difficulty in attending to multiple targets at once (Husain *et al*., 1997).

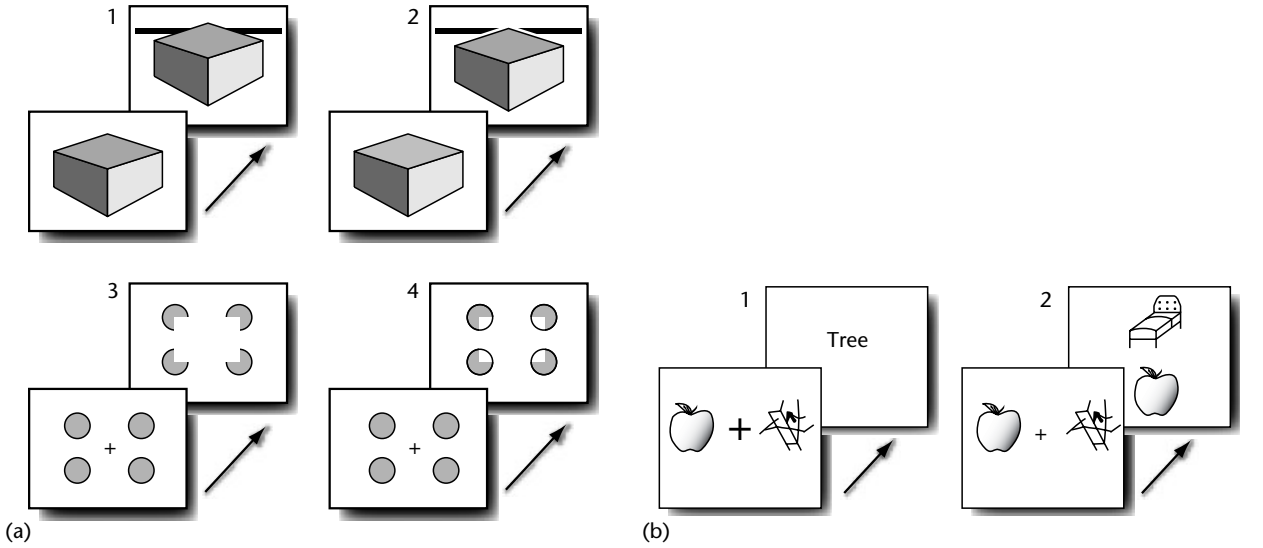

Figure 3. (a) Examples of sequences used to examine unconscious visual completion in a patient with visual extinction. In (1) and (2) the task was to detect the onset of black bars on the left or right alone, or on both sides simultaneously (shown). In (1) the bars appear to form a continuous, but partly occluded, rod, because of image segmentation processes. Marked extinction was observed for the left bar on bilateral trials as pictured in (2), but was significantly reduced in trials like (1), demonstrating the operation of preserved depth perception and image segmentation processes. In (3) and (4) the patient was asked to indicate which quarter-segments had been removed (left, right, both or neither) from four disks. The patient showed less severe left-sided extinction on bilateral trials when the removed portions formed an illusory rectangle, as in (3), than when segments were removed from other parts of the disk, or when arcs prevented the illusion, as in (4). (Adapted from Mattingley *et al.*, 1997.) (b) Example display sequences from a study of unconscious perception of contralesional stimuli in patients with unilateral neglect (McGlinchey-Berroth *et al.*, 1993). Neglect patients were faster to decide whether a target letter string (such as *TREE*) was a word when it was preceded by a semantically related picture (e.g. an apple) to the contralesional visual field, as in (1), than in conditions where the contralesional picture was unrelated to the prime. In a separate control task the same patients were unable to identify the contralesional prime at better than chance levels when presented with the prime and a foil, as in (2). These results suggest that neglected stimuli receive considerable unconscious (semantic) processing. (Adapted from Driver and Mattingley, 1998.)

Neurophysiological and Neuroimaging Contributions to the Study of Unconscious Perception

Recent advances in brain imaging techniques have begun to reveal the neural correlates of conscious and unconscious perception. Given the extent of unconscious perception in normals and in neurological patients, we might ask: what kind of neural activity is needed to yield conscious perception? Is it possible to localize conscious perception to a single area or circuit within the brain, or is it distributed across a network of areas? (*See* **Neural Correlates of Visual Consciousness**; **Neural Correlates of Consciousness as State and Trait**)

One approach has been to use masked priming techniques in combination with fMRI (Dehaene *et al.*, 1998). These studies have demonstrated that unconscious perception of words, objects and faces is associated with increased neural activity in brain areas specialized for processing these different kinds of stimuli. Other studies have investigated the neural correlates of visual perception with changes in selective attention. In an fMRI study of change blindness, observers had to detect changes in face photographs while performing an attention-demanding secondary task (Beck *et al.*, 2001). Brain activity was compared for trials in which there was no change in the face stimuli and trials in which a change had occurred but was not detected. Focal activation was observed in brain areas normally responsive to faces (the fusiform face area), despite the observers' failure to consciously perceive the change. Conversely, conscious perception of change was associated with increased activity in parietal and prefrontal cortices, perhaps indicating a special role for these areas in mediating conscious visual experience. (*See* **Object Perception, Neural Basis of**; **Face Perception, Psychology of**)

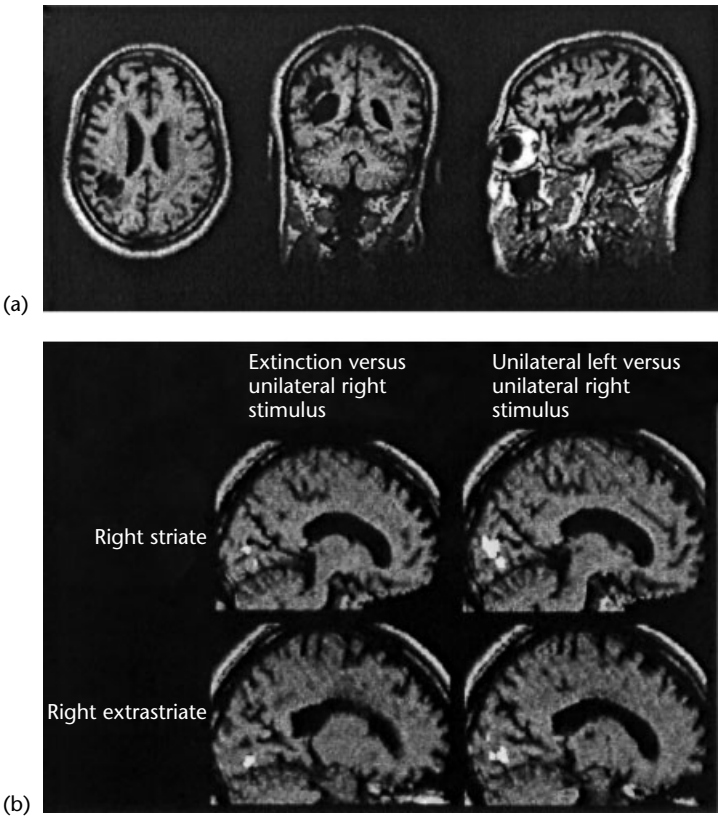

Figure 4. (a) The neural correlates of unconscious perception in extinction, revealed using fMRI. Patient GK suffered damage to the right inferior parietal lobe, as evident in these structural scans (from left to right: axial, coronal and sagittal views). Note that left and right are reversed in these images. (b) In the extinction study, the patient's task was to detect pictures of faces or houses to the left or right visual fields, or to both fields simultaneously. Significant activity was observed in early striate and extrastriate areas on bilateral face trials in which the left stimulus was extinguished and the right stimulus only was detected, compared with trials in which a right stimulus was presented in isolation (slices on left of panel). These regions of significant activity overlap anatomically with those obtained for unilateral left stimuli relative to unilateral right stimuli (slices on right of panel). (Adapted from Rees *et al.*, 2000.)

The results of these and other neuroimaging studies in normal observers are broadly consistent with the finding of substantial unconscious perception in patients with neglect and extinction. They imply that the processing of stimuli perceived unconsciously is correlated with activity in material-specific areas within the ventral pathway; and that conscious visual perception may be especially reliant on areas within the dorsal pathway, including the parietal cortex.

SUMMARY

The phenomenon of unconscious perception has been investigated from a number of theoretical perspectives. Empirically, unconscious perception has been explored using several different techniques, including behavioral investigations in normal observers and neuropsychological patients, and neurophysiological techniques such as scalp-recorded ERPs and fMRI. Although we have focused on evidence for unconscious perception in vision, analogous phenomena have been observed in other sensory modalities.

Taken together, the evidence suggests that significant perceptual processing can occur without awareness. Unconscious perception of objects, words, faces, and many other visual stimuli is associated with activity in specialized brain areas within the ventral pathway, and may also lead to activation of remote areas, such as those responsible for motor responses. Findings in normals and neuropsychological patients suggest that mechanisms of selective attention play a crucial role in conscious perception, while considerable unconscious perception may still proceed in the absence of attention. Activity within parietal cortex is associated with the conscious perception of change

in visual displays, and damage to this area results in contralesional spatial neglect and extinction.

While a comprehensive explanation for the cognitive and neural mechanisms underlying unconscious perception is still a long way off, convergent approaches that combine behavioral and neurophysiological methods are likely to reveal further aspects of it.

Personal Identity

Intermediate article

Jennifer Radden, University of Massachusetts, Boston, Massachusetts, USA

CONTENTS

Personal identity is a hotly contested topic in both definition and implication, which questions whether, and in what sense, an individual person can be understood as a uniquely definable entity at any one time (synchronic unity) and as that same entity through time (diachronic unity).

INTRODUCTION

Loosely understood, personal identity is nothing more than the customary unity and integration we expect of lived experience and personality. It is the assumption, presupposed in most social exchange and implicit in most human practices and institutions, that individual persons are one and the same through stretches of time. For all its commonplace and practical side, personal identity understood as a philosophical concept is complex and has generated immense controversy. Among other things, theorists differ over whether personal identity raises a philosophical problem at all, over what the problem is, over what a solution to such a problem might look like, and over the means to reaching such a solution. Recent postmodern theorizing has rejected many of the terms within which these philosophical discussions are conducted, dismissing as myth the unified subject of first-person narratives and the presumption of unified phenomenal experience.

This postmodern skepticism aside, however, so few points of agreement are shared among theorists of personal identity that it is misleading to speak of one philosophical problem or even one philosophical concept here, and an overview of the broad field is better undertaken by characterizing the separate controversies than by focusing on the modest points of agreement.

CENTRAL PHILOSOPHICAL ISSUES

Four different questions allow us to map the complex set of issues which fall under the broad head of philosophical theories of personal identity: (1) whether the reidentification of persons is to be understood on the model of the reidentification of all spatio-temporal particulars; (2) whether person individuation must be dealt with separately from person reidentification; (3) whether personal 'identity', or better 'survival', is a scalar concept, admitting of degree; and (4) whether any questions about personal identity are facts of the matter to be discovered rather than arbitrated.

Person Reidentification

Understood as a composite of bodily and psychological or mental states, a person is one kind of particular, with a unique and uniquely identifying spatio-temporal path in the world. In this respect, persons are not unlike other spatio-temporal particulars, such as chairs. The reidentification of chairs is not always easy in practice, but admits of a simple enough rule: a chair is judged the same between time 1 (t_1) and time 2 (t_2) when the spatio-temporal continuity can be established linking its earlier and later instantiations. This matter is complicated, even with particulars like chairs, inasmuch as we utilize the same language to indicate qualitative as well as numerical identity. 'The same chair' may mean a qualitatively similar chair (same color, style) or the very chair (numerical identity). Context usually prevents us from becoming confused by these potential ambiguities when we are talking about such things as chairs; speakers of English are adroit at distinguishing 'the same x' as bespeaking the spatio-temporal continuity of particulars, and the sameness which rests on similarity of qualities such as color and shape.

Some philosophers have insisted that the spatio-temporal continuity of the person's bodily attributes are similarly the source of personal identity judgments. The body is thus said to be criterial for personal identity (Williams, 1973). On this theory, the continuity of persons is just as strict, no more and no less, and for the same reasons, as the identity of the other material objects we judge to remain

the same through time. This may not be 'identity' in the strict numerical sense. But the workaday spatio-temporal continuity is all we ever need to reidentify particulars, be they chairs or persons, on this view, whether or not we describe the sameness we recognize to be 'identity' properly so called.

The normal person in everyday contexts has a high degree of continuity of several kinds. As well as the continuation of the body through its spatio-temporal path, continuity is also provided by enduring psychological states and dispositions, by memory, by the stream of consciousness, and by persisting capabilities and skills. Rejecting the view that bodily continuity accounts for personal identity, other theorists have identified some of these enduring or relatively enduring attributes as criteria for personal identity. Locke argued that the continuity of memory between earlier and later person or self stages explained personal identity. Several twentieth-century thinkers have pointed to psychological states and dispositions more generally understood to explain the person's sameness or survival through time (Grice, 1941; Parfit, 1984; Shoemaker, 1979). As long as these attributes are taken to be psychological occurrences (particular, datable, introspectible events in consciousness), there will be interruptions in this continuity, such as those resultant from sleep. But by treating these traits as dispositions or capabilities with causal powers (we remain disposed to do, feel, remember, believe, or will, even while asleep) it is not difficult to countenance their providing uninterrupted continuity. On such an analysis, the continuity of psychological states explains the customary presumption that the self or person remains constant through stretches of time, forming a causally related and overlapping series in most people's lives sufficient for us to speak of the same person surviving, if not as maintaining 'identity', strictly understood, through stretches of time.

Person Individuation

The question of whether person individuation must be dealt with separately from person reidentification requires us to consider the person's oneness or unity in two ways. The (synchronic) unity of the person's experiences at a given time and the (diachronic) continuity of the person through time seem to give rise to questions of differentiation, or self-ascription, such as 'On what basis do I know that all these experiences are *my* experiences?' as well as to the questions of reidentification introduced earlier ('Is this the same person between t_1 and t_2?'). But until Hume's famous, fruitless pursuit of the self as an object of experience, these two kinds of question were apparently conflated. The Cartesian subject or self, for which Hume searched in vain, was understood to encompass a unifying principle, linking items in the imagination at a given time, and as well, because it remained unaltered through time, providing the continuity of perfect identity persisting throughout the individual's life.

It was this Cartesian concept of subject or self which Hume believed he exploded. Rather than a simple, united whole which ensured differentiation and synchronic unity as well as reidentification and diachronic unity, Hume discovered an untidy bundle of heterogeneous and ever-changing impressions. Instead of the strict and perfect identity intrinsic to the self associated with its continuation through time, by which it was thought changeless, Hume pictured an imperfect and 'imaginary' or 'fictional' identity, imposed from without for the convenience of the observer.

Hume did not question the self's unity. But he denied the basis for making claims about unity and continuity – the Cartesian notion that underlying these two kinds of identity there stood a metaphysical subject of experiences. If, as Hume concluded, there was no subject of experiences, then the supposed unifying functions of that subject would be lost. Nonetheless, synchronic unity and the consequent differentiation it provided remained – ensured, Hume believed, by the imagination. A loose and relative continuity, misnamed 'identity', based on the relations of contiguity (proximity or closeness), resemblance, and causation linked earlier and later experience stages in a way sufficient for us to speak of the person as remaining the same through time. Hume's is a reductionist theory of the self, and if we speak of selves as unified both at and through time, it must be due to the rough empirical cohesion among and continuities between parts of the self, a cohesion ensured by the imagination.

Some philosophers (Kant was one) have rejected Hume's empirical approach, and appeal is still made to a transcendental subject in explaining the self's synchronic and diachronic unity (Korsgaard, 1989). Moreover, the imagination was hardly sufficient for the task Hume imposed upon it, as others came to recognize. Without the transcendental principle to at once unify the contents of consciousness at any given time and thus provide the means for differentiating one person's experiences from those of another, and to unify the scattered parts of a person's experience through time, permitting

person reidentification, these two kinds of unity required for personal identity were in need of, and received, separate theoretical treatment.

Questions about synchronic unity such as the one noted above ('How do I know these experiences are my experiences?'), and the means of differentiating one person's experiences from another's, concern what is known as self-attribution, or ownership. Different philosophical accounts share the conclusion that self-attribution is grammatically guaranteed: the concept of experience prevents our speaking of unowned experiences, thus 'this experience' entails 'my experience'. Whether this is a trivial or an interesting feature of human experience, however, is disputed.

Some theorists have emphasized the psychological necessity of ownership. As a contingent fact, they suggest, humans have evolved to own all and only our experiences (Dennett, 1991). Others insist that self-ascription is logically guaranteed in any subjective or introspective report. Any first-person account is by its nature an account in which 'this experience' entails 'my experience'. Examining the evidence from psychopathological symptoms of mental alienation, in which a patient appears to deny ownership of his or her experience, others have analyzed normal self-ascription into two parts, one concerning ownership (the assertion that experience *X* occurred within me), and the other agency (the assertion that experience *X* is my mental action, or a thought I think) (Graham and Stephens, 1994; Radden, 1996).This distinction between thoughts which merely occur in us, and thoughts we think, renders self-ascription and the grammar of ownership ambiguous.

Cut loose from the unifying function provided in the transcendental theories of personal identity which are largely rejected today in favor of empirical, psychological continuity analyses, the need for an account of self-attribution becomes more pressing. These efforts to understand self-attribution are important contributions.

Personal 'Identity', Sameness, or Survival as Scalar

If the self is experienced as relatively continuous through time, this may be because of our dispositions to remember, Locke believed. However, we do not remember perfectly. Recognizing this, Grice sketched a memory theory of personal identity which treats memory as an overlapping series (Grice, 1941). A 'total temporary state' (tts) is a set of simultaneous experiences of a single person, and Grice argued that a sequence of tts's comprise parts of the same person (and thus constitute an identity) when certain relations obtain between them: each tts is disposed to remember at least one experience contained in the last, or contains an experience of which the next contains a memory. A single person's tts's thus form an interlocking series, defined by Grice as one in which no subset of members is independent of all the rest. Memory is understood dispositionally here. A tts is 'memorable' when it contains as an element some experience a memory of which would, given certain conditions, occur as an element in some subsequent tts. A tts is 'memorative' when it would, given certain conditions, contain as an element a memory of some experience contained in a previous tts.

Grice's analysis calls for a very modest continuity of memories to ensure the continuation or survival of the same person through time. Though little else were to remain unchanged, one shared memory between two self stages may be sufficient for us to speak of those stages as earlier and later parts of the same person. Grice's account is thus relatively conservative; that is, a (loose) identity or 'singularity' conserving theory. In all but the most extreme cases of discontinuity it allows us to maintain the traditional presumption that just one person inhabits one body for its lifetime (a presumption dubbed the 'one to a customer' rule: Dennett, 1991).

More encompassing than Grice's theory, Parfit's influential empirical continuity argument accommodates not only memory but also other forms of psychological continuity (Parfit, 1984). On this analysis, the 'psychological states' whose continuity explains language suggestive of personal identity include behavioral traits and tendencies as well as occurrent mental items datable to a particular moment – not only memories, dispositions, and personality traits, but also other, more general capabilities, such as how to speak or swim. Like Grice, Parfit uses the notion of an overlapping or interlocking series. Earlier and later self stages housed in a single body at different times have continuity when and to the extent that they overlap. Should psychological states A and B overlap in this way between t_1 and t_3, then there is 'connection' between A and B at t_2. Rather than 'identity' strictly understood, Parfit employs the notion of 'survival'. If person P remains the same between t_1 and t_3 due to such overlapping connection, then P survives between t_1 and t_3. The more traits are continuous, the more survival there will be. So connections admit of, and can hold to, any degree. If between t_1 and t_3 person P's connected traits numbered 100, and person Q's numbered 50, we could conclude

that between t_1 and t_3 person P survived more fully than person Q.

Parfit's psychological continuity analysis permits a broad set of traits to determine survival. Thus, a person in whom brain injury has brought about total amnesia concerning her past life, together with radical personality change, may have retained no trait of memory and personality entitling us to judge her the same person after, as before, her injury. But while there remain some overlapping traits – she can still knit, let us say, or swim – then on Parfit's account we may speak of survival.

The notion of a disposition is a causal one. This means that the continuity provided by interconnected dispositions is 'causally grounded continuity' (Shoemaker, 1984, p. 84). This causal basis of psychological dispositions has been particularly emphasized by Shoemaker, who regards the continuity of persons through time as an instance of the more general continuity of 'continuants', things which we treat as the same through apparent change. Direct psychological connection between earlier and later stages of a person is guaranteed by the later stage's standing in the appropriate relation of causal dependence to a state contained in the earlier stage. (Theorists debate whether, for us to speak of personal 'identity' or survival, these chains of psychological continuity and connectedness must result from normal causal processes. The acquisition of artificially created 'quasi-memories' otherwise bearing the appropriate relation to a person's current states puts pressure on this requirement.)

Because survival admits of degree, the determination that one self has succeeded another is an arbitrary matter calling for decision. How much variance of psychological traits through time ranks as sufficient for us to judge one self to have replaced (or joined) another in a single body will presumably depend on context and on the purposes and interests we bring to the decision.

Personal 'Identity' or Survival as a Matter of Discovery or Adjudication

Some argue that questions about personal identity are facts of the matter – to be discovered, not arbitrated, and this discussion reveals the contrasting approaches and methods found in discussions of personal identity.

In the tradition of Locke's famous request that we imagine the minds of a prince and a cobbler, respectively, transferred to one another's bodies, and allow our intuitions to determine whether the cobbler's or the prince's body housed the person of each, philosophical discussions of personal identity usually employ a thought experiment to establish their claims. As in Locke's model, kinds of continuity are imaginarily eliminated and we are asked to consult intuitive convictions about the survival of the resultant entity and about our moral and other attitudes towards it. Elaborate thought experimental examples of fusion, branching, and brain transplant are constructed in support of these conclusions. For example, if A's brain is transplanted into B's body, we can ask whether reproaching A/B for A's earlier crimes would be right.

Implicit in this methodology is the notion that a metaphysical fact of the matter exists, and can be discovered through patient theorizing. Such a view is fundamentally at odds with the approach which allows that survival is a matter for arbitration.

Some theories of personal identity have been subject to a different kind of challenge. Serious normative costs appear to be associated with the merely empirical self which explains identity language and presuppositions without resort to a numerically identical subject, and admits that several selves might coexist or succeed one another within a bodily lifetime. The effect of Parfit's work, particularly, has been a marshaling of the reasons to value the unified and numerically identical self associated with individualism, and a rehearsal of the normative costs of rejecting it – costs which allegedly entail the loss of central moral and legal conceptions of autonomy, responsibility, agency, blame, praise, and so on. This reasoning takes the form not of discovering a metaphysical truth, but of emphasizing the normative tug of individualism, the several compelling reasons why, even if we could choose to adopt a survival threshold which violated traditional personal identity presuppositions, the costs of doing so in the loss of our most valued concepts, categories, and practices would be unacceptable. Initially raised by those who maintain allegiance to a transcendental subject which serves to ensure strict personal identity, such considerations also affect the position of those accepting an empirical theory of personal survival (Radden, 1996). Conceding the theoretical possibility that several selves or persons might inhabit one body through its lifetime, one might nonetheless argue for a more singularity-conserving survival threshold on the grounds that such normative costs are too high to be tolerated.

For all that they focus on the same issue, these contrasting approaches differ fundamentally. Whether something requires or, alternatively,

invites us to uphold belief in personal identity and/or survival are very different matters, and if we are required to uphold that belief, then we do not need to trouble ourselves over the blandishments of normative individualism.

These four sources of fundamental disagreement provide a rough map of the lines of inquiry found in philosophical discussions of personal identity. As this map indicates, the significance for personal identity of theorizing about brain science will hardly be an uncontested or straightforward matter, but a number of the issues raised above intersect with, and may be affected by, parallel explorations in cognitive science.

THE IMPACT OF COGNITIVE SCIENCE

Speculation about the impact of findings in cognitive science on these traditional philosophical questions of personal identity has been extensive, and may be categorized into four areas.

(1) As the result of surgery, disease, and damage to the brain, a deficiency in specific psychological functions has been correlated with particular brain structure or function. So-called deficit studies in some cases have been germane to issues of personal identity. Thus, for example, experimental data from patients suffering 'split brains' after commissurotomy (severing the connection between the brain hemispheres) has been used to challenge claims about the unity of consciousness (Nagel, 1971). The massive irreversible amnesias resulting from head injury which leave a person without selfhood or normal experience seem to confirm the philosophical claim that personal identity or survival requires memory. In a striking recent example, Damasio implicates the cingulate cortex in generating the 'self in the act of knowing' by showing the way damage to the cingulate cortex affects both the ever-changing consciousness of immediate experience and the extended consciousness in which both known and knower are represented (Damasio, 1999).

(2) So-called functional mental disorders (where no known disease or damage to the brain has yet been identified) have also been linked to philosophical claims about personal identity. In the most vivid of these disorders, multiple personality appears to challenge claims about the unity of the self both synchronically and diachronically understood; and the psychotic symptom of thought insertion in which a person 'disowns' certain mental or experiential content similarly casts doubt, and new light, on usual forms of self-ascription (Stephens and Graham, 2000).

(3) Both theoretical and experimental advances in cognitive science in recent years have provided a range of hypotheses affecting philosophical accounts of personal identity. Certain areas of the brain are apparently implicated in processes like those involved in traditional conceptions of personal identity. Penfield's work has linked the temporal lobe with the familiarity which attaches to feelings and memories (Penfield, 1973); both the limbic system (especially the amygdala) and the prefrontal cortex have been identified as seats of the kind of personal, emotional memory some philosophers regard as constituting personal identity. The complex, iterative nature of memory processes also appears to speak to traditional notions of personal identity (Edelman, 1993). Damasio (1999) has perhaps come closest to philosophical conceptions of personal identity in his speculation about the way brain nuclei, hypothalamus, medial forebrain, and insular and somatosensory cortices create a representation of current bodily states, including a nonconscious synchronic 'core self' modified, moment to moment, by experience, which in turn generates the conscious 'autobiographical self', a feeling of lived past and anticipated future which is diachronic or extended. Closely allied to philosophical questions about the synchronic unity of experience is the so-called binding problem raised by theorists of consciousness: how properties which are represented by spatially separated neurons in the brain come to cohere in the internal structure which allows us to experience the world as objective.

(4) Advances in artificial intelligence offer new ways of construing self-ascription. A self-ascription function which discriminates between self and not-self can be given computational characterization (Perlis, 1999).

In sum, no evidence from cognitive science offers unequivocal proof of claims about personal identity, but significant findings and theories in cognitive science have bearing on the continuing debates between philosophers on these issues.

Phenomenology

Intermediate article

David Woodruff Smith, University of California, Irvine, California, USA

CONTENTS

Phenomenology is the study of consciousness as experienced from the first-person point of view. Focusing the philosophical theory of mind on intentionality, or mental representation, it lays a foundation for empirical studies of mind in cognitive science.

INTRODUCTION

The theory of mind developed in philosophy from Plato and Aristotle, through Descartes, Locke and Kant, to Brentano and James. Around 1900, drawing crucial distinctions among ideas and their objects, Husserl formulated the basic theory of intentionality that is central to phenomenology. The computational model of mind emerged with cognitive science in the 1970s, and the issue of consciousness became central again in the 1990s. To contemporary cognitive science, phenomenology contributes a developed analysis of conscious intentional experience.

WHAT IS PHENOMENOLOGY?

Phenomenology is the study of consciousness as experienced from the first-person point of view. Its domain is the entire field of conscious experience: including perception, imagination, thought, reasoning, desire, emotion, volition, and embodied action, as well as temporal awareness, awareness of self and personal identity, awareness of others, and practical and social activity. Its focus is on the structure of conscious mental states, or experiences, especially intentionality, that is, the way in which mental states represent or are directed towards various things. (Alternative characterizations of phenomenology are noted below.)

So defined, phenomenology is a discipline: the study of consciousness. Its methodology will be addressed below. There has been controversy as to whether phenomenology should proceed by some form of inner reflection or introspection; or by a more artful form of interpretation of experience akin to textual interpetation; or by an analytic method more like that of logic or linguistics or mathematics; or by some variation on the empirical scientific method of observation, hypothesis, and theory confirmation.

As a program in philosophy, phenomenology would ground or center all philosophy in our own lived experience. As an empirical research program, phenomenology would focus on structures of consciousness as we experience them. The latter program of research intersects with parts of cognitive science. (*See* **Consciousness, Cognitive Theories of**)

HISTORY

Plato spoke of the *psyche* (soul, mind) and the forms or ideas (*eidos*) of things. Then Aristotle proposed that in perception the psyche takes in the form but not the matter of the object perceived. In the Middle Ages Islamic philosophers distinguished form-in-mind from form-in-object, and then the neo-Aristotelian Scholastic philosophers of the fourteenth century dubbed the form-in-mind 'intentio': the mental content that 'aims' at an object.

In the seventeenth century Descartes sharply advanced the conception of mind: firstly, he held, the mind can be known with a kind of certainty while all else is cast in methodological doubt ('I think, therefore I am'); secondly, he held, mind and body are distinct in kind, as a body is extended in space (and time) while a mental state is not. In the eighteenth century, Locke, Hume and Kant further stressed the radically different characters of mind and nature. In the same era Newton's physics laid down mathematical laws of motion, while Locke focused philosophy on the structure of our 'ideas', and so on consciousness and the 'self-consciousness' that, for Locke, distinguishes our conscious mental states. Locke also stressed principles of continuity over time that constitute our personal identity. Hume, however, cast doubt

on our pretensions to knowledge of the existence of the external world. Kant then distinguished 'phenomena', or things as they appear, from 'noumena', or things in themselves, holding that our representations of things were all we could know of things.

In the nineteenth century, following on from these lines of argument, the foundations of phenomenology were laid. First Bernard Bolzano distinguished between subjective ideas (experiences) and objective ideas (including the timeless propositions long studied by logicians). Then Franz Brentano revived the medieval notion of 'intentio': what distinguishes mental from physical phenomena, according to Brentano, is the way in which mental acts are 'directed' towards objects.

By 1900 Edmund Husserl had synthesized these lines of theory – from logic, epistemology, psychology, and ontology – into the discipline he called 'phenomenology' (Husserl, 1900, 1913). The term 'phenomenology' had been used loosely since the seventeenth century, roughly defined as the description of 'phenomena', or appearances, especially sensible qualities of things. Husserl defined phenomenology as the science of the essence of consciousness.

The central thesis of phenomenology, according to Husserl, is that consciousness is always consciousness of something. That is, every act of consciousness is 'intentional' (in Husserl's terminology), or directed towards some object. Alternatively, consciousness represents things in the world. Since the 1970s, cognitive science has stressed the empirical study of mental representation, what Husserl called intentionality. Husserl's great achievement was to analyze the structure of intentionality in general and then to pursue specific forms of intentionality in different forms of experience: in perception, imagination, action, speech, temporal awareness, and intersubjective awareness of other people. Husserl, for the first time, clearly drew the necessary distinctions among subject, act, content, and object of consciousness – though these notions had been developing since Plato and Aristotle. Husserl's account of intentionality, however, was not itself committed to the problematic ontologies of dualism, idealism, or reductive materialism that had dominated philosophy since the seventeenth century – or to the problematic distinction between phenomena and 'things in themselves' that dominated Kantian and post-Kantian philosophy in the eighteenth and nineteenth centuries.

Husserl's work in phenomenology was followed by the writings of Martin Heidegger, Maurice Merleau-Ponty, and Jean-Paul Sartre, often elaborating psychological and social aspects of human existence. Heidegger (1927a,b) stressed the 'being' of human beings in our intentional, practical and cultural activities, downplaying consciousness in favor of our modes of being. Merleau-Ponty (1945) emphasized the role of bodily experience in perception and other forms of human experience. Sartre (1943) stressed our experience of freedom of will, and again our being in the world with others. His account of the 'look' of 'the other' led, through Simone de Beauvoir, to the sociopolitical account of women and minorities being treated and conceived as 'other'.

In the first half of the twentieth century, phenomenologists argued over what is most fundamental in forming intentionality (consciousness or language or social practice), over what is most fundamental in being (the individual self, the act of consciousness, the body or embodied intentional act, the background culture, or 'they'), and over method. Husserl proposed a method of 'bracketing' the object of consciousness in order to focus on the form or content of one's experience, thus describing the object only as it is experienced. Some phenomenologists have pursued this 'transcendental attitude' in a way that resembles Zen meditation, observing the world as we experience it without judgment about the 'natural world' (cf. Sokolowski, 1999). Heidegger practiced a 'hermeneutic' method of interpreting modes of intentional activity within the context of being with others; Merleau-Ponty pursued the description of experience within the context of embodied activity, as even vision is seeing with and by the use of one's body. Phenomenological analyses often went beyond the obviously conscious elements of our experience and into more habitual activities and the background cultural practices that give meaning to our activities. In this way phenomenology spread beyond its original domain, which was the obviously conscious side of our intentional activities.

This work in phenomenology was part of the so-called continental tradition in German and French philosophy, though it developed from the more analytic work of Bolzano, Brentano and Husserl in the Austrian tradition that also produced the positivism of the Vienna Circle in the 1920s and 1930s. Meanwhile, a different philosophy of mind developed in England and then America, including the theories of behaviorism, materialism, and functionalism. Around 1950, logical behaviorism, inspired by Wittgenstein and Ryle, became popular. Ryle had read Husserl and Heidegger sympathetically, but he rejected the Cartesian view that our knowledge of our own mental states is incorrigible,

and he proposed that our language about mental states is logically committed to ascriptions of dispositions to overt behavior. Then materialism (the theory that mind is brain) was revived in the 1950s and 1960s, followed by functionalism (the theory that mind is neural or computational function), which led to the emergence of cognitive science in the 1970s. In these third-person accounts of mind, phenomenology occupied an uneasy position, as we see finally in Dennett (1991), where first-person 'autophenomenology' is rejected in favor of third-person 'heterophenomenology', an analysis of consciousness prompted by neuroscience, which Dennett claims rejects a Cartesian 'theater' where mental events take place in full view of the experiencing subject. (*See* **Materialism**; **Functionalism**)

In the 1970s, however, Dagfinn Føllesdal and others (Dreyfus, 1982; Smith and McIntyre, 1982) stressed the connection between Husserlian phenomenology and modern logical theory. Føllesdal (1969) realigned the theory of intentionality with the theory of reference (and truth) in logical–semantic theory and the philosophy of language.

As cognitive science developed, John Searle (1983, 1992) re-articulated the structure of intentionality. Searle's work was not explicitly phenomenological, but he stressed the first-person ontology of mind, arguing for the irreducibly subjective character of intentionality and consciousness – even though, for Searle, the world remains basically physical, humans basically biological, and the subjective character of mind a natural, biological phenomenon.

As the philosophy of mind developed through the 1980s, consciousness assumed a central position again. Behaviorism had banished consciousness, introspection, and the fruits of phenomenology; but then Nagel (1974) argued that an objective account of the world would necessarily omit the subjective character of mental states, 'what it is like' to experience these states. Gradually, the first-person perspective regained ground. Consciousness was widely studied in the 1990s, and when Chalmers (1996) surveyed the state of the art he declared consciousness – the subjective, first-personal phenomenon – the 'hard problem' for our scientific theory of mind.

PHENOMENOLOGY AS A PHILOSOPHICAL PROGRAM

Phenomenology is not an autonomous discipline designed to study consciousnes for its own sake. For Husserl, Heidegger, and the other pioneers of modern phenomenology, all of philosophy was at stake. Descartes had revolutionized philosophy by turning Aristotelian thought towards pure reason in the light of our own conscious thought. Locke and the empiricists had pursued philosophy through the new 'way of ideas', founding epistemology on sense experience rather than reason. Kant's 'critical' or 'transcendental' philosophy had sought to synthesize rationalism and empiricism, while avoiding the realism–idealism debate by placing all that is knowable within the category of 'phenomena'. Husserl's phenomenology was then designed as a way to approach traditional philosophical issues, by developing a clear method for studying consciousness, and thus knowledge, in an objective, scientific way. Today, phenomenology may be seen to contribute systematically to philosophy through its careful analysis of intentionality. Intentionality is relevant to the philosophy of mind, language, logic, knowledge, reality, and ethical evaluations of right and wrong action. (*See* **Philosophy of Mind**)

The relation between ourselves, our consciousness, and the rest of the world is a crucial theme for philosophy. That relation is called intentionality. According to the phenomenological analysis of intentionality, consciousness consists in a relation between a subject, an act, a content, and an object. The subject is the person, or 'I', who experiences the consciousness; the act is the unit of conscious experience; the content is the image, concept or thought entertained by the subject in experiencing the act; and the object is that which is represented or 'intended' in the act by the content. The overall structure is thus one of representation: consciousness consists in a mental representation of an object by a content in an act of a subject. (*See* **Intentionality**)

We will now discuss these notions in more detail.

Consciousness occurs in units of mental activity called 'acts' (events, states, or processes). Acts of consciousness include particular acts of perception, imagination, thought, desire, will, and so on. Every act of consciousness has a subject, a self or 'I' (*ego* in Latin): the person who has, experiences, or performs the act. Thus, as we say in everyday language, I see or think or will such-and-such. Every act also has a putative object: what I see or think (about) or will. I see a dog or a tree or an automobile: that object, and no other, is the object of my act of consciousness in so seeing. Thus, consciousness has the form of a relation between an act (of a subject) and an object. But this intentional relation is unusual, because in some cases the putative object – the object projected by the act – does not exist. When I see (or seem to see) a snake in the

corner, when there is no such thing present, then my visual experience really has no object; alternatively, its object does not exist. (In one rather unpopular ontology, there is such an object but it lacks existence.)

How do sensations, such as seeing red or feeling pain, fit into the act–object model? The British empiricists isolated 'pure' sensations, and twentieth-century empiricists (such as A. J. Ayer) took sensations either to have special objects called sense data (one sees a patch of red, rather than a tomato) or to have no object at all (one sees 'redly', an experience that is not intentional). Against the strict empiricists, however, Husserl, like Kant, took perception to be a fusion of sensation and conception (one sees, with a visual sensory quality, a red tomato). Recent discussions of sensory 'qualia' have focused on this quality of sensation, as distinguished from the property of intentionality in perception. (*See* **Perception, Philosophical Issues about**)

Different acts of consciousness may represent – 'present' or 'intend' – the same object in different ways. In a popular example, consider my two experiences wherein at dusk I see the evening star and then at dawn I see the morning star, not realizing they are the same. The same object, Venus, is presented in my first experience as 'the evening star' and then in my second experience as 'the morning star'. Accordingly, we must distinguish the content from the object of my experience. The content includes the way the object is represented, while the object itself is what is represented. Alternatively, the content is my concept, image, or percept of the object. The content of an act is sometimes called the 'meaning' of the act (or of the object for the subject in the act). Since different acts (in different times and places, or in different subjects) may share the same content, philosophers say the content is an abstract or ideal entity: something which itself does not have a location in space-time.

Of course, the same person or 'I' may have different experiences, or acts of consciousness. And different acts may have the same or different contents. Furthermore, different contents may represent the same or different objects. Thus, we must distinguish within the structure of intentionality the roles of subject, act, content, and object. Intentionality consists in the relation of representation that obtains between the relevant subject, act, content, and object. (*See* **Representation, Philosophical Issues about**)

No theory of intentionality, or mental representation, can be adequate unless it draws these distinctions and relates these types of entities in this way.

However, at this stage of analysis, there is room to specify further the ontology of the entities that play these roles of subject, act, content, and object. For example, choices among realism, idealism or materialism would have to proceed from here. The program of phenomenological philosophy could thus be pursued within the further assumptions of physicalism, idealism, cultural historicism, etc. One such program (Husserl's, under one interpretation) places phenomenology within a transcendental idealism like Kant's; another (Heidegger's, under one interpretation) pursues phenomenology within a philosophy of cultural practices, or alternatively language games. Another program suspends all metaphysical concerns and practices phenomenology within a reflective way of life – akin perhaps to Buddhist traditions.

In another way, phenomenological philosophy might relate the structure of intentionality to issues in the foundations of logic, mathematics, and science. Husserl (1900) himself developed phenomenology with these concerns in mind.

Finally, ethical and political philosophy may be pursued with phenomenological analyses of relations between self and other. The work of Sartre and his followers pursues this program.

PHENOMENOLOGY AS AN EMPIRICAL RESEARCH PROGRAM

How should we study the essence of consciousness from a first-person perspective? What methodology should phenomenology use? We all experience many states of consciousness and know how to express or articulate them: these methods are built into everyday language, with the psychological verbs, when we say 'I see', 'I hear', 'I think', etc. Yet a scientific formulation of phenomenological method has seemed elusive. Scientific method is regularly taught to students of physics, chemistry, and biology, but phenomenological method is not regularly taught and still seems unfamiliar, especially to scientists.

On the one hand, phenomenology is thoroughly empirical in that it proceeds by observation of our own conscious experiences: by introspection or reflection as we live experience. Yet how do we observe our own experiences? Not by seeing, touching or hearing them. The standard empirical method of noting what we see and hear and touch around us is not the method of observation in phenomenology. Yet we do observe our experiences: we know what it is like to experience familiar forms of consciousness.

On the other hand, phenomenology is highly analytic, like logic or linguistics. Phenomenology analyzes familiar forms of consciousness, somewhat as logic analyzes familiar forms of argument or linguistics analyzes familiar forms of speech.

How should phenomenological analysis proceed? Three different methods are particularly relevant to cognitive science. Broadly, these are: to focus on your own consciousness by 'bracketing' its object; to interpret your experience in terms of its practical context; or to analyze the 'meaning' or form of your consciousness as an instance of a familiar structure (such as logical or linguistic structure in your mother tongue).

Bracketing

In the method of bracketing (used by Husserl, 1913), you bracket the object of your consciousness, that is, put aside the questions of whether the object exists and of what it is really like in itself. Thereby focus on your consciousness of the object: the way the object is given, represented, or intended in your experience. For example, as I see a sheep in a field, I put aside whether it is really there and what it really is (whether a sheep, and so on). Now I can describe my visual experience: 'I see that sheep across the fence, a white sheep with a black face, as I've seen many times before.' This method of bracketing presupposes that we have the ability to focus on our own conscious experiences.

Interpretation

In the method of interpretation (called 'hermeneutics' by Heidegger (1927b) and contextual 'description' by Merleau-Ponty (1945)), you reflect on a particular intentional activity, and interpret its meaning by placing it in its everyday context of significance. For example, as I pick up a hammer and strike a nail, I reflect on the familiar things I encounter and assume while hammering a nail. Thus, I reflect that I am not merely performing the intentional action of hammering the nail; I am engaged in using the hammer to drive in the nail, but not actively thinking about this, or about my hammering style, while I am building a cabinet in my kitchen and selecting tools from my tool chest, and so on. Moreover, I am using my body, engaged in bodily action in hammering, with kinesthetic awareness of what I am doing. This method of interpretation presupposes that we live in the world as embodied, with objects around us, with other people in our community, with extant practices of how we move and act and think and speak.

Analysis

In the method of analysis (used by Smith and McIntyre (1982) with an eye to logical or semantic analysis), you reflect on a particular form of experience you are having (or have recently had), and specify the structure or content of the experience by analyzing this familiar form of experience, somewhat as you may analyze the meaning of a sentence familiar in your own language. The method of analysis presupposes that we have a repertoire of familiar experiences and can reflect on their structure, which we know tacitly from present and prior experience. This requires previous practice, as in logic or linguistics. However, the content of an experience is not usually a linguistic meaning, what philosophers call a 'proposition'; it is usually instead a visual or imaginary image, a concept for which we have no words, or a precept for action for which we have no words. (How do you describe the complex but familiar movement you make as you pick up a hammer and nail and drive the nail into a piece of wood while balancing yourself?)

These three methods are not contradictory (though phenomenologists have argued energetically over them, and their putative assumptions of idealism, dualism, historicism, etc.). Indeed, contemporary phenomenologists might prescribe these three methods in sequence, as a new scientific method for studying consciousness in an empirical way from the first-person perspective. As we move from introspection to contextual interpretation and then to the 'semantics' of experience, we move from observation towards theory. The 'logic' of consciousness is the 'mathematics' of phenomenology. We may then begin to construct, as in any science, a good account or theory of the objects of study: conscious intentional experiences as we know them in our own consciousness. That theory, as it develops, would be tested, and confirmed or refuted, by evaluating particular claims about the structure of consciousness and how these relate to our own experience.

In this way, phenomenology yields an empirical research program that can interact with cognitive science. (Of course, phenomenology can also be developed in other directions, such as literary or cultural criticism, with aims different from those of pure science.)

THE ROLE OF PHENOMENOLOGY IN COGNITIVE SCIENCE

Cognitive science brings the methodology of empirical science (from physics to neuroscience) into

the study of mind, long the province of philosophy. The term 'cognitive science' became widespread in the 1970s in an explicit effort to synthesize the disciplines of psychology, philosophy (of mind), computer science (artificial intelligence), and ultimately neuroscience. The computational model of mind has been a driving force in cognitive science, as algorithms offer mathematical models of certain aspects of mental function. Yet there has been a growing acknowledgement that the problems of consciousness – including qualia, intentionality, and conscious awareness – are not addressed by the computational model, or by any functionalist or reductive physicalist models of the mind.

These problems are the proper domain of phenomenology. Indeed, our understanding of mind begins with our own subjective experience, and phenomenology systematically analyzes our lived conscious experience. Hypotheses of computational or neural function, and experiments designed to test such hypotheses, are another matter. Where cognitive neuroscience seeks to explain how certain patterns of neural activity (implementing certain algorithms) are involved in certain forms of perception, thought, emotion, and so on, the phenomenology of these forms of experience is presupposed (though hardly explicit). It need not be assumed, with Descartes, that we know our own conscious minds with absolute certainty, but only that we experience familiar forms of consciousness, aspects of which are under investigation in neuroscience. (*See* **Neural Correlates of Visual Consciousness**)

In practice, phenomenology and cognitive science meet in many areas, especially in analyses of mental representation or intentionality, as in visual perception. In theory, there are some areas where phenomenology and cognitive science do not meet. Thus, where phenomenology appraises conscious mental states or processes and their character as experienced from the first-person perspective, other parts of cognitive science proceed from a third-person perspective, appraising non-experiential and unexperienced aspects of mental states.

One area where phenomenology and experimental cognitive science clearly interact is in the analysis of blindsight. Our overall theory of mind addresses vision, and phenomenology analyzes familiar cases of conscious visual perception. But then experiments discover the unfamiliar cases of 'blind' sight, or unconscious visual perception, where subjects correctly answer questions about what is before their eyes but insist that they have no awareness of seeing anything at all. These contrasting accounts of conscious vision and blindsight help to factor out of the known structure of perception two important but distinct aspects: intentionality and conscious awareness. It is one thing to see (to have a perception of) something, to take in information visually, but it is something further to be aware of seeing the thing, to consciously see. It is the task of phenomenology to describe and analyze conscious awareness. This description or analysis may then be presupposed in a cognitive theory of blindsight. (*See* **Blindsight**)

There is another way in which experimental cognitive science may interact with phenomenology. Features of conscious experience analyzed in phenomenology may be confirmed and perhaps sharpened by results in neuroscience. For instance, many philosophers have held that what makes a mental state conscious is a kind of awareness the subject has of the state: perhaps in a form of higher-order monitoring of the state. If neuroscience can find a distinctive activity in a certain part of the brain that is operative only when a person is consciously experiencing a given mental state, say, in conscious vision as opposed to blindsight, then the phenomenological analysis of this form of awareness will be confirmed.

Phenomenology and cognitive science intersect in content, and complement and supplement one another in method. None the less, there have been major controversies between the two disciplines, concerning both theory and method. Much work in cognitive science assumes a computational theory of mind. Yet many phenomenologists reject the computational model (and functionalism), concurring with arguments by Searle (1984) and Dreyfus (1979) that intentional content or meaning does not align with input-output rules of computation, and with arguments by Chalmers (1996) that the properties of consciousness are not captured by physicalist or functionalist reduction. (See the many discussions in Petitot *et al.* (1999).) So long as it is assumed that mind is identical with computation, or with neural function (effecting connectionist computation), the phenomenological methods of first-person reflection (cum interpretation and analysis) will seem misguided. However, if it is assumed instead that phenomenological properties of mental states supervene on neural properties of the brain (*pace* Kim, 1998), then the methods of phenomenology will be seen as appropriate for the study of experienced structures of mental activity. In that case phenomenology will take its proper place in relation to cognitive science.

Philosophy of Language

Intermediate article

Kenneth A Taylor, Stanford University, Stanford, California, USA

CONTENTS

Philosophical investigations of language focus on issues about the metaphysical nature of meaning, logical form and compositional semantics, and the pragmatics of conversation.

WHAT IS THE PHILOSOPHY OF LANGUAGE?

Language is a central object of philosophical reflection. Philosophers seek to understand the nature and source of linguistic meaning, the distinctive character of linguistic understanding, how communication works, how language relates to the external world, what the structure of language reveals about the structure of thought and about the nature of cognition more generally. There has been significant cross-fertilization between philosophy and linguistics. This is particularly true of formal semantics and of pragmatics. Nonetheless, there are broad and unmistakable differences of emphasis and methodology. Philosophers often use, but seldom produce, results in syntactic theory. Nor have they been much concerned about linguistic universals, linguistic variation, or linguistic change. Philosophers pay scant attention to phonology and phonetics. On the other hand, linguists have been less engaged than philosophers by certain essentially metaphysical questions about language, such as: how it is possible for expressions in a language to be meaningful at all? What is the mechanism by which words in a language manage to refer to objects in an external world? What is the nature of truth?

A BRIEF HISTORY

Philosophers of antiquity, the medieval period, and early and late modernity all concerned themselves with language and its workings to one degree or another. Beginning near the turn of the twentieth century, the whole of philosophy became reoriented toward the analysis of language. During this linguistic turn, as it has been called, the resolution of issues ostensibly in metaphysics, ethics, the philosophy of mind, and epistemology were taken to depend on the analysis of linguistic meaning. Eventually the linguistic turn gave way to a naturalistic turn. During the naturalistic turn, philosophy of language was demoted from its formerly lofty perch as 'first philosophy' and became merely one philosophical discipline among others. Indeed, naturalistic philosophers tend to view philosophy itself as merely one form of broadly empirical, scientific inquiry among others, possessed of no distinctive methodology. Partly as a consequence of this naturalistic turn, many scientifically minded philosophers of language now see themselves as engaged in a common endeavor with linguists and the cognitive sciences generally. In their view, the borders between these disciplines mark no deep or principled divide.

The linguistic turn had two main sources and two distinct phases. Its first source was the sudden emergence of modern logic, especially in the work of Frege and Whitehead and Russell, with its drastically improved understanding, relative to the systems of classical and medieval antiquity, of the logic of relations and multiple quantification. Though the main advances in logic were directly driven by concerns relating to the foundations of mathematics, those advances had far reaching implications for the philosophical study of language in general. The power and precision afforded by the newly emerging logical calculi, together with the evident distance between those calculi and the resources of traditional grammars, convinced many that the traditional grammars were, from a logical point of view, both unrevealing and misleading. Moreover, they believed that the logically unrevealing and misleading nature of surface grammar was a significant source of philosophical confusion and error. Uncovering the true 'logical grammar' of language and thought was taken to be key both to avoiding error and to positive philosophical

progress. Laying bare the true logical grammar of language and thought would enhance philosophical understanding of the logic of inference and would drastically diminish temptations to ontological extravagance.

The search for logical grammar bears a superficial affinity to the contemporary linguist's search for so-called competence grammars. Like the logical grammarian, many contemporary linguists believe that language has significant 'hidden' structure not revealed by either superficial word order or traditional grammar. But one should not take this line of reasoning too far. Contemporary linguists are engaged in a descriptive, explanatory enterprise. They want to know the psychological basis of our actual linguistic competence. The logical grammarians, on the hand, were really concerned to say what a 'logically perfect' language would be like. Only a logically perfect language could serve, for example, as a perspicuous medium for the expression of thought, or for carrying out rigorous and complete mathematical proofs, or for conducting scientific inquiry. They struggled mightily to say just what a logically perfect language would be like and much of what they said about actual natural languages *per se* was intended to point up their logical imperfections. Because natural languages are shot through with logical imperfections, the logical grammarians took natural languages to be of derivative interest at best. They were hardly concerned at all to describe and explain the psychological basis of our competence in them. (*See* **Performance and Competence**)

If one takes the search for competence grammars to be a search after the language of thought, then the assimilation of logical grammar to competence grammars is more nearly justified. But one should still exercise considerable caution. As true as it was that the logical grammarians were attempting to outline the structure of the medium for thought, they were deeply and avowedly anti-psychologistic. They were more concerned with thinking as it ought to be rather than with thinking as it is. Frege was quite explicit. He distinguished the thought grasped by a thinker from the individual psychological act via which a thinker comes to grasp the relevant thought. The individual act, he held, is a psychological process that takes place over time and within the mind or brain of an individual thinker. Such acts are subject to psychological laws. He professed no interest in such laws. Indeed, he distinguished sharply between the laws of thought and the laws of psychology. The laws of thought govern the unchanging and timeless structure of thought. They are to be articulated not by psychology but by logic. The laws of thought determine that certain thoughts follow from other thoughts. But the *following from* relation he took to be a logical one and not a causal–temporal one at all. (*See* **Language of Thought**)

An enduring landmark of the first wave of the linguistic turn was Russell's theory of descriptions. The so-called definite description 'the present king of France' may appear to be a genuine constituent of the sentence 'the present king of France is bald' and may appear to serve the function of standing for an object. But Russell argued that such expressions are a sort of logical illusion and that they disappear when we execute a proper logical analysis. The eye-opening clarity of Russell's arguments helped to set philosophers off on a relentless search for hidden logical forms. The path-breaking work of Frege played a significant role as well. So too did the work of the early Wittgenstein. Indeed, Frege's work serves still as the point of departure for much contemporary work. This is especially true of his distinction between sense and reference and his explanation, defense, and elaboration of the consequences of the principle of compositionality in semantics. Frege's general approach received systematic and rigorous elaboration at the hands of thinkers like Carnap, Church, and Montague; but until the advent of Quine's wide-ranging attack on the very coherence of notions like sense and reference in the 1950s, the subsequent emergence of Davidson's purely 'extensionalist' approach to semantics, and the still later emergence of the so-called new theory of reference in the work of Kripke, Kaplan, and Putnam in the 1970s, there were no systematic competitors to Frege's main theories.

The second source of the linguistic turn in philosophy was the widespread acceptance of the analytic/synthetic distinction. A statement is analytic just in case its status as true or false depends solely on the meanings of the terms the statement contains and on how those terms are combined. The statement that bachelors are unmarried is paradigmatic. A statement is synthetic if it is not analytic. If a statement is synthetic, fixing the meanings and organization of the terms will not suffice to determine whether the statement is true or false. Though the roots of this distinction reach back to the eighteenth century, the rise of modern logic enabled philosophers to offer a more precise and rigorous characterization of that distinction. (*See* **Sense and Reference**; **Reference, Theories of**)

The analytic/synthetic distinction was central to the logical positivist's defense of logical empiricism. Logical empiricists took the entire fabric of

our knowledge to be a vast logical construction out of the givens of sensation. Once the world order is seen as a vast array of logical complexes, logically constructed out of the logically simple elements of the stream of sensation, logic alone promises to be sufficient to spread warrant upward from statements about the stream of sensations to statements about the vast array of putative 'logical complexes' which the sciences reveal to us. This entire approach demanded, however, that statements about putative logical complexes – middle sized objects, persons, minds, to name but a few – be analytically reducible and thus translatable without loss of meaning into statements about the course of the stream of sensation. Though logical empiricists struggled mightily to provide such reductions, this exercise ultimately proved as futile as it was ambitious.

The second wave of the linguistic turn had the character of a counterrevolution. The main inspiration of that counterrevolution was the work of the later Wittgenstein. Though Wittgenstein was a pioneering logical grammarian, he eventually came to see the very idea of a logically perfect language as misguided. Natural languages, he claimed, are 'perfectly in order' as they stand and are well suited to the multifold and workaday uses to which we put them in ordinary life. Philosophers who seek to understand language and its powers should not seek after some logical ideal; they should seek to understand the hurly-burly workings of living, breathing languages. Wittgenstein had come to believe that the traditional problems of philosophy arise one and all merely from the abuse of language, from language 'gone on holiday'. Philosophy properly done will strive merely to describe the various language games in which certain putatively philosophically problematic expressions have their real homes. The professed goal of philosophy done in this style is not so much to solve philosophical problems but to dissolve them and to cure philosophers of the very urge to theorize beyond the boundaries of ordinary language.

Despite its destructive tendencies, Wittgenstein's work played a decisive role in the rise of so-called ordinary language philosophy which in turn played a significant role in the rise of the pragmatics of communication as an area of major concern within the philosophy of language. The central thought of the ordinary language philosophers was that the key to discovering the nature of some philosophically problematic item – such as goodness, knowledge, or experience – is to determine what it is that we say of a thing when we say that it is good, or of a person that she knows that such and such or has experience as of so and so. This we can do by examining the meanings of relevant expressions. To know the meaning of an expression is to know how it is used in the language game that is its home. With the analyses of meaning in hand, philosophical issues of a more traditional sort can be addressed, sometimes with surprising results. Ordinary language philosophers positively delighted in demonstrating that some philosophically problematic discourse was not, after all, 'fact-stating' discourse but served some heretofore unnoticed communicative purpose – such as expressing our attitudes of approval or disapproval, or issuing 'inference tickets' of various sorts.

At their best, ordinary language philosophers made many penetrating and subtle observations about the multiplicity of things that we do with language. The work of J. L. Austin is a sterling example. But the legitimacy of their methodology depended crucially on there being a principled distinction between matters of meaning and matters of belief. Consider the use of the term 'bankruptcy'. Suppose that it is universally believed that only slovenly people declare bankruptcy. That would not suffice to make it the case that part of what we say when we say that a person is bankrupt is that that person is slovenly. Yet, in a linguistic community in which such a belief was universal, saying that a person is bankrupt might well convey that she is slovenly. Without some principled basis for distinguishing what is strictly literally said by an utterance from what is merely 'conveyed' without being said, the methodology of ordinary language philosophy is hopeless. It was Paul Grice who first and most clearly grasped the need to distinguish what is said by an utterance from what is 'implicated' or 'conveyed' without being said. His masterful attempt to provide such a basis nearly single-handedly laid an enduring foundation for the study of pragmatics.

Though Grice's work dashed some of the methodological pretensions of the ordinary language philosophers, he remained deeply embedded in the linguistic turn. With the advent and widespread acceptance of Quine's attack on the very coherence of the analytic/synthetic distinction, however, the linguistic turn began to unravel entirely and philosophy of language began to lose its status as first philosophy. This unraveling was greatly helped along by Putnam and Kripke. Particularly crucial was Kripke's defense of the claim that there are necessary truths that are neither analytic nor discoverable on any *a priori* basis. Kripke made a convincing case that empirical inquiry has the power to deliver knowledge of so-called

a posteriori necessities. Though Kripke's arguments and Quine's are too complex to recapitulate here, their joint role in reorienting philosophy can hardly be overstated. If there is a principled basis for the analytic/synthetic distinction and if all and only analytic truths are true *a priori*, there can be a distinctively philosophical methodology – linguistic or conceptual analysis – with the power to deliver truths about the constitutive natures of things. If there is no principled basis to that distinction and if, moreover, science itself is in the business of discovering constitutive natures, then the method of conceptual analysis has no legitimacy and no peculiar power to reveal the constitutive natures of things.

Despite unseating philosophy from its privileged perch above the fray of empirical inquiry, the unraveling of the linguistic turn led not to the end of philosophy but to its reorientation. If there are no distinctively philosophical methods, many concluded, then philosophical inquiry is, and ought to be, broadly continuous with empirical scientific inquiry generally. Though philosophers did not rush to become experimentalists as a result of the naturalistic turn, many did come to see their work as being related to work in the empirical cognitive sciences, say, in much the way that work in theoretical physics relates to work in experimental and/or applied physics. Of course, since one can seldom declare complete victory in philosophy, there remain to this day many serious minded philosophers who endorse the analytic/synthetic distinction and with it an a prioristic methodology akin to that practiced by linguistic philosophers of an earlier day.

AREAS OF THE PHILOSOPHY OF LANGUAGE

Contemporary work in the philosophy of language clusters within three broad areas: (1) the metaphysics of meaning and reference; (2) formal semantics; (3) the pragmatics of communication.

Metaphysics of Meaning and Reference

Philosophers concerned with the metaphysics of meaning are preoccupied with two main questions: what endows an expression with meaning? What is the nature of meaning? The endowment question arises because expressions in language are evidently not intrinsically meaningful. Something in nature, human psychology, or human social life has to make it the case that linguistic expressions are meaningful at all. The nature question arises in part because of the manifest variety of linguistic expressions, the variety of different things we do with language, our ability to grasp meaning, and puzzles about the place of meanings in the order of things. Thus the nature question might be put this way: what are linguistic meanings such that: (1) they are potentially graspable by us; (2) they have a place in the natural order of things; (3) they play central roles in explaining the plethora of different things we do with language?

Philosophers of language have proposed a variety of answers to both the endowment question and the nature question. Sentences have been said to have propositions, truth conditions, assertability conditions, or states of affairs as their meanings. And each of these candidate meanings has been construed in a wide variety of ways. Some, for example, take propositions to be abstract, structured mind-independent, extra-linguistic entities. Others are deflationist and claim that propositions are pleonastic entities with no substantial nature. Still others hold that some propositions have concrete constituents.

In connection with the endowment question, philosophers differ over the relative priority of sentence meaning and word meaning. Holists maintain that sentences, or even entire languages, are the primary bearers of linguistic meaning and they take words to have meaning in only a secondary or derivative sense, in so far as they play roles in sentences. Atomists ascribe priority to word meaning and hold that sentence meanings are 'composed' from antecedently given word meanings, in much the way that a house is composed, brick by brick, from antecedently given constituents. Holists tend to think that only sentences can be directly endowed with meaning on the grounds that it is only in the production of sentences that we perform determinate speech acts. In this view, words are endowed with meanings only indirectly in virtue of the speech acts we perform with the sentences in which they are contained. By contrast, atomists believe that words can be directly endowed with meaning and that sentences have their meanings as a consequence of the meanings of the words they contain and the way those words are combined.

An endowment question and a nature question also arise for reference. Atomists tend to think of reference as a real word–world relation, the full fledged nature of which is an open and substantive issue. They take the reference relation to play a substantive role in explaining the power of sentences to express claims about the world. The fact that name 'Smith' stands for or refers to Smith is

supposed to explain, for example, why sentences containing that name can be used to make claims about Smith. But unless the atomists can say what it is for a term to refer to an object, the appeal to the reference relation will be explanatorily idle. Many atomists favor some version or other of the so-called causal theory of reference. A causal theory of reference holds that an expression *e* refers to an object *o*, if *o*-involving events play a distinguished causal role in the production of instances of *e*. The challenge for any such theory is to say just what causal relation is the reference-making relation.

By contrast, holists tend either to deny that there is any such thing as the reference relation, or to deny that it has a substantive nature waiting to be uncovered by either philosophical speculation or empirical investigation. If there is no such relation as reference, or if the reference relation has no substantial nature, talk of reference will play no role in explaining the very possibility of aboutness.

Formal Semantics

Work in formal semantics is closely connected to the nature question. Once it is determined what sorts of meanings are enjoyed by expressions of various sorts, space opens up for a precise and systematic account of how such meanings combine and interact. Formal semanticists seek rigorous, exhaustive, and systematic accounts of the rules and/or principles which determine the meanings of syntactically complex expressions as functions of the meanings and syntactic organization of their parts. The array of alternative approaches and theories here is breathtaking. Merely citing their names may give the reader a feel for the number of extant alternatives: possible worlds semantics, situation semantics, game-theoretic semantics, dynamic semantics, discourse representation theory, model-theoretic semantics, inferential role semantics, categorial grammar. Contemporary formal semanticists are the heirs of the early logical grammarians, but they differ from the logical grammarians in seeking to deploy rigorous formal methods to describe the semantic workings of language as it is and not merely to characterize some abstract logical ideal.

PRAGMATICS

Four kinds of phenomena constitute the core subject matter of pragmatics: speech acts; indexicality and other forms of context-sensitivity; non-truth-conditional aspects of meaning; and conversational implicatures and the like.

Speech Acts

Speech act theory seeks to characterize the totality of so-called illocutionary acts. Such acts come in an apparently dizzying variety: assertions, boasts, promises, threats, requests, commands, vows, greetings, questions, to name just a few. But many have claimed that there is much system and order beneath the variety. The problem of exhaustively and systematically characterizing the topology of illocutionary act space, as we might call it, is a major task for any student of pragmatics.

Context-Sensitivity

Consider the sentence 'I am hungry now'. Taken apart from any particular context, this sentence expresses no determinate proposition. It expresses one proposition in one speaker's mouth and a different proposition in another speaker's mouth. But this sentence does have a certain fixed significance which does not vary from context to context. For example, it is a fact about its fixed significance that for any utterance *u* of it produced by speaker *s* at time *t*, *u* will be true just in case *s* is hungry at *t*. We can represent the situation as follows: Fixed significance + context → proposition. Several questions naturally arise. What is the exact character of the fixed semantic significance of context-sensitive expressions? What is a context? How does context interact with the fixed significance to yield further semantic values? Philosophers interested in pragmatics have proposed a variety of answers to such questions.

Demonstratives like 'this' or 'that', indexicals like 'I', 'here' and 'now', tense, and aspect all introduce elements of contextual variability. With such-constructions, there are relatively precise rules that determine the semantic content of the relevant expressions or constructions as a function of 'objective' features of the context of occurrence, such as who is speaking where or when. Such rules are not always available. The possessive introduces an element of context-sensitivity, but there is no precise rule for determining the semantic significance of a particular occurrence of the possessive as a function of objective features of the context. Context-sensitivity in the absence of precisely specifiable rules has become a subject of considerable philosophical and linguistic investigation.

Non-truth-conditional Ingredients of Meaning

Consider the following pairs:

John went to that wild, raucous party and did not drink. (1)

John went to that wild, raucous party, but did not drink. (2)

The fact that there is no scenario in which (1) and (2) differ in truth value leads many to conclude that 'and' and 'but' are truth conditionally equivalent. Nonetheless, it seems clear that there is a difference in meaning between 'but' and 'and': 'but' is contrastive but 'and' is not. (1) does and (2) does not 'intimate' that there is a contrast between John's going to the wild raucous party and his not drinking. The exact contrast cannot simply be read off of the relevant sentence, but is in some way a function of context. It is a fact about the meaning of 'but' that an occurrence of 'but' in a sentence serves to set up some contextually determined contrast between conjuncts. 'But' is a striking and much studied example of an expression whose meaning contains ingredients which are not potential ingredients of truth conditions. Such non-truth-conditional ingredients are reasonably studied under the rubric of pragmatics because they relate to and give indications of the kind of speech act a speaker performs in using the relevant expression.

Conversational Implicatures and other Pragmatic Externalities

We often convey by our utterances more than we strictly, literally, say. Smith asks whether Jones wants to go out to a movie with him. Jones replies that she has a great deal of work to do. Though Jones has not explicitly said that she has no time for a movie, she has implied as much. Grice called such implications 'conversational implicatures' and developed a groundbreaking theory, based on the notion that conversation is a form of rational cooperation, to explain how they are generated.

Conversational implicatures must be distinguished from garden variety logical entailments. Unlike logical entailments, conversational implicatures exhibit a high degree of cancellability. Jones might have continued the conversation with Smith by saying, 'I have a great deal of work to do, but I really could use a break.' Here Jones forestalls a conversational implicature which might otherwise be generated. We cannot do the same with logical entailments.

Consider the old sexist chestnut 'Have you stopped beating your wife?' One who utters the relevant question in some sense 'implies' that her interlocutor formerly beat his wife. She does not assert or say as much. This kind of implication is commonly known as *presupposition*. A presupposition of a speech act is, roughly, a condition which must be presumed to be satisfied in order for that speech act to be felicitously and non-defectively performed. Suppose that the person to whom this query is addressed has manifestly never once beaten his wife. The very question is illegitimate. Neither the answer 'Yes, I have stopped beating my wife' nor the answer 'No, I have not stopped beating my wife' seems appropriate.

Presupposition remains a topic of considerable debate. Some think of presupposition as a semantic phenomenon. Others take presupposition to be largely pragmatic in nature.

RELEVANCE OF THE PHILOSOPHY OF LANGUAGE TO COGNITIVE SCIENCE

Work in the philosophy of language is relevant to cognitive science in two ways. To the extent that cognitive science is concerned with the nature of language and the plethora of things we do with language, philosophy of language is one more source of insight. Indeed, naturalistically and scientifically minded philosophers of language see themselves as engaged in something of a common enterprise with linguists. Moreover, philosophers of language are expert in clarifying what we mean, for example, by terms like 'representation,' 'consciousness', or 'rationality.' If one endorses the analytic synthetic distinction, one may take this expertise as expertise at the *a priori* specification of the constitutive natures of things. Philosophy thus conceived purports to provide *a priori* specifications of what it is to be a conscious mental state or what it is to be a representation. Even without the analytic/synthetic distinction, one can still afford to give close attention to what we mean by terms expressive of notions of concern to cognitive scientists. Such attention can play an indispensable role both in providing an initial orientation for empirical inquiry and in making interpretive sense of the intermediate and final products of such inquiry.

CONTENTS

The philosophy of linguistics addresses both general issues in the philosophy of science that occur in the scientific study of language, and philosophical issues that arise in linguistic theorizing. It shares many issues with the philosophies of language and of mind, but is distinct from them in that it focuses directly on questions about linguistic theories, the epistemology and metaphysics of linguistic science, and the psychology of language.

INTRODUCTION

Linguists investigate many aspects of natural language, but current debates in the philosophy of linguistics are generally dominated by issues that arise in syntactic and semantic theory. There are exceptions: there has been sporadic philosophical interest in phonology (Twaddell, 1935; Botha, 1972; Bromberger and Halle, 1992), and occasional attention to biological and social aspects of language (Millikan, 1984; Itkonen, 1983). But Noam Chomsky's success in popularizing an approach to the study of language and languages centered on syntax has dominated discussion.

The following four questions have figured prominently: (1) what natural languages are like; (2) what linguistics is about; (3) how language acquisition can be explained; and (4) whether language use is governed by normative standards. The answers to these questions are conceptually distinct, but they are connected in Chomsky's research program, which claims that: (1) natural languages are generative systems; (2) those grammars are realized in the brain states of competent speakers; (3) they are acquired through the assistance of an innate system of tacit knowledge about universal grammatical principles; and (4) they participate causally in the production of linguistic behavior.

Unlike its competitors, the Chomskian program has articulated a set of fundamental questions and given an integrated response to them. This integrated approach has given the program very broad appeal; and much recent philosophy of linguistics looks like an extended commentary on Chomsky's work.

WHAT ARE NATURAL LANGUAGES?

The currently dominant view about what natural languages are emerged in the 1950s when Chomsky (1957) applied the production systems developed in mathematical logic to the description of natural languages, yielding what is now called 'generative grammar'. A generative grammar is comprised of a lexicon and a set of rules (or parametrized principles extensionally equivalent to a set of rules) that generate (recursively enumerate) explicit structural descriptions. These structural descriptions are the theoretical reconstruction of natural-language expressions. On this view a natural language is a generative grammar that states the characteristic function of a set of expressions in a way analogous with the formal 'languages' of logic and computer science.

This technical conception of a natural language shares little with commonsense notions of language as a shared way of speaking. A generative grammar, by definition, requires specification of a fixed and closed lexicon. The addition of even one new vocabulary item to that grammar produces a new and distinct language.

Advocates of the generative conception of language claim that the commonsense notion has no scientific interest. This view is based, in part, on the controversial claim that only generative grammars can provide fully explicit descriptions of natural-language expressions. It is perhaps also based on the uncontroversial claim that generative grammars state precise individuation conditions for languages, while the commonsense conception of a language has no precise individuation conditions.

Not all linguistic theories take languages as generative grammars. Bloomfield (1933) took a language to be the totality of all the physically possible utterances of a speech community. He took this to

mean that a natural language is a finite set of expressions. Against this, generative linguists have argued that, firstly, natural language use is creative, and secondly, there is no longest sentence in a natural language. Assuming that native speakers have the ability to produce and understand novel, well-formed expressions, and there is no longest expression, a generative grammar defines a denumerably infinite set of expressions. From this, proponents of generative grammar conclude that natural languages are infinite. But the argument is question-begging, since natural languages are infinite only if it is further assumed that a language is a generative grammar – and that is precisely what is at issue.

Evans (1981) argued that the size of the expression set generated by a grammar is irrelevant to linguistic creativity. What is required for creativity is that a language is acquired by learning the systematic recombinability of its linguistic components. In other words, it is systematicity, not size of the generated expression set, that explicates linguistic creativity.

WHAT IS LINGUISTICS ABOUT?

Do the theoretical terms of linguistic theories refer? If so, to what? Early debates in phonology focused on the referent of the term 'phoneme'. Sapir (1925) held that phonemes are mentally real; and Bloomfield (1926) argued that phonemes are physically real. By contrast, Twaddell (1935), citing earlier remarks of Otto Jespersen's, argued that phonemes are a useful fiction.

Hockett (1948), declaring fictionalist views to be misguided, proposed that the structures identified by linguistic theories denote brain states. He took the result of a person's language acquisition to consist in 'a mass of varying synaptic potentials in his central nervous system'. This view was later much elaborated by Chomsky. Katz (1981) refers to it as 'conceptualism'.

Chomsky (1986, 1997) conjoins the conceptualist view that a language is 'a relatively stable element of transitory brain states' with the claim that a language is a generative grammar, and calls the resultant object an 'I-language'. The 'I' of 'I-language' is an allusion to three claims about language: that it is individual, internal, and intensional. (Before 1986, I-languages were usually called 'linguistic competence states'.)

Itkonen (1978) argues against Chomskian conceptualism. Katz (1981) independently takes a similar line to Itkonen, and argues for a kind of Platonism on which the theoretical terms of generative grammars denote abstract objects with no causal efficacy.

The debate between Chomskian conceptualists and Katzian Platonists assumes that the theoretical vocabulary of linguistics denotes only one ontological category of object. This assumption has not gone unchallenged: George (1989) argues that in generative grammar the term 'grammar' is polysemous, denoting abstract objects, the content of mental states, and causally efficacious brain states. If George is right, then conceptualist–Platonist disputes rest on an equivocation.

HOW CAN LANGUAGE LEARNING BE EXPLAINED?

'Linguistic nativism' is the view that language acquisition requires innate information with linguistic content (the so-called 'substantive linguistic universals') utilized by specialized cognitive structures specific to linguistic information processing (e.g. linguistic processing modules). However, the dispute between linguistic nativists and their opponents is not a dispute over whether sensory organs are specialized devices for processing auditory information. It is focused on whether there is innate linguistic content (often misleadingly called 'domain-specific content'). Without this claim, an opponent of linguistic nativism might argue that a complex variety of innate, informationally biased sensory–perceptual modules, with no specifically linguistic content, are required for first-language acquisition.

The most popular argument for linguistic nativism is called the 'argument from the poverty of the stimulus'. There are two forms of this argument: one empirical, the other *a priori*. The empirical versions contain an empirical premise that claims that children (at some particular age) know some rule or generalization about the target language that they could not have learned from their linguistic experience. Since children's experience seems to be too impoverished to support induction of what children actually know, nativists conjecture that language learning is assisted by universal linguistically contentful innate rules (or parameters), called 'universal grammar'.

Any argument for this conjecture needs to articulate: exactly what counts as exposure to and uptake of evidence by the child; an adequate identification of what is learned; and a reason to think that the child does not receive enough information to induce what he or she comes to know.

Statistical analyses of appropriate corpora might help to provide support for the latter. Pullum and

Scholz (2002) present the results of preliminary corpus searches for some of the most famous cases of alleged stimulus impoverishment. These results suggest that the linguistic evidence may not be so impoverished after all.

There are at least two kinds of *a priori* arguments from the poverty of the stimulus. One is based on the simple fact that theories (and in particular, I-languages) are deductively underdetermined by the evidence. The other is based on a result in mathematical learning theory.

The argument from underdetermination assumes that children learn languages by deducing a unique I-language from some finite body of evidence. Since no theory, generative or otherwise, is entailed by any finite number of observations, the nativist concludes that child language learning requires innate knowledge of linguistic universals with specifically linguistic content, which together with the evidence entails an I-language. However, the assumption has been challenged (Scholz and Pullum, 2002).

The *a priori* argument for linguistic nativism based on mathematical learning theory is due to the results of Gold (1967). Gold proved that for all well-known classes of formal languages (regular, context-free, etc.), learning, under one particular definition, is impossible if the evidence is limited to positive evidence, i.e. grammatical strings. However, Gold showed that if negative evidence (about what is not in the language) is supplied, then learning by an algorithmic, inductive method is possible.

Cowie (1999) and others have pointed out that positive evidence can provide implicit negative information: absence of evidence can be evidence of absence. The problem with this line of argument is that there is so much implicit evidence of absence that false hypotheses about the target language would be supported (for example, the absence of utterances in which *papacy* and *wombat* occur together in a clause would spuriously support the hypothesis that their co-occurrence is syntactically forbidden).

Gold's work assumes that learning a natural language amounts to inducing a generative grammar. Thus, his theorem can be seen as a *reductio ad absurdum* of this assumption. A conservative revision of the program might propose that language learners acquire some grammar – perhaps necessary conditions on subsentential expression recombinability – but not a generative grammar. More radically, it could be proposed that learners acquire no grammar at all.

IS LANGUAGE NORMATIVE?

Is an I-language a standard of correct (grammatical, acceptable, interpretable) linguistic performance? Are speakers mistaken when their linguistic performance diverges from what their I-language generates? If so, can having an I-language be explained naturalistically? These questions arise for all who claim that grammatical rules guide linguistic performance.

Structuralist linguists emphasized the difference between explicit description of languages and traditional prescriptive injunctions (e.g. 'don't split infinitives'). Generative grammarians followed suit: I-languages are not normative in the sense of being prescriptive.

However, I-languages generate a set of structural descriptions that are claimed by generative grammarians to be the well-formed expressions for the speaker. This suggests they provide a standard in virtue of which an individual speaker's actual performance is correct or mistaken. Thus the concept of an I-language seems to have normative force because it incorporates a notion of individual error.

An extended argument that there can be no naturalistic or causal explanation of rule-guided behavior was elaborated by Kripke (1982) (from suggestions by Wittgenstein). Chomsky (1986) responded by claiming that I-languages play a purely causal role in linguistic performance and are not a standard of correct individual performance. Wright (1989) argued to the contrary that the Wittgensteinian argument poses a deep challenge to the Chomskian research program. Linguists do take I-languages as standards of correct performance; performance errors are taken to be mistakes, not indications of broken causal mechanisms.

In addition, the hypothesized innate universal grammar suggests that language is normative in two related senses, both biological: one issuing from the claim that innate universal grammar aims to explain what all 'normal' humans beings share; the other from the claim that innate substantive universals are biologically encoded information.

It is a substantive question in the philosophy of biology whether the appeal to what is 'normal' for a species constitutes an illegitimate remnant of folk-biological explanation. If the linguistic content of substantive universals is claimed to be genetically encoded information, the question is whether a non-semantic notion of information is adequate to explicate substantive linguistic universals.

SUMMARY

That a language is a generative grammar is the fundamental thesis of the Chomskian research program. It plays a central role in integrating answers to the main questions of that program. But the resulting integrated answer comprises distinct claims that require separate and independent support.

Philosophy of Mind

Introductory article

Georges Rey, University of Maryland, College Park, Maryland, USA

CONTENTS

The philosophy of mind is concerned with general questions about the nature of mental phenomena, such as thoughts, feelings, perceptions, consciousness, and sensory experience. Philosophers generally ask these questions where it is not clear how an empirical investigation might settle them.

WHAT IS THE PHILOSOPHY OF MIND?

Philosophical Versus Empirical Issues

Empirical psychologists, who confirm hypotheses by observation, are by and large concerned to discover facts that *happen to be true* of actual people and animals. For example, they might discover that a certain chemical is released in a certain region of the brain whenever someone is in pain. But the philosopher asks whether releasing that chemical is *necessary* or *essential* to being afraid or in pain: would beings lacking that particular chemical or cranial layout be incapable of fear or pain? Answering such questions requires considering not only *actual* cases, but *possible* ones, such as extraterrestrials, ghosts, angels, or human beings with a different embodiment; we cannot observe such cases, but must consider them by some kind of conceptual reflection. The questions become more urgent when the possibilities loom closer, as in the case of computers: what would it take to create a computer that had genuine thoughts, feelings, and sensations? Or can this possibility be somehow ruled out in advance, independently of what any empirical science could discover?

One reason why these questions are so difficult to answer is that there are substantial methodological disagreements about the appropriate way to answer them. In the first place, mental phenomena often seem essentially 'private' and 'subjective', not open to the kind of 'public', 'objective' inspection required of serious science. How, after all, are we to find out what a person's private thoughts and feelings really are? Isn't the person in a special, privileged position with regard to them, a position that no one else could ever occupy? What should we make of the claims of psychotherapists, cognitive psychologists or neurophysiologists about people's thought processes?

A second difficulty is that the *meaning* and *significance* of the products of mind, such as deliberate action, do not seem to be open to the usual kind of causal explanation, by which, for example, one explains why the planets move as they do. Explanations of planetary motion either invoke simple generalizations about regularities in the motion (as in the case of Kepler's Laws) or, more deeply, by appealing to general laws, such as those of universal gravitation. By contrast, to understand why people, say, go the beach in the summer, it is not enough merely to subsume their behavior under a good generalization relating heat, metabolism and beach attendance. Rather, one needs also to understand their *reasons* for going to the beach, what going to the beach *means* to them, what *role* it plays in their lives. Now perhaps this can be understood as simply subsumption under specific laws of psychology concerning how, for example, thoughts and preferences bring about action, but many people have thought that this kind of understanding can only be attained by empathizing with the person, 'putting oneself in their shoes' (a view associated with the work of Max Weber). Alternatively, psychological understanding can seem to involve seeing how the person's actions accord with certain *rational norms* (a view associated with the work of Donald Davidson and Daniel Dennett).

Some Basic Distinctions

Mental phenomena, like phenomena in most other domains, occur in a variety of basic categories, and it is often important which category is being discussed. Thus, in thinking about mental phenomena it is important to bear in mind whether one is talking about a *mental substance*. (Are thoughts and pains *composed* somehow of something fundamentally *nonphysical*, unlike the electrons and

quarks and mass energy of which all physical phenomena seem to be composed?) Or is there only one, perhaps purely physical, substance, with many nonphysical, mental *properties*?

Thoughts and propositions

Thoughts are typically described by *sentential complements*, or sentences prefixed by 'that'. Thus, there is the thought *that broccoli prevents cancer*; or the thought *that Caesar conquered Gaul*. That a thought is different from the sentence that expresses it is entailed by the fact that different sentences can express the same thought: the thought expressed by the English 'snow is white' is also expressed by the German 'der Schnee ist weiss'. Indeed, thoughts are often taken to be the meanings of sentences, and so are also often called 'propositions'. The constituents of propositions are concepts, which correspond roughly to individual words. Note that concepts may or may not correspond to real properties in the world: although there may be the *concept* of 'unicornhood' – which is a constituent of the thought 'there are no unicorns', – there may be no genuine (say, causally efficacious) *property* of unicornhood in the actual world. This is an important distinction to which we will return below. (*See* **Philosophy of Language**)

People, of course, can stand in many different relations to these propositions: they can, for example believe, hope, expect or wish that they are true. These various relations that minds can bear to propositions are called *propositional attitudes*: states that are picked out by mental verbs that take a proposition as their direct object. (The actual grammar of attitudes is quite complex, and can be abbreviated in a number of ways, as in 'Mary wants to fly', which means something like 'Mary desires that she herself fly'.)

Types versus tokens

Thoughts regarded in this way are clearly sharable: two people who don't even speak the same language can have the same thought, for example that snow is white. But these sharable thoughts are to be distinguished from the individual thoughts that each of us has at particular times, which are not sharable: the thought I had on that winter night that snow is white is different from the similar thought I had the next day.

This ambiguity is related to an important ambiguity that also arises in the case of language, where we can, for example, write 'the same word' twice. When we want to talk about words that are located in a specific place for a specific stretch of time, we can talk about *tokens* of the word; when we want to talk about 'the same word' that can appear in different places and times we can talk about word *types*. (Note that only some word tokens are written down; many are pronounced, and others are encoded on magnetic tape in computers.)

Sensations, phenomenal states and 'qualia'

Many mental phenomena do not appear (at least initially) to be propositional attitudes. There are, for example, the *conscious sensations*, such as the pains, itches, tastes and colors that we seem to experience in most of our waking moments. Our talk of sensations is rather loose, in ways that may be crucial: we sometimes talk about 'phenomenal objects', such as *the pains*, itches, tickles and mental images themselves, and sometimes about *the feeling of pain*, or itchiness, or the properties of sounds (e.g. loud, shrill) or images (e.g. red, elliptical). And in these latter cases, where we take our experiences to be reflecting real phenomena in the world, our talk is often ambiguous between the external fact ('the rose is red') and the inner experience ('my mental image is red'). It is this ambiguity that gives rise to the familiar puzzle of whether a tree falling in a lonely forest makes any sound: one might say that it makes a sound in the external sense, but not in the experiental, or phenomenal sense. Phenomenal objects and properties are often called 'qualia'.

The Main Problematic Phenomena

There are many specific mental phenomena with which the philosophy of mind is concerned: for example, free will, intention, introspection, mental causation, personal identity, qualia, reasoning, mental content, and consciousness. This article will discuss in general terms how many of these topics are related both to each other and to what have been some of the central issues in the philosophy of mind since the seventeenth century.

Three phenomena in particular have been the primary focuses of discussion in the philosophy of mind: consciousness, rationality, and intentionality.

Consciousness

Conscious phenomena are the phenomena with which people generally think they are 'directly acquainted': our sensations, pains, itches, joy, pride, and so on. For many people, the existence of these phenomena, at least in their own case, is more obvious and undeniable than anything else in the world. The seventeenth-century mathematician and philosopher René Descartes regarded his immediate conscious thoughts as the basis of all the

rest of his knowledge. Theories that emphasize this first-person immediacy of conscious states have come to be called 'Cartesian'.

However, not all mental phenomena have always been regarded as essentially conscious. Freud and Chomsky have drawn attention to ways in which unconscious attitudes might explain a variety of phenomena, from neurotic syndromes to language acquisition. Still, one might wonder what makes an unconscious mental process mental at all: if a person doesn't have an immediate knowledge of it, why isn't it just part of the physical machinery of the brain? (*See* **Freud, Sigmund**)

Rationality

One common reason for ascribing mental phenomena to other people is to make 'rational sense' of their behavior. There are four standard methods by which we do so: deductive, inductive, and abductive reason, which have to do with increasing the likelihood of believed truth; and practical reason, which has to do with the determination of action (or 'practice'), based on believed truth and the rankings of one's desires. In the twentieth century there was extensive development of formal characterizations of portions of deductive and inductive reason, most dramatically in the case of deduction and with some success in the fields of inductive logic and statistics. Abduction, or 'inference to the best explanation', is less well understood. It is what we engage in when we explain observed phenomena by unobserved phenomena: diseases by microbes, heredity by genes, chemical combination by atoms. (*See* **Deductive Reasoning**; **Inductive Reasoning, Psychology of**; **Philosophy of Science**)

Practical rationality involves proceeding from belief to action. Here, desires become relevant, in addition to truth: successful action is action that satisfies one's desires. One rough definition might be that rational action is what maximizes the probability of successful action: it is what should be done given that the agent has certain desires and otherwise rational beliefs (e.g. beliefs formed by processes likely in general to issue in truth). Suppose, for example, you want some coffee, and think that coffee can best be had from the café at the corner. Other things being equal (you have no other more pressing desires, or beliefs about serious risks of going out) the 'rational' thing for you to do would be to go to the corner café and buy some coffee. Indeed, if we were to hear that this was the 'reason' someone else left their house and did so, we would think that we had found a satisfactory explanation of their actions. Much of life is, of course, much more complex than this, and formal decision theory tries to understand decision making by means of 'cost–benefit–risk analysis', whereby people consider the probabilities of different outcomes and reconcile competing preferences.

None of this focus on rationality is meant to suggest that people are always rational. Many people report being 'weak-willed' and failing to think or do what they deem to be the best or most rational thing. And sometimes rationality does not seem relevant: kicking a stalled car, fondling a lover's locks, and twiddling one's thumbs are all actions that do not seem to be performed for any particular purpose and are neither particularly rational nor 'irrational'. Such actions have been termed 'arational'.

Intentionality

Medieval philosophers noticed a peculiar property of at least a wide class of mental phenomena: that they are *about* things. Thus, a thought that Moriarty is the thief is *about* Moriarty, and a desire for coffee is *about* coffee. By contrast, consider a star or a stone: it does not seem to make much sense to ask what it is 'about'. The medievals called this 'aboutness' property 'intentionality' (not to be confused with the very different use of 'intentional' as meaning, roughly, 'deliberate'). The property has some logical peculiarities: although a hat cannot rest on a head that does not exist, a thought cannot only be about a nonexistent head, but even about an impossible one (say, one that is round and square). Moreover, aboutness seems to be relative to a way of describing something: although a hat resting on Mark Twain is a hat resting on Samuel Clemens, a thought about Mark is not a thought about Samuel (someone might even think that Samuel is different from Mark). (*See* **Intentionality**)

The central cases of intentional states are the propositional attitudes, such as beliefs and desires. Whether all mental states can be regarded as intentional is controversial: it is not obvious what pains or itches or 'free-floating anxiety' are about. There are other mental phenomena that do not obviously fall into either of the two categories of conscious and intentional states: for example, emotions, character traits, and virtues. And many of the peculiar *products* of minds – words, paintings, gestures – are also 'about things', although this 'aboutness' is often *derived* from the minds of their users, and is hence called 'derived' intentionality, as opposed to the 'intrinsic' or 'original' intentionality of mental states. One major controversy is whether computers have genuine intrinsic intentionality, or whether it is merely derived from the intentional states of their creators. (*See* **Propositional Attitudes**)

HISTORY

Although consciousness seems to be what first comes to mind when people nowadays think of the mind, this may not always have been so. The ancient Greeks discussed it very little, concerning themselves with issues of rationality and character (such as being fair or courageous). In the Middle Ages, there was a great deal of development of religious ideas about the mind, especially in the work of Augustine, Maimonides and Aquinas, as well as the discovery of some of the peculiarities of intentionality that we have noted. And in the seventeenth century, particularly in the work of Descartes, it is the issue of rationality that is at the forefront. Descartes argued that matter was incapable of exhibiting the kind of 'universal reason' that he thought was exhibited by human beings. Although resistance to 'materialism' is still influential, it has come to be associated more with consciousness than with rationality.

Historically, the main positions with regard to the nature of mental phenomena have been: 'dualism', whereby mental phenomena are regarded as a fundamental feature of reality different from physical (or 'material') phenomena; and various versions of 'physicalism' (sometimes called 'materialism' or 'reductionism'), whereby mental phenomena are regarded as specific manifestations of the physical.

Dualism

In its most radical, Cartesian form, dualism is committed to the view that mind constitutes a fundamentally 'different substance', one whose functioning cannot be entirely explained by reference to physical phenomena. However, there are other, more modest forms. Many contemporary philosophers who reject Descartes' postulation of some kind of special mental substance are quite comfortable with a dualism regarding special mental properties (or states or events). For example, the property of being in pain may be a particular non-physical property of a nevertheless quite physical human body.

It is important to distinguish such claims about the nature of mind from claims about its causal relations. In Descartes' view, despite their immateriality, mental phenomena can be *both* causes *and* effects of physical phenomena ('dualistic interactionism'). Leibniz, however, claimed that they were neither, but were synchronized with physical phenomena ('parallelism'). An intermediate view, originally advocated by Thomas Huxley and recently resuscitated by F. Jackson, is that mental phenomena are the effects, but not the causes, of physical phenomena ('epiphenomenalism'). Recently, dualism has been energetically defended by D. Chalmers, who claims that there is a law of 'structural isomorphism' between the mental and the physical: our experience and our brains have a certain structure even though they are fundamentally different phenomena. (*See* **Epiphenomenalism**)

There are a number of interesting arguments for dualism. Most of them tend to be negative ones, arising, as we will see shortly, from specific problems with materialism. Perhaps the most striking such problem is what Joseph Levine has called the 'explanatory gap'.

Consider how we explain most ordinary, non-mental phenomena. It is one of the impressive achievements of modern science that it seems to afford, in principle, illuminating explanations of almost every non-mental phenomenon one can think of. For example, if one wants to understand why water expands when it freezes, why the sun shines, continents move, or foetuses grow, most educated people can at least imagine how possible explanations might in principle proceed. They would have to do with the physical properties of many small particles, their spatial and temporal relations, and the physical (e.g. gravitational, electrical) forces between them: put enough of these particles together with just the right forces between them, and it would follow that the water would have to expand, the sun shine, and foetuses grow. As Levine nicely puts it, the microphysical phenomena 'upwardly necessitate' the ordinary macrophysical phenomena.

But it is precisely this upward necessitation that seems very difficult to supply in the case of the mental, particularly in the case of the two phenomena we have discussed, consciousness and intentionality. Consider the question: how do you know that someone else sees colours in the same way you do? To put it in terms of physicalism: what physical facts about a person uniquely determine that it must be 'red' experiences that the person is having when he or she looks at ordinary blood, and not 'green' ones? Or, to take an analogous problem raised by Quine about intentionality: what facts about a person's physical make-up uniquely determine that the person is thinking about rabbits, as opposed to 'rabbithood' or 'undetached rabbit parts'?

Physicalism

For all these conceptual difficulties in relating the mental to the physical, many philosophers are

convinced that the world is nevertheless fundamentally a physical world, and that the mental must be a specific manifestation of it. Interest in this issue is not confined to those with an interest in the centrality of physics. On pain of circularity, if mental phenomena are ultimately to be explained in *any* way, they must be explained in terms of non-mental phenomena. It is a significant fact that the only non-mental phenomena we know of are physical (even the biological has turned out to be physical). Physicalism (also called 'materialism') is the view that all mental phenomena are in some sense just physical phenomena.

The identity theory

Although materialist ideas can be found in the Greek atomists and in Lucretius, Thomas Hobbes is often thought of as the father of modern materialism. However, Hobbes does not clearly distinguish between mental phenomena being the *effects* of physical processes, and their actually *being* physical processes themselves. This latter view, the so-called 'identity theory', whereby the mental is 'nothing but' the physical, emerged only in the twentieth century, in the work of U. T. Place and, most influentially, J. J. C. Smart. Here the proposal is to identify every mental state with a physical state, in the way that, for example, episodes of lightning could be identified with episodes of electrical discharge. The primary argument for this view is a kind of economy about the different kinds of things in the world, and a unification of causal claims: mental events enter into causal relations with physical ones because they are in the end physical events themselves. This view is also called 'reductionism', which unfortunately carries the misleading suggestion that the mental is somehow 'made less' by being physical. This is a mistake: lightning, after all, is not 'less' lightning for turning out to be 'reduced to', or being 'nothing but', electrical discharge.

The analogy with lightning, however, carries what many have thought to be an implausible implication: every instance of lightning is indeed an instance of electrical discharge; but is every instance of, say, *believing that grass grows*, an instance of the very same type of physical state, say, an excitation of specific neurons in the brain? Why couldn't you have silicon implants where I have neurons, without disturbing our shared belief that grass grows?

A way of avoided this unwanted implication was proposed by Nagel, who noticed an ambiguity in identity statements, between identifying type and token mental states. He and others proposed limiting the identity theory to the latter: just as different 'token' occurrences of the same 'type' alphabetic letter need not share any one physical property, so different token mental states might be 'realized' in different physical substances. In this view, all that is important for physicalism is that there are no nonphysical tokens.

Even if we restrict ourselves to token identity claims, however, there are still some problems with the identity theory. One simple problem concerns the relation of many mental phenomena to physical space. It is ordinarily unclear exactly where such things as beliefs and desires are located. We ordinarily say they are 'in your head': but where exactly? Does it make sense to say that my thought that grass grows is 2 mm to the right of my hypothalamus? Or, to take a harder example, many people claim to have vivid 'mental images', and, indeed, experiments suggest that they play a significant role in ordinary reasoning. These images seem to have certain spatial properties: they may be 'oval' and 'vividly colored', and even 'rotate' as we try to solve some problem. But if they too are to be identified with physical things, then it would follow that there should be oval, vividly colored, rotating images in the brains of people who experience such images. This seems absurd: neurosurgeons do not discover such images in brains – and, even if they did, how would such images ordinarily be seen? By an 'inner eye'? So it would seem that a mental image cannot be a physical thing. (*See* **Mental Rotation**)

These difficulties might well lead one back to dualism. However, there is another, even more radical response.

Eliminativism and radical behaviorism

Exasperation with dualism, but also with the difficulties of reductionism, led many psychologists of the twentieth century to the extreme position of eliminativism, or the denial of the existence of any mental phenomena at all. This may seem a preposterous position, but it is worth taking seriously both for the light it sheds on certain issues, and because certain versions of it may be true for specific classes of mental phenomena.

Moreover, there is an interesting argument that can be made on its behalf. This has to do with the evident lack of any causal break in the internal processes of the human brain. So far as we know, there is no movement of anything in anyone's body that fails to have a physical explanation (if it has any explanation at all). If this is true, as many

psychologists believe, then we should ask what reason we have to believe there are any mental phenomena at all: they seem superfluous.

Of course, if one reduced mental phenomena to physical phenomena, then one could perhaps claim that the action of the mind is 'nothing but' the action of the body. Like dualists, eliminativists are impressed by the difficulty of pulling off the reduction. Unlike dualists, however, they are impressed by this lack of a causal break. The point could be put this way: if the difficulties of reductionism force us to regard mental talk dualistically, then the lack of a causal break should further force us to deny the existence of any mental phenomena. They are no more needed to explain the motions of our bodies than are angels to explain the motions of the planets. (*See* **Eliminativism**)

One might retort by asking how any physical theory explains one's own present conscious thoughts and experiences. Why don't the same explanatory gaps that argue against reductionism argue equally against eliminativism? But this begs the question against the eliminativist, who will simply reply: 'What conscious thoughts and experiences? You may as well say that Newton didn't explain the motion of the planets because he didn't explain the beating of the wings of the angels who were pushing them.' What is needed in either case is non-tendentious evidence for the questioned postulation, be it mental or angelic.

At first sight, this seems a difficult challenge. We do not ordinarily think about providing non-tendentious evidence for the mind, and so most of the evidence we might be tempted to provide presupposes mental talk, as when we talk not only about our own thoughts, but even about other people's deliberate actions ('raising an arm') rather than just the motions of their limbs ('an arm rising').

However, there is a source of evidence that may provide at least a good deal of what we need. Consider 'standardized tests' (such as the 'SAT' and 'GRE' regularly given to students in the United States). Here the 'standardization' consists in the fact that both the question sheets and the answer sheets are prepared in such a way as to be in principle physically type-identical: the question sheets consist of identically printed marks on paper, and the rectangles on the answer sheets are supposed to be filled in with a graphite pencil in such a fashion that a machine can mark the test. The correlations between these physical types of 'input' and 'output' is surely no accident. Science is in general concerned with explaining such regularities as these, and, although physics could explain every such *token* event, it is hard to think of any purely physical explanation that stands a chance of explaining such *correlations* between the types. The only explanation that seems plausible is a mentalistic one that talks about the students' thoughts, desires and reasoning abilities.

In the twentieth century, some eliminativists thought they did have an alternative explanation of such intelligent behavior. For about 50 years, they pursued a program, which B. Skinner called 'radical behaviorism', of trying to explain all human and much animal behavior in purely physical terms, specifically in terms of patterns of 'conditioning' among physically specified stimuli, responses and reinforcements. The programme is now of little more than historical interest, partly because its main tenets were refuted by the careful experiments of the behaviorists themselves. They found that rats displayed a variety of navigational skills that defied explanation in terms of conditioning, and that seemed explicable only by reference to 'mental maps' and 'curiosity drives'. K. Lashley provided some theoretical reasons for thinking that many serial behaviors could not be explained by conditioning. Finally, Chomsky provided a devastating refutation of Skinner's efforts to provide a behavioristic account of human language.

Irreferentialism and analytical behaviorism

A more moderate response to the difficulties of both dualism and reductionism was proposed by Wittgenstein. He claimed that philosophers too often presume that words gain their meaning by referring to various phenomena in the world, and that this leads them to think of our inner mental lives using a model too close to the familiar outer one of material objects. He proposed instead that we think of the meaning of a word as its 'use', or role in various 'language games' of which our ordinary talk consists. If we do this, there is no reason to suppose, for example, that our talk of mental images need be taken to refer to objects in a mysterious mental realm; rather, terms like 'mental image' (and, Wittgenstein seems to suggest, most of our mental talk) should be seen more on the model of an expression like 'the average American family', which, of course, does not refer to any actual family (its use is a convenient way of speaking of a ratio).

However, it is not easy to provide a positive account of the meaning of mental talk. Popularizing the then-unpublished views of Wittgenstein, Gilbert Ryle attempted to exorcize what he called the 'ghost in the machine' by showing that mental terms function in language as abbreviations of

dispositions to overt bodily behavior. This programme came to be called 'analytical behaviorism' (a thesis about the *meanings* of mental words, not to be confused with radical behaviorism, which is a thesis about how to do *without* mental words). A famous example of a behaviorist analysis was Alan Turing's proposal that a machine be counted as 'intelligent' if its teletyped answers to questions were indistinguishable from those of a normal human being. (*See* **Turing Test**)

Analytical behaviorism did not meet with great success. It is not hard to think of possible cases of creatures that might act exactly as though they were, say, in pain, but actually were not: consider expert actors, or human bodies wired to be remotely controlled. Nor is it hard to imagine machines passing Turing tests by merely emulating a conversation without having any understanding of it at all.

What all such examples show is that mental states are not tied directly to behavior. Typically, they issue in behavior only in combination with one another: a belief issues in behavior only in conjunction with, for example, desires and attention, and conversely. For example, it is because an actor has different motivations from a normal person that he can behave as though he were in pain without actually being so; and it is because a person believes that she should be stoical that she might be in excruciating pain but not act as though she is. The internal organization responsible for a person's behavior, and not just the behavior itself, determines the identity of a mental state. The Turing test, which ignores such internal organization, is thus a poor test for intelligence. (Wittgenstein had a more subtle view than Ryle: he never claimed that mental expressions could be *analyzed* in behavioral terms, but that 'an inner process stands in need of an outward criterion', a view that is still held by some today.)

Functionalism

The fact that mental terms seem to be applied in ensembles has led some philosophers to think about technical ways to define an entire set of terms together. David Lewis invoked a technique, called 'ramsification', whereby a set of 'new' terms could be defined in terms of their relations to one another and to other 'old' terms already understood. This captured an idea already noted by Hilary Putnam with regard to the set of standard states of computers. Turing's most important work was in the conceptualization of the modern computer, in terms of 'states', each of which is defined in terms of the others and what the machine would do when it receives an input: the machine produces a certain output and passes into another of the states. The states can then be defined together in terms of the overall pattern produced inthis way. (Note that Turing's important thesis that such a machine can compute anything computable is quite independent of his 'test' for intelligence.)

States of computers are not the only things that can be defined in this way: most reasonably complex entities that have parts that function in specific ways will do as well. For example, a carburator in an internal combustion engine can be defined in terms of how it regulates the flow of petrol and oxygen into the cylinders where the mixture is ignited, causing the piston to move. It was such analogies between mental states and the functional parts of complex machines that provided the inspiration for functionalist approaches to mental terms. Such approaches have dominated the philosophy of mind since the 1960s.

There are many different ways in which the functionalist approach can be deployed, depending on the kind of view of the mind that one thinks is constitutive of the meaning of mental terms. Some people take the view reflected in common folk beliefs; some take views informed by philosophical reflection on possible cases; others take views informed by empirical psychological theory. Furthermore, definitions may vary according to whether they are derived from a view of the *whole system at once*, or only of *specific parts* of it, and whether the old terms are confined to observable behavior, or may include references to specific features of our bodies and the environments we inhabit. The most influential form of functionalism is based on the analogy with computers, which, of course, have been independently developed to solve problems that seem to require a kind of intelligence.

The computational–representational theory of thought

The idea that thinking, and mental processes in general, could be treated in computational terms, was inspired by the successes in the formalization of certain portions of reasoning that we mentioned above. It emerges in the work of Newell and Simon, Putnam, Harman, and especially J. Fodor, who has been most explicit in developing the computational–representational theory of thought (CRTT), or the idea that thinking consists in computing upon sentences in a 'language of thought'.

Note that CRTT is not the claim that any computer – even any existing computer – is or has a mind. Rather, it is the claim that a mind is a certain *kind* of

computer, one with specific internal structures and specific relations to the environment, which, together, are responsible for its having certain intentional content. (Hence, *pace* Searle's famous 'Chinese room argument', the Turing test is quite irrelevant to CRTT.) It is, in fact, not so much a claim as a research program: the hope is that by understanding the brain as an elaborate computer – or, more realistically, as a complex assemblage of computers – one could ultimately define mental states in terms of the specific computational roles they play in that assemblage. This research program is more or less the subject matter of cognitive science. (*See* **Artificial Intelligence, Philosophy of**; **Bayesian Belief Network**; **Bayesian and Computational Learning Theory**; **Means–Ends Analysis**; **Reasoning**; **Turing, Alan**; **Unified Theories of Cognition**; **Chinese Room Argument, The**; **Connectionism**; **Artificial Intelligence, Gödelian Arguments against**; **Cognitive Development, Computational Models of**; **Analogy-making, Computational Models of**; **Mental Disorders, Computational Models of**; **Games: Trust and Investment**; **Computational Models: Why Build Them?**)

THEORIES OF CONSCIOUSNESS

Development of computational theories of mind, as well as of more detailed neurophysiological knowledge, has stimulated a renewal of interest in consciousness, which had long been avoided, in philosophical discussions, as a quintessentially subjective phenomenon. However, although much has been written, we are still nowhere near a satisfactory theory.

There has recently been a great deal of investigation of neural correlates of consciousness, e.g., of a 40 Hz oscillation in the primary visual cortex of a cat whenever the cat is having a visual experience. But however robust this finding may turn out to be, a correlation is not an explanation. As we noted at the outset, it is a distinctive concern of philosophy to determine the nature of a phenomenon, and a correlation alone does not provide that. (Would having such an oscillation render a radio conscious, or lacking it render an animal unconscious?)

Executive, Buffer, and Higher-order State Theories

Sometimes 'conscious' is used merely to mean 'awake', as in: 'Is the patient conscious?' But the meaning of interest to philosophers tends to be more specific, involving the availability of certain contents as objects of introspective knowledge. There are three (not necessarily exclusive) sorts of theories of that availability: what might be called 'executive' theories, 'buffer' theories, and higher-order state theories. Executive theories stress the role of conscious states in deliberation and planning. According to buffer theories, consciousness consists in a person standing in specific relations to a specific location in which material is stored for specific introspective purposes, along the lines of the material available to a press secretary, whose claims may or may not match those of an executive. Ray Jackendoff makes the further interesting suggestion that such material is confined to relatively low-level sensory material.

An important family of much more specific proposals are variants of the idea that consciousness involves some kind of state directed at another state. One variant is that it involves some kind of 'internal scanning' or 'perception'; another is that it involves an explicit 'higher-order thought' (HOT), or a thought that one is in a specific mental state. For example, the thought that one wants a beer would be conscious only if one thinks that one wants a beer. This does not mean that the HOT is itself conscious; only that its presence is what renders its target, lower-order thought conscious. D. Rosenthal defends the view that the HOT must actually be occurring at the time of consciousness; Carruthers defends a more modest view that the agent must simply be *disposed to have* the relevant HOT.

'What It's Like'

Ned Block has pointed out an important distinction between two concepts of consciousness that many of the above discussions do not distinguish: 'access' consciousness and 'phenomenal' consciousness. Although it might be defined in a variety of ways, depending on the details of the computational (or other) theory of thought under consideration, access consciousness (of some material) consists in being accessible to various mental processes, particularly, say, introspection. Block points out that the fact that material is accessible to processes does not entail that it actually has a qualitative, phenomenal feel, that there is something 'it's like' to have that material being so accessible.

This latter issue has been made particularly vivid by two influential articles about the very special knowledge we seem to acquire as a result of conscious experience. Nagel pointed out that no matter how much someone might know about the 'objective' facts about the brains and behavior of bats and their peculiar ability to locate objects by means of a kind of built-in 'sonar', that knowledge would not

suffice to convey the 'subjective' facts about 'what it's like to be a bat': indeed, it is unlikely that human beings will ever be able to know what the world seems like to the bat. Frank Jackson made a similar point by imagining a brilliant color scientist, 'Mary', who happens to know all the physical facts about color vision, but has never had an experience of red (either because she was color-blind or because she happened to live in an unusual environment). Suppose that one day (either through surgery, or by leaving her strange environment) she finally does have a 'red' experience. Does not she learn something 'new', something that she didn't know before even though she knew all the physical facts of color vision?

Qualitative States

'Qualiaphilia', as it has come to be called, is the view that no functionalist theory of consciousness can capture phenomenal consciousness: in conscious experience we are aware of 'qualia' that arenot *relational*, in the way suggested by the functionalist, but rather somehow *intrinsic* features ofour experience. It is this sort of consideration that still leads many philosophers to varieties of dualism.

Representationalism

An intruiging alternative to qualiaphilia is a suggestion that has gained a good deal of attention in the last decade whereby qualia are not understood as *real* phenomena in experience, but rather merely *intentional* phenomena: that is, although they are the sorts of 'objects' on which we can direct our intentional states (such as thought and desire), they are no more real than are 'intentional objects' such as Santa Claus or Zeus. We already noted a form of this view when we observed that there is no need to believe in objects such as pains. One of the most interesting suggestions philosophers have made about the mind concerns the apparent properties of our qualitative experience: the look of red, the taste of beer. As noted above, there is no need to believe in objects such as pains, tickles or even mental images: one can just as well speak about experiences of these things, affirming that there are such states, but denying that these further 'objects' actually exist (cf. irreferentialism).

Although this is a widely accepted view in the case of these sorts of phenomenal objects, many people find it harder to accept in the case of phenomenal properties: how can one deny the existence of such properties as say, the intense painfulness of unanaesthetized surgery?

But what makes us think there is an actual property there in experience? As we noted earlier, the concept of 'unicornhood' need not entail the existence of any corresponding property. Perhaps certain stimulations of the nervous system can cause people to possess certain concepts (or, more specifically, certain modes of presentation) of certain phenomenal properties, concepts that could not be possessed by knowledge of physics alone, but there need not be any corresponding properties whose existence is at all problematic. (Think of one's mental life as being like an animated cartoon: does it matter that there are no real things represented by the flickering images on the screen?)

Remaining gaps, and first-person scepticism

What nevertheless continue to bother the qualiaphile are the problems of the 'explanatory gaps' between the physical and various mental phenomena, described above. For all their (potentially elaborate) accounts of the organization of a typical human being, functionalist theories have not yet been shown to 'upwardly necessitate' the specific qualia of experience (red versus green), the specific intentional content of thought (say, thinking of rabbits rather than 'rabbithood'), or even conscious experience: it seems possible to imagine a computer with precisely the same functional organization as a human brain, which is nevertheless a zombie and has no conscious experiences at all. A problem with taking this possibility seriously, however, is that it can leave one wondering about oneself: if there is a possibility that other people may have all the computational organization of a mind but not be conscious, then why shouldn't that be a possibility in one's own case as well? How do you know that you are a conscious agent, and not merely a 'robot' that thinks it is?

Philosophy of Neuroscience

Intermediate article

Ian Gold, Monash University, Clayton, Victoria, Australia

CONTENTS

The philosophy of neuroscience is concerned with the philosophical investigation of neuroscience as a science and is distinguished from neurophilosophy, which is concerned with the application of neuroscience to the philosophy of mind and epistemology.

INTERACTIONS BETWEEN PHILOSOPHY AND NEUROSCIENCE

Philosophy interacts with neuroscience in two different ways, although the boundary between the two is fluid. The first kind of investigation, usually referred to as philosophy of neuroscience, is concerned with philosophical questions raised by neuroscientific data or theory, or by the status of neuroscience as a whole. The second kind of investigation, usually called neurophilosophy, attempts to exploit advances in neuroscience to solve philosophical problems about the mind. The philosophy of neuroscience is thus a branch of the philosophy of science. Neurophilosophy, in contrast, is a branch of the philosophy of mind and is closely related to cognitive science.

Because both of these branches of philosophy are of recent vintage, general principles and clear foci have not yet been identified; nor are there many clearly delineated 'debates' that characterize more established areas of philosophy. For these reasons, no attempt is made here to present a comprehensive picture of the field. Instead, this article discusses some representative illustrations of work in neurophilosophy and philosophy of neuroscience. Many philosophers of neuroscience – like some neuroscientists themselves – are also pursuing research that is better described as theoretical neuroscience. This is not dealt with here.

HISTORY

The modern incarnation of the view that the mind is identical to the brain and its functions was introduced into psychology and philosophy in the late 1950s. This doctrine, known as the identity theory, was eventually supplanted by functionalism, according to which mental states are to be analyzed in terms of their relations to one another, to perceptual input, and behavioral output. Functionalism holds that any material that embodies these relations – the silicon chip of a computer, for example – has a mind. Thus, while the view that the mind is to be explained by science has been the overwhelmingly dominant position in contemporary philosophy, the brain and its properties had been, until recently, as little emphasized in philosophy as in cognitive science and artificial intelligence research.

Against this mainstream position Patricia S. Churchland (1986) articulated a new vision for the philosophy of mind which she called neurophilosophy. With Paul M. Churchland, she has continued to argue that an understanding of the mind requires abandoning the purely functional investigation of philosophy and cognitive science in favor of a biologically based science of mind. Indeed, the Churchlands have defended the view that a successful theory of the mind will be exclusively neuroscientific (see below).

Although philosophical work deserving the name 'neurophilosophy' had existed prior to 1986, Churchland's book baptized new branches of the philosophy of mind and science, and this has produced a new generation of philosophers whose work straddles the boundary between philosophy

and neuroscience. Even if functionalism, broadly speaking, remains the right framework for a theory of the mind, the specific details of biological minds is of independent interest. Further, the facts of how natural minds operate may provide novel ideas for the development of artificial intelligence systems.

NEUROPHILOSOPHY: PHILOSOPHY OF MIND AND EPISTEMOLOGY

Neurophilosophers have addressed a wide variety of traditional problems in philosophy by applying the findings of neuroscience. In what follows, five representative illustrations are presented.

Perception and Intentionality

Perhaps the most significant and striking fact about mental states is that they are about things in the world. This 'aboutness' is usually referred to as the intentionality of mental states, and it is closely related to what is often called perceptual content – that is, how perception represents the world to be. How this is possible, and how it occurs, are two of the most important questions in the philosophy of mind. A paradigm case of the intentionality of the mental is the putative intentionality of perceptual states. When I stare at the ocean from my window, I am in a visual state which is about the ocean. Because this case seems simpler than many others – for example, my ability to imagine what it would be like to visit the Taj Mahal – theories of intentionality often begin with perception as a first step in the development of a comprehensive theory of intentionality.

Kathleen Akins (1996) argues that the relation between sensory states and what they represent may be quite different from the received view about intentionality. According to that view, sensory states represent aspects of the external world which are, typically, informative for the organism. Akins doubts that this is generally true; sometimes sensory states are not about the external world in the familiar sense. An investigation of sensory states, therefore, may not illuminate the 'aboutness' of mental states in the traditional sense.

Akins's argument takes as an illustration the simple sensory system of temperature detection or thermoreception. According to the received view, the purpose of thermoreception is to represent the temperature of the environment to the organism, and this view assumes that temperature receptors function like thermometers. However, the neurophysiology of thermoreception reveals a rather different picture. Temperature receptors do not function like thermometers; they are nonlinear and produce exaggerated responses to temperature changes. The reason for this, according to Akins, is that thermoreception is, as she says, 'narcissistic'. It functions not to give the organism information about the temperature of the environment, but rather to tell the organism how the temperature of the environment affects the organism. Consider, for example, the familiar illusion that comes from running one hand under cold water, one under hot, and then putting both into the same tepid water. One hand will report that the water is hot, the other that the water is cold. On the view that perception is designed to reveal the way the world is, this is a spectacular failure. On the narcissistic view, however, it is a success because each hand is reporting something of relevance, namely, that its environment is rapidly heating or cooling. Because rapid changes in temperature are of great practical importance to organisms, this is important information.

A neurophysiologically inspired conception of sensory function, therefore, produces a rather different picture of perception from the traditional one. If this picture is correct, whatever the lessons of perceptual systems for the nature of intentionality, there is no simple and direct route from the properties of sensory systems to the nature of intentionality.

Pain

The nature of conscious experience and its relation to the external world is a perennial concern of the philosophy of mind and epistemology, and pain experience is a common test case for this investigation. There is, however, considerable controversy over what pain reveals about the mind, and the phenomenon of pain has been used as a way of defending myriad views; for example: that some mental states are entirely subjective; that we have a special access to the states of our own minds; that experience has properties that cannot be explained in purely physical or functional terms; that the mind is something over and above the brain; and that some aspects of our experience are entirely mysterious.

Pain experience is often used as a test case because it is thought to be a 'simple' kind of experience. As against this view, however, Valerie Gray Hardcastle (1997a) argues that philosophical confusions about pain arise as a result of a failure to understand the neural complexity of pain, in particular, the fact that pain perception is an overarching prozcess made up of a number of subsystems.

These include systems that subserve the conscious experience of pain, the sense of suffering typically associated with pain, the affective-motivational aspect of pain, and pain behavior.

Hardcastle argues that philosophers have tended to identify pain with only one of these subsystems and have therefore drawn erroneous conclusions about pain as a whole. She further argues that a correct understanding of pain requires positing two broad pain mechanisms, the first responsible for the experience of pain and the second responsible for the inhibition of pain experience. Each of these putative systems explains many of the features philosophers have thought ascribable to pain as a whole, and together they resolve many philosophical disputes about pain. Disagreement over whether pain is a 'subjective' or an 'objective' phenomenon, for example, results, on Hardcastle's view, from taking a part of the phenomenon for the whole. The existence of a pain sensory system explains many of the features of pain that have led philosophers to argue that pain is an objective phenomenon, whereas the existence of a pain-inhibiting system explains many of the features of pain that support a subjective account of it. Once pain is understood to be composed of both of these functionally distinct subsystems, the disputes over objectivity disappear.

Dreams

The phenomenon of dreams has been a frequent case study in the history of philosophy's attempt to understand consciousness. The causes and function of dreams also, famously, take centre stage in psychoanalysis. Recent work in neurophysiology and neurochemistry has begun to elucidate the biological processes of sleep, including rapid eye movement (REM) sleep, the stage of sleep in which the sleeper dreams. The function of dreams, and what neuroscientific findings say about psychoanalytic theory, remain controversial.

What has recently occupied philosophers most about dreams is the question of whether they are genuine experiences. Dreamers awaken and believe that they have had experiences in dreams of events and adventures of various kinds. However, dream experience is very uncritical. For this reason, the mere memory of a dream is poor evidence for establishing that the dream experience has actually occurred. Other hypotheses – such as that dreams are confabulated upon awakening – are equally plausible and have been fodder for philosophers of mind of a skeptical bent who have denied that dreams are experiences.

Owen Flanagan (1996) argues that neurophysiology can do philosophical work here to refute this skeptical position. The relevant evidence comes from studies showing that the patterns of neural activity during REM sleep are highly similar to the patterns of activity in the waking state. This similarity provides evidence for the accuracy of dreamers' memories of their dreams: dreams are indeed experiences similar in some respects to waking experiences because the state of the brain in REM sleep is much like the state of the brain in wakefulness.

Flanagan (1995) also considers the question of what function dreams perform in mental life. He evaluates the recent neuroscientific theories of dreaming and argues that, strictly speaking, dreams perform *no* function in the cognitive economy of the dreamer. They are, rather, evolutionary 'spandrels' – phenomena that come into existence not because they themselves are adaptive but because they are necessary for, or are a by-product of, some other function that is selected for. Flanagan claims that dreams arise as a necessary, but non-functional, consequence of REM sleep though what the function of REM sleep itself is remains controversial. He suggests, however, that the practice of dream interpretation, ubiquitous both before and after Freud, can be thought of as a technique for self-reflection and understanding. Dreams can, in this sense, be seen to have a cultural, if not a psychological, function.

Rationality

Dreams are sometimes said to be states in which dreamers are irrational. The concepts of rationality and irrationality have also been explored in neurophilosophy by the investigation of delusion. A paradigm case is the Capgras delusion in which sufferers become convinced that intimates (or sometimes significant objects) have been replaced by exactly identical duplicates. As if this is not strange enough, while sufferers are puzzled by this occurrence, they do not seem to be terribly troubled by it.

Other equally bizarre beliefs include the belief that one is dead (Cotard delusion); that one is being followed by familiar people in disguise (Frégoli delusion); that someone else is inserting thoughts into one's mind (delusion of thought insertion); that someone else is controlling one's actions (delusion of control); and that the person one sees in the mirror is someone other than oneself (mirrored-self misidentification). Traditionally, delusional subjects were referred to psychiatrists, and

this practice continues. There is now evidence, however, that some delusions may be brought about by damage to the right hemisphere of the brain. Neuropsychiatrists have, therefore, begun to try to explain delusion in neuropsychological terms.

Two significant questions for neurophilosophy are: in what sense is delusion an instance of irrationality? And what is the correct account of the character of this irrationality? A number of possibilities have been suggested. One is that delusions are not irrational because they are attempts to explain very strange experiences. On this view, the delusional belief is a rational response to that experience. A second view holds that delusions are irrational to the extent that they represent biases in hypothesis-generation or in the evaluation of the plausibility of hypotheses adopted as beliefs. A third view holds that the irrationality of delusion lies in the way experience represents the world. According to this position, certain representations, though not full-blooded beliefs, none the less deserve to be called irrational.

A third question for neurophilosophy is: what, if anything, does the functional anatomy of delusion reveal about the functional organization of belief? Here research is just beginning. Martin Davies and Max Coltheart (2000; Davies *et al.*, forthcoming) are defenders of the view that the source of delusion is to be found in a combination of a strange experience together with a second cognitive factor. They argue that while the strange experiences of delusional subjects could be explained in any number of reasonable ways – including that the subject has a mental or neurological disease! – delusional subjects opt for explanations that are impossibly farfetched. Delusional subjects must, therefore, have some other cognitive dysfunction that does not prevent this extreme hypothesis from establishing itself as part of the subject's store of beliefs. If this view is correct, and if right hemispheric damage is confirmed as the site of damage in delusion, we would have the beginnings of a functional anatomy of belief.

Unity of Consciousness

An early illustration of the relevance of neuroscience to philosophy was provided by Thomas Nagel (1971), who discussed experiments with commissurotomy, or 'split-brain', patients in order to explore the traditional view that consciousness is unified – that our experience is constituted by a single stream of experiences of which we are aware. The neuropsychological phenomenon is well known. Individuals with severe epilepsy can be treated by severing the corpus callosum and anterior commissure (the bundle of fibres that connect the two hemispheres of the brain) in order to prevent the spread of epileptic fits. Despite the fact that subjects who undergo this surgery appear entirely normal in their everyday behaviour, studies of these individuals reveal subtle but dramatic behavioral effects. The absence of anatomical connections between the hemispheres prevents perceptual input from one hemisphere from being transferred to the other, and the behavior elicited from the patients makes it evident that the two hemispheres can function and drive behavior separately and, sometimes, competitively. However, because only one of the hemispheres (usually the left) subserves language, only that hemisphere can express the thoughts of the patient.

Nagel considers the question of what these phenomena say about the apparent unity of consciousness. How many minds exist within the body of the split-brain patient? Nagel considers five possibilities: (1) that there is one mind whose consciousness is located in the linguistic left hemisphere and whose right-hemisphere behavior is caused by a sort of automaton; (2) that there is one mind associated with the left hemisphere, but right-hemisphere behavior is caused by conscious mental activity that is unintegrated into the larger consciousness of the person; (3) that there are two minds only one of which can speak; (4) that there is only one mind, the contents of which come from both hemispheres and are therefore dissociated; and, finally, (5) that there is one mind when the two hemispheres are acting together but two minds when experimental conditions elicit different behavior from each separately.

Nagel argues that there are no principled reasons for choosing any of these options over the others and concludes, therefore, that there is no whole number of minds that can be associated with split-brain patients. The even more radical proposal that follows from this is that the same holds true of normal subjects. The belief that the mind is a single thing is an illusion, Nagel suggests, that arises because every agent experiences his or her own consciousness as unified and imports the assumption of unity into his or her experience of the minds of others. It is rather the case, Nagel argues, that a mind is a conglomeration of diverse functions that operate so harmoniously as to appear, from both the inside and the outside, as a single thing. The falsity of the appearance is revealed when the two hemispheres can no longer operate in concert. (*See* **Split Brains, Philosophical Issues about**)

PHILOSOPHY OF NEUROSCIENCE AND ITS RELEVANCE TO COGNITIVE SCIENCE

Neuroscience and the Cognitive Sciences: Relations among Theories

In contrast to the interests of neurophilosophy, the philosophy of neuroscience investigates philosophical issues within the theories and practice of neuroscience itself. A number of issues have been addressed by philosophers of neuroscience including levels of explanation in cognitive neuroscience; the nature of representation; and the significance of neuroscientific evidence. Perhaps the central question that has been addressed thus far in the philosophy of neuroscience, however, is a very general one: what is the relation between the cognitive sciences and neuroscience? A number of relations are in principle possible, among them that neuroscience and cognitive science will provide separate but equal descriptions of the mind at different theoretical levels; that cognitive science will provide a functional description of the mind for which neurobiology will provide a mechanistic description; and that cognitive science will reduce to neuroscience as genetics reduces to molecular biology. In the process, it is likely that some parts of cognitive theory will be discarded and replaced by neuroscience.

The views of the Churchlands (see especially P. M. Churchland, 1981; P. S. Churchland, 1986; Churchland and Churchland, 1996) have focused debate in this area. They defend a view known as eliminative materialism. According to this view, the cognitive sciences will eventually be entirely replaced by a mature neural theory of the mind. The view is eliminativist because it holds that ordinary psychological concepts, and perhaps the concepts of theoretical cognitive science, will be eliminated and replaced by novel concepts from neuroscience.

Although according to eliminativism neuroscience will provide the final theory of the mind, the historical process of reaching this state of knowledge will, according to the Churchlands, involve a co-evolution of neuroscience and cognitive science. Results from neuroscience will, on this view, constrain cognitive models of mental phenomena which will, in turn, stimulate and direct investigation in neuroscience. Once neuroscience is sufficiently rich in theoretical resources, however, it will be in a position to explain mental phenomena directly. If this view is correct, then the consequences of eliminativism for cognitive science are dramatic. While cognitive science will play an important historical role in the development of the theory of the mind, it is neuroscience alone that will remain once the process of co-evolution is complete.

Eliminative materialism can be supported by a number of lines of argument, but two are particularly important. The first is based on the apparent fact that 'folk psychology' – the quotidian explanations of behavior by appeal to belief and desire – and, to some extent, cognitive science, have, according to the Churchlands, largely failed to provide adequate explanations of mental phenomena. One reason for this failure is that the fundamental psychological concepts are so flawed that no science based on them can get very far. Eliminativism concludes that they must be abandoned in favor of a set of concepts that is more promising.

A second line of argument proposes that psychological notions cannot be unified with the scientific world-view being developed by the other natural sciences. Only a biological science, such as neuroscience, is likely to produce a theory of the mind that will fit naturally into this picture. This argument has two possible conclusions: first, that neuroscience *ought* to be pursued and, second, that the unifiability of neuroscience with the natural sciences provides prima facie evidence that a neural theory of the mind will in fact be successful. The latter conclusion expresses the eliminativist view.

Beyond Eliminativism

Although eliminativism has been repeatedly challenged by philosophers of mind, it continues to represent a mainstream view among neuroscientists themselves. A different view is developed by Ian Gold and Daniel Stoljar (1999). They argue that the view that neuroscience alone will provide the successful theory of the mind embodies two quite distinct pictures of the development of the science of the mind that often fail to be distinguished. According to one view, 'neuroscience' can refer narrowly to cellular and molecular biology of the brain, or it can refer, more broadly, to the interdisciplinary effort to understand the mind and brain usually known as 'cognitive neuroscience'. The eliminativist view that the biological science of the brain alone will provide the successful theory of the mind is a radical view, but it is not as yet supported by anything in neuroscience itself. All of the putative accounts of mental phenomena available in neuroscience – even those that are framed largely in neural terms – turn out to be amalgams of

neurobiology and cognitive science. The present state of the sciences of the mind supports the view that the science of the mind is likely to be an interdisciplinary one.

In contrast, the view that it is cognitive neuroscience alone that will provide the successful theory of the mind is not a radical thesis at all. It is simply the view that some combination of sciences will collectively explain the mind. In particular, this view does not entail, and the radical view does, that cognitive science will form no part of a final theory of the mind. These two quite distinct views are regularly conflated and lead to a distorted picture of the current state of neuroscience. Which sciences will provide the necessary theoretical concepts, and what their relative contributions to successful theory will be, remain open questions.

Interpreting Neuroscience: An Illustration

In addition to addressing the status of neuroscience as a whole, the philosophy of neuroscience is concerned to elucidate particular neuroscientific concepts and their role in theory. One example of the kind of question that is of interest to the philosophy of neuroscience comes from the theory of vision and its relation to the investigation of consciousness. It will be clear that this problem is closely connected to the neurophilosophical discussion of consciousness described above and exemplifies the fluidity of the boundary between neurophilosophy and the philosophy of neuroscience.

Visual experience represents the environment as having a range of different properties such as color, shape, and motion, and the perception of these features are subserved by different cortical regions. These elementary facts raise a family of questions that is usually referred to collectively as the *binding problem:* how do brain areas interact so that the color of a stimulus, for example, is associated with its shape? And how does this neural activity produce perceptual experience that is unified (see Hardcastle, 1997b)?

One recent proposal about how the binding problem is solved at the level of neurons runs as follows. Many neurons exhibit regular physiological patterns of firing called oscillations, and it has been suggested that synchrony of oscillation (especially around the frequency of 40 cycles per second, or 40 Hertz) is a sign of functional connection. If two neurons, one responsive to color and one to edges, were to fire synchronously, this temporal property could signal that the two neurons were responding to the same stimulus. Stimulus identity and perceptual coherence would thus be captured by the temporal features of neural activity. It has further been suggested that synchronous oscillatory firing could be a marker of perceptual consciousness. According to this view, 40-Hz oscillation not only solves the binding problem but brings the stimulus so bound into consciousness.

There has been a good deal of debate about the 40-Hz proposal, and it raises many questions, some empirical, some theoretical. Does 40-Hz oscillation have the right properties to solve the binding problem? What is the relation between neural oscillations and the computational processes posited in cognitive theories of vision? What exactly is the relation between binding and consciousness? Does the 40-Hz theory address both problems equally well? Will the 40-Hz account generalize to other perceptual modalities? If not, how is the binding problem solved across modalities? Some of these questions are being addressed by philosophers together with cognitive and neuroscientists, and it is this kind of investigation that may represent the collaborative and interdisciplinary future of the theory of the mind.

Philosophy of Science

Intermediate article

Pete Mandik, William Paterson University, Wayne, New Jersey, USA
William Bechtel, University of California, San Diego, California, USA

CONTENTS

Philosophy of science concerns the principles and processes of scientific explanation, including both processes of confirmation and of discovery.

Philosophy of science is primarily concerned to provide accounts of the principles and processes of scientific explanation. Early in the twentieth century, philosophers of science focused on the logical structure of scientific thought, whereas in the later part of the century logic was de-emphasized in favor of other frameworks for conceptualizing scientific reasoning and explanation, and an emphasis on historical and sociological factors that shape scientific thinking. While tracing through the landmarks of this history we note many points of contact between the philosophy of science and the cognitive sciences.

THE LOGICAL STRUCTURE OF SCIENCE

The Deductive-nomological Model of Explanation and Hypothetico-deductive Model of Theory Development

The appeal to logic to articulate the structure of scientific explanation and scientific reasoning was the hallmark of the Logical Positivists, a group of early twentieth-century philosophers and scientists, working initially in Eastern Europe, who sought to provide an explication of science that could explain its high epistemic status. They offered a model of explanation, the Deductive-nomological (D-N) model, which holds that explaining a phenomenon involves deducing its occurrence from laws (Hempel, 1966). Something like this view is thousands of years old and may be discerned in the work of Aristotle. The D-N model was extremely influential in some areas of psychology earlier in the twentieth century. Many behaviorists, for example, sought to discover general laws of learning to characterize how various kinds of experiences (e.g. reinforcement) would change the behavior of organisms.

Laws, which are central to the D-N model, are taken to specify general relations (as in Newton's law that force equals mass times acceleration ($f = ma$)). To apply these general relations to particular events, one must specify conditions holding at a previous time, which are usually called *initial conditions*. Recognizing that multiple laws and initial conditions may be involved in a given explanation, such explanations can then be represented in the following canonical form (where L designates a law, C an initial condition, and E the event to be explained):

$$\begin{array}{l} \text{L1, L2, L3, } \ldots \\ \underline{\text{C1, C2, C3, } \ldots} \\ \therefore \text{ E} \end{array}$$

Advocates of the D-N perspective generally assumed that the Cs and Es were sentences whose truth or falsity could be determined directly through observation. These *observation* sentences also provided the empirical support for the laws. Most advocates of a logical analysis of science disavowed interest in scientific discovery, restricting their focus to justification. Their characterization of the relationship between observations and laws make it clear why they saw little hope for a logic of discovery. (More recently, artificial intelligence (AI) researchers and philosophers sympathetic to AI have proposed discovery tools to employ within this framework: Langley *et al*., 1987; Thagard, 1988; Darden, 1991.) The challenge in discovery is to construct new laws to account for more or new phenomena. Since laws are to be general, not specific, they must go beyond any finite set of data, and thus there inevitably seems to be a major inductive leap to a new hypothesis. Once a hypothesis was put forward, the process of testing could begin by deducing its observational consequences

in accord with the D-N model. This process of hypothesizing general laws and testing their deduced consequences was termed the Hypothetico-deductive model of theory development.

Hempel (1966) illustrates H-D with the example of Semmelweis' work during the 1840s on childbed fever. Semmelweis observed cases of 'puerperal fever' or 'childbed fever' contracted by women who delivered children in his hospital. He noted that cases were especially frequent in groups of women where deliveries were handled by physicians instead of midwives. Semmelweis' key insight into the cause of childbed fever came when he observed that a physician came down with similar symptoms upon injuring himself with an instrument during an autopsy. Semmelweis hypothesized that 'cadaveric material' on the injurious instrument caused the disease, and that, similarly, the physicians associated with outbreaks of childbed fever had cadaveric material on their hands prior to delivering babies. Semmelweis tested this hypothesis by examining its implications. One implication of the hypothesis that cadaveric material is the cause of childbed fever is that its removal from the hands of physicians would result in a decrease in cases of childbed fever. When Semmelweis tested this implication by requiring that physicians wash their hands in chlorinated lime prior to examining patients (which he assumed would remove the cadaveric matter), he observed that groups of women examined by physicians who washed with chlorinated lime had lower incidents of childbed fever than groups of women examined by physicians who did not.

The example of Semmelweis' hypothesis and test conforms to the H-D model in the following way. Semmelweis' observations could be formulated as a series of observation statements, statements of particular states of affairs such as 'Jane Doe was exposed to cadaveric material and contracted childbed fever', 'Mary Smith was exposed to cadaveric material and contracted childbed fever', and so on. His hypothesis took the form of a law-like general statement, 'Any woman exposed to cadaveric material will contract childbed fever'. And, in accordance with D-N, the original observation statements may be deductively inferred from the statement of law. Thus the relation of observation statements to statements of law has a reciprocal structure as depicted by H-D and D-N. (See Figure 1.)

If the only support for a hypothesis were the observation sentences it was intended to explain, the reciprocal relationship between proposing hypotheses and explanation would be circular. Circularity is avoided, though, since a law, being a general statement, deductively entails not just the particular observation statements it was advanced to explain, but an indefinite number of others. The theory is confirmed by demonstrating the truth of some of these additional observation statements.

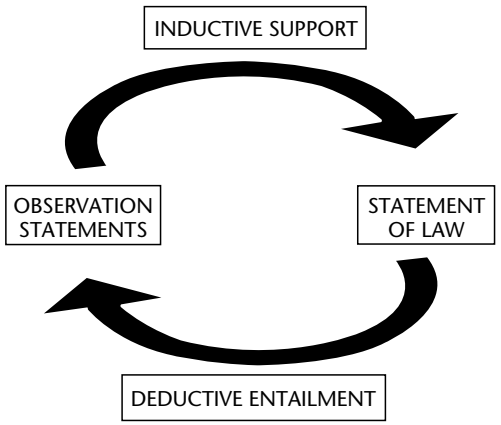

Figure 1. The reciprocal relationship between hypothesizing laws from observations and deriving observations from laws.

Intertheoretic Reduction

Recognizing that one might want to explain why laws held, the proponents also generalized this framework, allowing for the derivation of one or more sets of laws (each comprising a theory) from another set of laws (comprising another theory). The second set of laws will be more general ones from which, under specific boundary conditions, the first set of laws might be derived. (Thus, the boundary conditions replace the initial conditions in the above formalism.) Proponents also suggested that this approach might be extended to relations between laws in one science and those of a more basic science by providing bridge laws relating the vocabularies of the two sciences (by translating the terms of one into the terms of another), giving rise to the following schema:

Laws of the lower-level science
Bridge laws
Boundary conditions

$\therefore$ Laws of the higher-level science

These derivations are known as *reductions*; they figure prominently in discussions about the relation between psychology and neuroscience in which some theorists propose that the theories of

psychology ought to reduce to those of neuroscience (Churchland, 1986). Analogously, reductions are posited, or at least hoped for, for any two adjacent levels, such as from biology to chemistry and from chemistry to physics.

One example of a successful reduction that conforms to the above account is the derivation of the Boyle–Charles Law of classical thermodynamics (specifications of the temperature and pressure relations in an ideal gas) from statistical mechanics. Boyle–Charles Law terms such as *temperature* and *pressure* are translated into the terms of statistical measures of the kinetic properties of molecules in a volume. Equating temperature with mean kinetic energy supplies one of the bridge laws enabling translations of the Boyle–Charles Law into the laws of statistical mechanics. Boundary conditions include specifications of the kinds of molecules, the volume to which their motion is restricted, and the range of temperatures and pressures they are subject to. With translations of terms and boundary conditions in place, the Boyle–Charles Law is derivable from the laws of statistical mechanics.

Just as laws gain their empirical support from the true observation sentences that are derived from them, so reducing laws gain their support from the already confirmed laws that can be derived from them. Reduction, though, can also provide justification for reduced laws. Insofar as the reducing laws are more general, confirmation they receive in some domains can provide indirect support for other laws that can be derived from them.

CHALLENGES TO LOGICAL POSITIVISM

Popper's Critique of Confirmation

By making predictions which turn out true, the Logical Positivists thought we could justify laws. On this claim, however, they were criticized by Karl Popper (Popper, 1935/1959), who noted that such arguments had the invalid form of affirming the consequent:

If L were true, then prediction P would be true
P is true
∴ L is true

This formalism is invalid since it is possible for both premises to be true, but the conclusion false. Instead, Popper argued that the only way evidence could bear upon laws was through the use of *modus tollens* arguments in which failed predictions could be used to falsify a purported law:

If L were true, then prediction P would be true
P is false
∴ L is false

Accordingly, Popper emphasized that the method of science was a method of conjectures and refutations in which scientists proposed explanatory laws and then sought evidence showing that they were false. If a proposed law resisted all attempts at falsification, Popper would speak of it as corroborated, not as true or confirmed, recognizing that future evidence could always reveal it to be false.

Mechanisms instead of Laws

Although the D-N model seems to apply well to a number of scientific domains, especially in physics (for example, to explanations of phenomena that appeal to the laws describing ideal gases or principles of thermodynamics), it does not seem applicable to many domains in the life sciences. A major reason is that explanation does not tend to involve showing that a phenomenon follows a law (Cartwright, 1983; Giere, 1999). Instead, explanation often involves identifying and describing the mechanism that generates the phenomenon (Wimsatt, 1972; Machamer *et al*., 2000). A key component to the idea of mechanism is that of a set of processes that generate a phenomenon, with these processes being performed by different parts of a system. Thus, an explanation consists of functionally decomposing the process of producing the phenomenon into a set of different component processes and localizing these component processes in actual physical parts of a system (Bechtel and Richardson, 1993). (Often actually identifying the component physically is not possible, and researchers settle for indirect evidence that such a component exists.) For example, to explain basic physiological processes such as cellular respiration, biochemists had to identify a set of activities (oxidation of substrates, electron transfer, and phosphorylation of adenosine diphosphate (ADP)) and determine the components of the cell responsible for them (enzymes, co-factors, and membranes with restricted permeability).

An emphasis on mechanisms does not eliminate appeal to laws – sometimes key relations between parts of a system (e.g. between a substrate and an enzyme) are expressed in laws. But laws play a subsidiary role. The emphasis is on differentiating the operations performed in the system, linking

them with physical parts of the system, and then showing how the component parts and processes interact with each other to produce the phenomenon. Some of the individual interactions can be stated in laws, but the specification of the particular components involved and the intricacy of their interactions is generally far too specific to render into laws. Quite often such explanations are presented in diagrams (these are especially useful when the component processes are organized nonlinearly with multiple interactions and feedback loops), not linguistically (although diagrams are typically accompanied by linguistic commentary).

Many of the endeavours of the cognitive sciences can be interpreted as advancing mechanisms. Grammars, for example, are often presented as mechanisms for generating sentences. Psycholinguists who investigate the psychological reality of particular grammars are investigating whether they are actually implemented in language users. Researchers in AI, especially those creating programs to account for human performance, are decomposing an activity into component operations. Implementing the program on a computer provides an existence proof that the hypothesized set of operations is sufficient to generate the phenomenon in question. Behavioral experiments using such tools as reaction times and error analysis are required to demonstrate that the processes actually figure in human information processing.

When the explanatory vehicle is assumed to be a description of a mechanism, scientific inquiry is not restricted to producing data to be subsumed under a hypothesis or to being used in testing a prediction derived from a hypothesis. Early in the process of inquiry, researchers are simply trying to figure out what are the processes that contribute to a particular effect. One strategy is to show that processes are actually separable in the system by showing that one process can be impaired while the other is retained, or that an experimental manipulation produces a crossover interaction between measures of the two processes. When these manipulations are performed after a mechanism has been proposed, they serve the more traditional role of testing the proposed explanation. In such ways, empirical inquiry contributes both to discovery of models of mechanism and to testing them.

Alternative Conceptions of Reduction

The application of the model of mechanistic explanation in the previous paragraphs focused on the traditional disciplines of cognitive science: cognitive psychology, linguistics, and AI. But a very natural place to employ this framework is to relations between more traditional cognitive explanations and neuroscientific ones. Although interest in the neural realization of cognitive mechanisms did not play a critical role in cognitive science until recently, this was largely due to the paucity of techniques that could link cognitive and neural investigations (Bechtel *et al*., 1998). But the emergence of cognitive neuroscience as a major area of scientific collaboration in the 1990s reveals that cognitive and neural modes of investigation can be invoked together. Indeed, neuroimaging experiments, whether with positron emission tomography (PET), functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), or evoked response potentials (ERP), require use of cognitive tasks and measures along with measures of neural activity. In terms of the model of mechanistic explanation, what these tools are providing is localization of the functions decomposed in a cognitive analysis of the task (e.g. by showing where various attentional processes are realized in the brain). Like more purely behavioral research, moreover, such studies can not only serve to confirm a cognitive decomposition, but also play a heuristic role in determining the functional decomposition itself (Bechtel *et al*., 2000).

Such connections between cognition and neuroscience are commonly construed as reductionistic. But since one is not starting with laws at the cognitive level, and deriving them from laws of neuroscience, such research does not fit the theory reduction model (above). Rather, relating a functional decomposition to a structural localization provides an alternative conception of reduction, one much closer to Darden and Maull's (1977) conception of an interfield theory. Such an account may be much closer to actual scientific practice. Moreover, it does not raise the specter of either explaining away the higher-level approach (with a successful reduction) or eliminating it (if reduction fails). Rather, it weaves the two approaches closely together; functional decomposition and structural localization are contributors to the common inquiry of understanding the mechanism. Each can provide not only support for the other, but heuristic guidance to the other, and the resulting explanatory account is an integrated one.

There is a further way in which reduction emerges in the context of a mechanistic model of explanation. Once a system has been decomposed into component functions and these localized within the system, a new explanatory task arises – explaining how each component function is performed. Developing this explanation requires

repeating the process: decomposing the component process into its component processes, and localizing these within the subsystem where the process from the first decomposition was localized. Recognizing that this can be done successively, the model of mechanistic explanation provides a framework for reduction through multiple levels (Wimsatt, 1976). There is an important point to recognize about this multilevel conception of reduction – at each level, a different phenomenon is being explained. Moreover, at each level, the explanation involves not only the contributing components, but the interactions that are specified in the account at that level. A process such as seeing is reductively explained in terms of the contributions of the different components of the visual system and their interactions, while it is the activity of a given component which is explained by going into it and identifying its subcomponents and their interaction.

THE SOCIOHISTORICAL STRUCTURE OF SCIENCE

Paradigms and Revolutions

While the Logical Positivists were themselves very interested in the science of their time, their account was grounded primarily in logic, not in the details of scientific practice. (A consequence of this is that they viewed it as a normative model characterizing any possible science.) Kuhn's work drew philosopher's attention (as well as that of historians and sociologists of science) to the specific details of the process of scientific research. Kuhn (1996) challenged the views that science employed a set of general methods that remained constant over time and accumulated a body of truths. In their stead, Kuhn suggested that scientific approaches vary so significantly at different eras of a discipline that the findings and theories at one time cannot be meaningfully related to the findings and theories of other times. Instead of viewing the historical progression of science as the progressive accumulation of truths, Kuhn offered a cyclic model of the stages of scientific activity through history. The cycle involves the five stages of: (1) immature science; (2) normal mature science; (3) crisis science; (4) revolutionary science; and (5) resolution, which is followed by a return to normal science (see Figure 2).

The key notion in understanding Kuhnian philosophy of science is the notion of a *paradigm*. The five stages of the Kuhnian cycle may be unpacked in terms of this notion, since normal science is paradigm-based science, and four of the stages are understood by way of contrast with normal science. For Kuhn, paradigms are 'Universally recognized scientific achievements that for a time provide model problems and solutions to a community of practitioners'. Further, paradigms serve for a time implicitly to define the legitimate problems and methods of a research field for succeeding generations of practitioners. They do so in virtue of two essential characteristics (p. 10): first, 'Their achievement was sufficiently unprecedented to attract an enduring group of adherents away from competing modes of scientific activity.' Second, their achievement 'was sufficiently open-ended to leave all sorts of problems for the redefined group of practitioners to resolve'. Examples of paradigms include Ptolemaic astronomy, Copernican astronomy, Aristotelian dynamics, Newtonian dynamics, corpuscular optics, and wave optics.

Normal science, then, just is paradigm-based science. Immature science is science studying a domain recognizably the same as that studied by paradigm-based successors, but without the utilization of any paradigms, as in the cases of optics prior to Newton and of electrical research in the first half of the eighteenth century (pp. 12–14). A stage of crisis emerges for a science when the requisite consensus regarding the applicability of a paradigm begins to unravel. Patterns of problem-solving in normal science give way to novel approaches, and where new consensus emerges, a stage of resolution of a new paradigm returns the cycle to normal science.

One of Kuhn's views that garners much attention in the philosophy of science is his claim that different paradigms are incommensurable and thus choice of one over another cannot be subject to rational procedures. One way of thinking of incommensurability of paradigms is by thinking of paradigms as involving different languages, the terms of which cannot be translated into each other. For

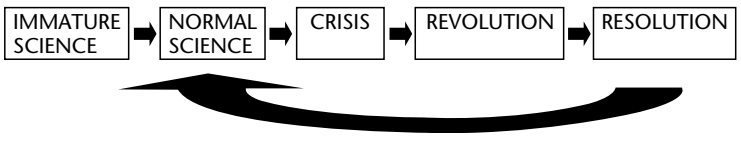

Figure 2. The stages in Kuhn's account of scientific change.

example, the term 'space' as used within a Newtonian physical paradigm cannot be translated as the term 'space' as used within an Einsteinian physical paradigm, and vice versa. Einsteinians differ from Newtonians in holding that space is curved by mass, for example. The meaning of 'space' depends on the theory it is embedded in; where theories diverge, so do the meaning of their terms. Part of Kuhn's argument that paradigms are not open to rational choice hinges on the notion that observation statements cannot serve as neutral points of arbitration since there is no theory-neutral observation language. In other words, observation is theory-laden: how one perceives the world depends on the theory with which one conceives the world. For instance, a newborn baby, if shown a cathode-ray tube, would not see it *as* a cathode-ray tube because the baby would understand an insufficient amount of theory to know what cathode-ray tubes are.

Kuhn's thesis that paradigms are incommensurable leads to another of his theses, namely, that the history of a scientific discipline is noncumulative. Noncumulativity follows from incommensurability in the following way. Since the language of one paradigm cannot be translated into the language of another, the statements held to be true within one paradigm cannot be expressed, let alone judged to be true, within another. The theory-ladenness of perception guarantees that not only can items of theory not be accumulated across paradigms, but neither can observations. Since not even observations are retained from one paradigm to the next, the history of a discipline cannot be viewed as the accumulation of truths or as progressing towards a truer account of the world. This challenges the traditional view of science as an intellectual enterprise that progresses over time. The history of science, as viewed through the Kuhnian lens, is of a series of paradigms and revolutions, none bearing any rational relation to any other.

Challenges to Kuhn

Kuhn's hypothesis of incommensurability has been challenged on several fronts. One denies that the meanings of theoretical terms are determined wholly by factors internal to a paradigm, but holds instead that they may be determined, at least in part, by causal relations between the term and items in the external world. Putnam (1975) suggests that the meaning of certain scientific terms involves causal relations between the terms and things in the world that they denote. For instance, part of the meaning of water is the substance H_2O that was present when the term 'water' was first brought into use to denote that substance. A causal chain leads from current uses of 'water' to the initial dubbing of H_2O as water. These causal chains remain constant regardless of a scientist's theory. Thus, water discourse need not be incommensurable between adherents of divergent theories about water. Appealing to causal relations to fix the content of representations is mirrored in much cognitive scientific practice, especially in the cognitive neurosciences where representations are thought of as carrying information about their environmental causes.

Another challenge to Kuhnian incommensurability arises from theorists who propose that the mind is modular. Fodor (1984), for example, argues that many perceptual processes are modular in the sense of being 'informationally encapsulated' so that their outputs are immune from influence by theoretical and other acquired beliefs. Fodor, therefore, contends that observational reports can be treated as univocal even when theorists hold different theories.

Though many of the issues raised by Kuhn continue to be debated, the Kuhnian spirit is a pervasive force in post-Positivist philosophy of science. It has, for example, led philosophers to focus much more on the diachronic nature of science as well as the actual research processes of science (see, for example, Lakatos, 1970; Laudan, 1977) or to apply Bayes Theorem to model rational theory choice (Howson and Urbach, 1993; Mayo, 1996). None the less, no consensus has emerged in contemporary philosophy of science that is on a par with the status once accorded the Positivists. For cognitive scientists, one of the attractive features of current philosophy of science is the increasing effort to employ ideas from cognitive science in the attempt to understand science (Giere, 1992; Thagard, 1988).

Possible Worlds Semantics

Intermediate article

Manuel García-Carpintero, University of Barcelona, Barcelona, Spain

CONTENTS

Possible worlds semantics is a framework for semantics that takes as primitive the notion of possible world. This framework is used to explain how modal expressions creating intensional contexts work, and more generally to characterize propositional content.

WHAT IS POSSIBLE WORLDS SEMANTICS?

We contrast the way the world is with alternative ways that it might be. In reviewing the course of a chess game, we may explore how the game would have gone if we had made alternative moves. As a broad generalization of this notion, we may postulate alternatives to the entire course of the world, in every detail. Possible worlds semantics (PWS) is a framework for semantic theorizing that takes as primitive for explanatory purposes this notion of 'possible world' (counting the actual world as one such), together with less specific logical and set-theoretic notions. The immediate explanatory task of PWS is to characterize the behavior of modal expressions, such as subjunctives, *necessary*, *contingent* and *possible*, *obligatory* and *permissible*, *must* and *may*, which create so-called intensional contexts. The framework is also used to characterize propositional content in general. PWS is applied in accounts of natural languages, and other representational systems, including intentional mental states.

Wittgenstein (1921) introduced PWS, to characterize propositional content, and Carnap (1947) elaborated on Wittgenstein's suggestions. Both Wittgenstein and Carnap focused on declaratives, sentences that count as true or false. Leaving aside 'analytic' sentences (*bachelors are male*), whose truth is constitutive of the meaning of certain expressions, whether a sentence is true or false is not for a linguistic theory to establish. Competent speakers can fully understand *Mallory reached the summit of Everest* without knowing whether in fact he did. As Wittgenstein pointed out, however, if one understands a declarative, one typically knows conditions that might in fact obtain in the actual world, whose obtaining would make the declarative true. Wittgenstein and Carnap explicated this central semantic notion of truth-conditions in terms of possible worlds: to know the truth-conditions of a declarative is to know the class of possible worlds such that, if any of them were actual, the declarative would be true. This does not mean that in understanding *Mallory reached the summit of Everest* one contemplates in every detail each possible world compatible with its truth. It suffices to have generic knowledge, discriminating a subclass of the class of possible worlds including only worlds in which two specific individuals, Mallory and the summit of Everest, stand in a certain relation, that of the former reaching the latter.

PWS is also used to characterize the semantic behavior of modal expressions. Semantic theorists assume that the semantic features of a sentence are compositionally determined by those of its lexical units and some of its syntactic features, constituting the sentence's 'logical form' (LF). Logicians traditionally distinguish two semantic features of expressions: 'extensions' and 'intensions'. Expressions that can occupy the position of the restriction of a determiner (*all … think*) or its scope (*all unicorns …*) are called 'predicates'. The extension of a predicate (relative to a given domain) is the class of entities (in that domain) of which the predicate is true. For example, the predicates *renate* (of an animal with kidneys) and *cordate* (of an animal with a heart) have the same extension.

A position in LF is 'extensional' if and only if replacement of the expression occupying it by another coextensional (of the same LF category) always preserves the original sentence's truth-value: expressions in those positions appear to signify their extensions. It was once debated among logicians whether the restriction and the scope of quantificational determiners are extensional contexts; most now agree with Frege (1892) that they

are. Other positions in LFs are non-extensional in particular, positions governed by modal expressions. Thus, *if that organism were a renate, it would be a renate* is true, but the sentence obtained by substituting *cordate* for the second *renate* can intuitively be taken to be false; similarly with *necessarily, if an organism is renate, it is renate*. Such positions in LFs are said to be 'intensional': expressions occupying them signify their 'intensions', which, in the case of predicates, have traditionally been characterized as concepts.

In PWS, the intension of a predicate is a function that maps a possible world to the extension the predicate would have if the possible world were actual. The concept of extension is extended from predicates to expressions of other LF categories. The extension of a referential expression like a proper name or a demonstrative is its referent, and the extension of a sentence is its truth-value; the extension of a simple sentence consisting of a referential expression and a predicate results compositionally from applying the extension of the predicate to the extension of the referential expression. The concept of intension is generalized accordingly. In PWS, the meaning of a modal expression is defined relative to the intensions of the expressions on which it operates, so that semantic intuitions concerning non-extensional contexts are accounted for. Thus, the truth-conditional import of *necessarily* in *necessarily*, …, with a sentential expression filling in the blank, is such that the complete sentence is true if and only if the intension of the sentence filling in the blank is the function that assigns truth to every possible world. The intuition that *cordate* and *renate* cannot be interchanged *salva veritate* in certain sentences is explained by the fact that they have different intensions, i.e. different extensions in some possible world. Replacing one with the other may result in a sentence with a different truth-value if the sentence included intension-sensitive expressions.

Before the introduction of PWS, modal logicians, including C. I. Lewis, advanced and studied different systems of modal logic characterized syntactically. The system of propositional modal logic *T* results from adding to a system appropriate for propositional logic the inference rule of necessitation – allowing the deduction of any instance of the schema $\Box\phi$ from the null set of premises whenever an instance of ϕ is so deducible – and the axiom schemata $\Box(\phi \rightarrow \psi) \rightarrow (\Box\phi \rightarrow \Box\psi)$ and $\Box\phi \rightarrow \phi$. (In modal logic, the square '$\Box$' is used for 'it is necessary that' or 'it must be that'.) There is also the system *S4*, obtained by adding to *T* the axiom schema $\Box\phi \rightarrow \Box\Box\phi$; and *S5*, obtained by adding to *S4* the axiom schema $\Diamond\Box\phi \rightarrow \phi$. (The diamond, '$\Diamond$', is used for 'it is possible that' or 'it is permissible that', equivalent to '$\neg\Box\neg$'.)

The relationships between the different systems, and their potential applications, became clearly understood through the use of PWS, in particular through the notion of an accessibility relation among worlds with different set-theoretic properties (simultaneously discovered by Hintikka (1957), Kanger (1957) and Kripke (1959)). A modal sentence like $\Box\phi$ is evaluated relative to a given possible world w; it is true relative to w if ϕ is true in all possible worlds accessible from w. The requirement that the accessibility relation be reflexive validates *T*. Thus, if ϕ is true relative to a given world w, it is true relative to any world w' accessible from w; given that the accessibility relation is reflexive, w is itself one of those worlds, and therefore ϕ must also be true in w. Similarly, the requirement that the accessibility relation be transitive validates *S4*, and the requirement that it be symmetric validates *S5* (Hughes and Cresswell, 1995). Together with a measure of 'closeness' or similarity between worlds, PWS has also been used to provide a clear understanding of the semantics of counterfactuals (Lewis, 1973; Stalnaker, 1968). Roughly, according to Lewis's semantics, 'if it were the case that p, then it would be the case that q' is true with respect to possible world w if and only if q is true with respect to all the closest worlds to w in which p is also true.

ADVANTAGES OF PWS

The knowledge that linguistic theories articulate is possessed by speakers in an intuitive form. Intuitive knowledge leaves more matters undecided than is required by the nature of what is thereby known. Correct theoretical articulations of intuitive information help to determine such matters. PWS articulates our modal intuitions, about the truth-values of sentences including modal expressions, and about the modal information encoded by declaratives in general, by explicitly conceptualizing a type of entity, the possible world. This allows for explicit reference to possible worlds and quantification over them. Developments of Montague's (1974a, 1974b) program, the most fully elaborated application of PWS, reap the benefits of this. For example, the nature of scope ambiguities like the one in *Alex will necessarily marry a Catholic* for instance, can be perspicuously explained. Given the PWS explication of truth-conditions, this ambiguity is accounted for as one of the already familiar scope ambiguities induced by the interaction of universal

and existential quantifiers, as in *every congressman hates some journalist*. The two readings can be paraphrased thus: *in all possible worlds, there is a Catholic whom Alex will marry; there is a Catholic whom Alex will marry in all possible worlds*.

Modal expressions are highly context-sensitive: the class of all possible worlds with respect to which the above sentence is true, in either of its readings, is not the class of all possible worlds whatsoever. According to the PWS account, this has to do with the fact that different contexts select different domains of possible worlds: those in which certain moral norms obtain, say, or those that share their physical laws with the actual world. This introduces an additional measure of complexity and intuitive indeterminacy, which PWS helps to resolve.

The context-sensitivity of modal expressions as articulated in PWS also accounts for a remarkable fact about modal logic. Logicians interested in the logical facts essentially involving modal expressions tried to systematize the relevant valid sentences and inference patterns in the form of axiomatic theories, without providing a semantics to justify them. In the case of what we now know as first-order logic, the work of Frege, Russell, Löwenheim, Tarski and others, following this methodology, soon produced a unique system. This was conspicuously not so in the case of modal logic, as illustrated above. On the basis of the semantics that PWS provides for the different systems of modal logic, the explanation can be suggested that, when different domains of possible worlds are at stake, different modal propositions are valid. Thus, instances of the *T* axiom are not valid when the necessity operator is understood deontically. If an instance of *it must be the case that* ϕ is true in the actual world, it is true in all worlds accessible from it, i.e. all worlds in which certain norms obtain; but the actual world itself need not be one of them. If, however, physical necessity is at stake, the axiom is valid.

In support of PWS, Wittgenstein and Carnap pointed out that it provides a clear and intuitively appealing account of one of the central semantic notions, entailment. A sentence *S* is entailed by a class of sentences *K* if and only the class of worlds with respect to which all sentences in *K* are true includes all worlds with respect to which *S* is also true. If we take the relative degrees of informativeness of sentences to increase with the number of possible worlds excluded by their truth, this notion of entailment clarifies the intuitive idea that the information provided by a sentence *S* entailed by a class of sentences *K* is already contained in *K*.

PROBLEMS WITH PWS

Descriptive Problems

The main descriptive limitation of PWS concerns whether the propositional contents expressed by natural-language sentences are fully captured by it. Consider any contingent sentence *p*, i.e. any sentence that is false in some non-actual possible world (*Hesperus shines in the morning*), and any necessary sentence *q* (*two plus two equals four*). Intuitively, *p* and *p* and *q* have different linguistic meanings. However, they appear to be true with respect to the same possible worlds, and thus to have the same intension. PWS also ascribes the same intension to all necessary truths. Stalnaker (1984) has attempted to make this result palatable. Cresswell (1985) pursues another strategy, substituting structured meanings for bare PWS intentions.

A related difficulty is Frege's problem of cognitive significance. This is exacerbated by compelling views advanced by Kripke (1980) and Kaplan (1989) on the truth-conditional import of referential expressions like proper names and indexicals inside the PWS framework. Kripke discusses deep-seated semantic intuitions best explained by taking genuinely referential expressions to be 'rigid designators': when they designate an object *o* they designate it with respect to every possible world in which *o* exists, and do not designate anything else with respect to any possible world. As Kripke points out, this view has the consequence that genuinely referential expressions with the same referent, such as *Hesperus* and *Phosphorus*, have the same truth-conditional import when this is explicated according to PWS. This makes Frege's problem of cognitive significance particularly salient, to the extent that cognitive significance depends on meaning: *Hesperus is Phosphorus* can be informative for a competent speaker, while *Hesperus is Hesperus* is not. To deal with this problem, Stalnaker (1978), Davies and Humberstone (1980) and others have advanced so-called 'two-dimensional' versions of PWS, which ascribe two different intensions to expressions, without apparently departing from the PWS framework.

Foundational Problems

The main foundational problem for PWS is of an ontological nature: are we metaphysically entitled to posit such entities as possible worlds? Defenders of PWS have advanced various views regarding their ontological status. These include Lewis's (1986) view that each possible world has the same

status as the actual world constituted by 'me and my surroundings', Stalnaker's more moderate but still realist view that they are complex properties that the actual world might have, and Carnap's view that they are like fictional stories.

A second foundational objection is Quine's argument that quantified modal logics pragmatically commit their proponents to a discredited view, Aristotelian essentialism: roughly, the view that, among the properties that objects instantiate, some are constitutive of their identities, and thus possessed by them no matter what possibilities may obtain regarding them, and some are accidental. It is, however, unclear whether any commitment to essentialism within modal logic is indefensible. Kripke's (1980) influential discussion of these matters has helped to restore the credibility of essentialism.

PWS AND COGNITIVE SCIENCE

Cognitive science is an interdisciplinary research effort to provide scientific understanding of matters involving the representational states of ordinary people, in particular those states that constitute semantic competence in their native language. A common objection to PWS is that ordinary competent speakers of a language, whose semantic knowledge linguistic theories attempt to characterize, know nothing of such things as possible worlds, and thus that PWS is of no use for cognitive scientists.

This conclusion is unwarranted. A semantic theory need not confine itself to notions that are part of the competent speaker's metasemantic knowledge. We have suggested reasons to believe that a PWS should be included in theoretical accounts of the semantics of natural language. This suggests that competent speakers somehow know about possible worlds. They know about them in virtue of their capacity to distinguish what is necessary from what is merely possible, and also in virtue of their capacity to provide and receive information by means of linguistic sentences – for, as Wittgenstein and Carnap argued, this is already a capacity to discriminate among alternative possibilities. Ordinary speakers may lack a theoretically articulated conception of possible worlds; but this is surely the case for many other theoretically interesting notions required for scientific characterizations of their representational states.

Propositional Attitudes

Intermediate article

Jay L Garfield, Smith College, Northampton, Massachusetts, USA

CONTENTS

Propositional attitudes are psychological states such as belief, desire, hope, and fear that seem to take propositions as their intentional states. Propositional attitudes constitute a central concern for cognitive science, and questions about the attitudes focus on the relations among diverse branches of cognitive science.

INTRODUCTION

The term 'propositional attitude' refers to such psychological states as belief, desire, hope, fear, etc. which, at least *prima facie*, take propositions as their intentional objects. Even this much is controversial but will do as a preliminary characterization. A propositional attitude comprises the subject of the attitude, the attitude, and the proposition towards which the attitude is directed. Albert [subject] may believe [the attitude] *that unicorns eat hay* [the proposition]. But so might Beatrice [subject]. Carlos [subject] might hope [the attitude] *that unicorns eat hay* [the proposition]. Deirdre [subject] might hope [the attitude] *that they eat only clover* [the proposition].

Propositional attitude verbs sometimes do not take propositions as objects. Eric might fear *that a wolf will eat him* (a propositional attitude), but he might simply have an inchoate fear: he fears *wolves*. In English, the word 'that' (sometimes elided as in 'Eric fears a wolf will eat him') marks the propositional attitude construction. Propositional attitudes are those states that are reported by verbs that take 'that clauses' as objects (perhaps minus the verbs of saying, which can also take quoted expressions as objects). Given that clear marking of complementation is not universal, and that 'that clauses' have no obvious syntactic analogues in some languages, this may be a rather parochial characterization, however.

Even where we have a classical propositional attitude construction, there is considerable disagreement among philosophers and cognitive scientists whether the object of the attitude is actually a proposition (and, indeed, exactly what a proposition is). Some argue that it is properly conceived as a sentence (Carnap, 1931); others that it is merely a property and a sequence of objects satisfying that property (Russell, 1912; Quine, 1956); still others maintain that these verbs in fact take no objects (Sellars, 1956; Kiteley, 1964).

The propositional attitudes constitute a central concern for cognitive science, and questions about the attitudes focus on the relations among diverse branches of cognitive science. Psychologists worry about the degree to which propositional attitudes explain behavior, and the mechanisms by which they do so, if indeed they do; neuroscientists are concerned with their physical realization in the brain (if indeed they are realized in the brain); cognitive developmentalists investigate the acquisition of our representation of the attitudes; linguists are concerned with their semantics; and philosophers ask whether there really are propositional attitudes, or indeed propositions, and whether if indeed there are, they can be localized in the brain, and what the relation is between propositional attitudes and the language used to represent their apparent objects. These questions are intertwined, and this entanglement is what makes the exploration of the nature of this (apparent) class of psychological phenomena so focal to cognitive science.

CRUCIAL PROPERTIES AND PHENOMENA

We can identify five crucial properties that sentences ascribing propositional attitudes must explain according to any theory which posits them as genuine phenomena: their opacity; the *de dicto*/*de re* ambiguity; complementation; content-sensitive causality; systematicity.

Propositional attitude contexts are often (though as we will see below, not always) opaque. In propositional attitude contexts we cannot substitute coreferring terms: (1) Frederique believes that the

richest woman in the world lives in Seattle; (2) Frederique kicked the richest woman in the world. Unknown to Frederique, 'the richest woman in the world' and 'Queen Elizabeth II' refer to the same individual. While it follows from (2) that Frederique kicked the queen, it does not follow from (2) on its most obvious reading that Frederique believes that QE II lives in Seattle. We can substitute coreferring terms in transparent contexts ascribing physical attitudes, such as kickings, but not in those ascribing propositional attitudes (*de dicto*), such as believings. Existential generalization over referring terms occurring in propositional attitude contexts also fails. (3) George hopes that Santa will come down the chimney. (4) Hetta sat on Santa's knee at the mall. It does *not* follow from (3) that there is somebody George hopes will come down the chimney. It *does*, however, follow from (4) that there *is* somebody upon whose knee Hetta sat. Transparent contexts permit 'quantification in'; propositional attitudes typically do not.

The second feature of the attitudes complicates this picture. For there are some propositional attitude contexts in which substitution of coreferring expressions and quantification in are permitted. The systematic semantic ambiguity of propositional attitude reports between those in which substitution and quantification is prohibited (*de dicto* reports) and those in which it is permitted (*de re* reports) is another hallmark of the propositional attitudes. So, knowing that Ignatius hopes that he will be the owner of Black Beauty, I might say 'Iggie hopes that he will own a horse', quantifying in to the clause giving the content of the attitude. And even though Jocasta reports her desire with the sentence, 'I want to marry Oedipus,' we can explain the unfolding of the tragedy by the permissible substitution into this *de re* context of the coreferring expression 'her son', even though she would never do so. There are important debates concerning whether the *de dicto/de re* ambiguity marks a distinction between two kinds of psychological states or between two kinds of reports of psychological states (Garfield, 1988).

Propositional attitude reports embed the sentences representing the contents of the attitude reported as complements of the propositional attitude verbs. Syntactically, the contents are reported in clauses which themselves are sentences and from which such operations as wh-extraction are permitted. So the content of Jeremiah's hope in 'Jeremiah hopes that there will be joy to the world' is reported by a complete sentence, and one can follow this utterance with 'What did Jeremy hope would be joyful?' and answer 'The world'. Direct quotation, for instance, ('He said "joy to the world" ') neither requires a sentential object nor permits extraction, even where a sentential object is present. Semantically, the truth-value of the complement sentence does not contribute to the truth-value of the entire sentence. Karl Marx said that the dictatorship of the proletariat will be followed by the withering away of the state. We can truly ascribe false beliefs.

When we use propositional attitudes in psychological explanation, we expect that the causal properties of the attitudes mirror the contents of the attitudes we ascribe and their logical relations to one another. So, we expect that Leila's belief that there is chocolate in the box, and her desire that she have chocolate and her knowledge *that Lottie buried the key*, will generate her hope that Lottie will dig up the key. When we posit nonpropositional attitude states as causes there is no comparable content-sensitivity expected of corresponding causal patterns.

Finally, propositional attitudes exhibit a closely linked triad of properties referred to as 'systematicity', 'compositionality', and 'productivity' (jointly the 'systematicity properties'). That propositional attitudes are systematic means that when someone is able to stand in any one or any set of attitudes, the referent is inevitably capable of standing in a range of closely related attitudes: from the fact that Margaret is able to believe that the Eagles will defeat the Swans, it follows that she is able to believe that the Swans will defeat the Eagles, that she is able to hope that the Swans will defeat the Eagles, etc. The productivity of the attitudes is the fact that from a finite vocabulary or set of concepts we can generate, using logical and syntactic operations, an infinite number of possible objects of attitudes. Since Norbert believes that Noam yet lives, and since he believes that Noam is nativist, he also believes that a nativist yet lives, and that not all nativists are dead, etc. Compositionality is the mirror image of productivity. We can explain Ophelia's capacity to fear that the prince is mad by her grasp of the concept of madness and her possession of a representation of the prince. The fact that she can stand in attitudes to novel propositions is explained by the fact that she can determine their meanings based upon her knowledge of the meanings of their parts and of their structure.

Any theory of the attitudes must explain these phenomena. This constrains psychological theories of the attitudes, semantic theories of attitude ascriptions, and philosophical accounts of the role of the attitudes in cognitive science. If nothing

satisfies at least most of this cluster of properties, there are no propositional attitudes.

BRIEF HISTORY AND SUMMARY OF PRINCIPAL POSITIONS

Frege pioneered research into the attitudes and into propositions in his two essays, *On Sense and Reference* (1892) and *The Thought* (1899), in which he proposes the idea of compositionality and makes the first proposal for an explanation of opacity, suggesting a theory of propositions as objects of thought. Frege distinguishes between the sense and the reference of an expression, arguing that in the context of propositional attitude verbs expressions denote not their customary reference but their sense. This, he argues, explains the failure of substitutivity of coreferential terms (they may have different senses) as well as the failure of existential generalization (some senses fail to be instantiated). Moreover, since the senses of the components of sentences tally to form the sense of an entire sentence (a proposition), and since propositions (what sentences express, as opposed to their truth-values, which Frege argues are the referents of sentences) are precisely what the mind grasps in thought, the fact that the attitudes are attitudes towards *propositions* explains why the attitudes are opaque. Frege's influence on research into the semantics of propositional attitude locutions in the twentieth century cannot be overstated.

Russell (1912) argued that for a proposition to be true just is for a sequence of individuals in the world to have a property, and that the mind is directed towards that state of affairs in a propositional attitude, and not to some intermediate Fregean abstract entity. If Paul believes that elephants can fly, Paul's belief is not, Russell argued, directed on the sense of that English sentence, but rather on elephants, and the property of flying. And the fact that those pachyderms do not possess that property explains the falsity of Paul's belief. Russellian propositions are hence concrete sequences of objects and properties, and a propositional attitude is therefore a relation between a subject and such a sequence. This approach is gaining favor among those disenchanted both with the metaphysics of representations intermediate between subjects and the world and those who see recent attempts to formalize the Fregean approach as encountering intractable problems.

Carnap (1931), suspicious of abstract entities and of properties, thought of propositional attitudes as sentential attitudes, replacing the idea of a proposition with that of an equivalence class of intertranslatable sentences. The attitudes, on this account, are behavioral dispositions towards sentences or their translation-equivalents, or to their truth-conditions. Querida's belief that cows eat grass is her disposition to utter that sentence when asked what cows eat, or, depending on her native language, perhaps to reply 'bzas kyi red' when asked 'ba phyugs kyis tsha bzas kyi red pas?' Her hope that it will not rain tomorrow might be a disposition to say, 'I hope it won't rain tomorrow', or just her disposition to be elated at tomorrow's blue sky. Carnap's account has been criticized both for being overly behavioristic and for failing to expunge abstracta (equivalence classes of sentences may be as problematic as Fregean propositions) but also for its reliance on linguistic items as the direct objects of the propositional attitudes (Fodor, 1978). None the less it has also been influential in part because it has demonstrated a kind of naturalism with respect to the attitudes that harmonizes well with the empirical goals of cognitive science.

Davidson (1968) follows Carnap, taking sentences seriously as objects of attitude ascriptions, and in taking them as functioning as exhibited exemplars of translation-equivalence classes. Davidson argues that propositional attitude locutions are properly understood not as containing sentences embedded as complements in that-clauses but rather as the demonstrata of paratactic constructions. So on Davidson's view, 'Rudolf believes that propositional attitudes are dispositions towards sentences' has the following structure: *Rudolf believes that: Propositional attitudes are dispositions towards sentences*. The lexical specificity of the demonstrated sentence explains opacity. Pragmatic considerations regarding what counts as an equivalent sentence explains the availability of *de re* readings. The linguistic character of the object of belief explains the systematicity phenomena.

Sellars (1956) and Kiteley (1964) have argued for the elimination of the objects of the attitudes entirely, treating the content-clauses of attitude ascription sentences as adverbial, characterizing the manner in which one believes, desires, etc. So on this reading, when we say that Susan believes that Plato was wise, the phrase 'Plato was wise' modifies 'believes' in the same way that 'quickly' modifies 'walks' in 'Susan walks quickly'. This approach eliminates metaphysically problematic entities, but its resources for explaining the fact that we seem to be able to quantify over objects of belief are not obvious, and the explanations this approach suggests for the various properties particular to the attitudes strike some as ad hoc.

The last third of the twentieth century saw an explosion of research into the formal semantics of propositional attitude expressions. Montague's (1974) possible world semantics for English is enormously influential. Though not entirely successful, it suggests a plausible and rigorous strategy for formalizing Frege's insights regarding opacity and compositionality, and predicts many of the central properties of propositional attitude expressions. This research program is still vigorous, prosecuted most notably by Cresswell (1984). Other significant formal approaches include the situation semantics of Barwise and Perry (1983) and the discourse representations semantics of Kamp (1981).

There is also much recent debate concerning the psychological role and realization of the propositional attitudes, much of it inspired by Sellars's (1956) argument for the theoretical character of the attitudes and their essential connection to language. Fodor (1975) argues for the reality of a language of thought and for a model of the attitudes according to which they are relations to internal sentential tokens in that language of thought. Churchland (1979) has argued that there is no such language of thought, and hence that there really are no propositional attitudes, since there are no available sentential representations in the mind. Others (Baker, 1988; Garfield, 1988) have argued that the reality of the propositional attitudes does not depend on the reality of internal representational states and that the attitudes in fact supervene broadly on environmental and linguistic facts. These debates continue to be active, with virtually every imaginable position regarding the ontology of the propositional attitudes finding a champion.

Semantics of Propositional Attitude Locutions

Frege's distinction between sense and reference and his emphases on compositionality and a truth-conditional theory of meaning guided most approaches to the semantics of natural language in the twentieth century. Frege regarded the reference of each sentence to be its truth-value, and the sense to be the proposition it expresses; the reference of each predicate expression to be the set of (sequences of) entities satisfying that predicate and the sense to be the property in virtue of which they do; the reference of every name its bearer, and the sense an individual concept, and so on. The sense of each expression determines its reference. The reference of a sentence, he argues, is determined by composing those of its components; the sense of the sentence is determined by a composition of senses.

In the Montague grammar framework the intentionality of the propositional attitudes is represented by the intensionality of the contexts propositional attitude verbs create, and compositionality is realized by representing the semantic values of all phrases as functions with functional composition as the primary semantic operation. Montague's model for natural language is a structure comprising an infinite set of possible worlds with a universal accessibility relation defined over them, a designated actual world, and an interpretation function assigning nonlogical constants values at each world. The logic is a higher-order intensional logic with modality and tense augmented with lambda-abstraction and with a semantics relying heavily on functional application. Extensional contexts are treated in a standard first-order way through evaluation in the actual world: intensional contexts require evaluation in other worlds, following techniques familiar from Kripke's semantics for modal logic.

The great virtue of Montague's approach is that the semantics provides a rigorous account of how a compositional semantics can preserve all of the crucial features of propositional attitude contexts. Because within the intensional context created by the propositional attitude verb the semantic value of each expression is a function from worlds to extensions, expressions with different meanings will contribute different functions to the meaning of the proposition composed, thus generating distinct propositions, and explaining the failure of substitutivity. So, for instance, let us recall Frederique's belief that the richest woman in the world lives in Seattle, and her failure to believe that the Queen of England lives in Seattle. Without going into too much detail, the intension of 'the richest woman in the world' will be a function from possible worlds to individuals which will yield Elizabeth II in exactly those worlds where she in fact is the richest woman *in that world*. The intension of 'the Queen of England' will be a function from possible worlds to whoever is the Queen of England in each world, yielding Elizabeth II in exactly the worlds where she reigns. Now in the actual world, these two expressions have the same reference, Elizabeth II. If the expressions in these two belief contexts each contributed their reference, there would be no difference between these beliefs and so it would be impossible for Frederique to believe one and not the other. But since there are worlds in which Wendy Gates is wealthier than the queen (e.g. the world where Bill gave all of his

fortune to her), there are worlds in which the function the semantics assigns to one of these propositions yields true and in which that assigned to the other is false. Hence we can see that these propositions are different, and one might be believed by Frederique and the other not believed.

Montague semantics also explains the *de dicto*/*de re* ambiguity very neatly in terms of a contest of scope between quantifiers and the propositional attitude verbs that create intensional contexts. A consequence of the alternative orderings of the quantifiers and verbs in the logic is that *de dicto* and *de re* attitude verbs will have different semantic types, thus explaining the distinct properties of the contexts they create. Suppose that I see Tenzin admiring a yak and I say, 'Tenzin desires to purchase a yak', having that particular yak in mind, thus attributing the attitude *de re*. I see Uma reading a primer on yak care and feeding, and say of her, 'Uma desires to purchase a yak', having no yak in particular in mind, hence attributing the desire *de dicto*. Montague grammar regards each of these sentences as syntactically (and hence semantically) ambiguous, and the ambiguity concerns whether the quantifier phrase 'a yak' applies to the entire phrase 'Uma/Tenzin desires to purchase x', or whether the attitude phrase 'Uma/Tenzin desires' applies to the entire phrase 'Uma/Tenzin purchases a yak'. In the first case we get the reading we want in the Tenzin sentence – true – just in case there is a yak which has the property of being desired by Tenzin. In the second case we get the *de dicto* reading appropriate to Uma – true – just in case she has the property of desiring to own any yak whatsoever.

Montague's system, however, is beset by a number of difficulties. Some of these concern the lack of fit between Montague's syntax and that posited by the most powerful current syntactic theories; some concern the oddness of asserting that the objects of our beliefs are functions from worlds to truth-values; others concern the grain at which Montague grammar can distinguish distinct readings of sentences. Cresswell (1984) has introduced the latest refinement of Montague's system, showing how to explain semantic ambiguities in attitude ascriptions that Montague's formalism cannot clearly represent.

Russell's intuition that objects and properties themselves, as opposed to sets of worlds or functions, are the semantic values of propositions has led to alternative approaches to understanding the semantics of propositional attitude ascriptions. Barwise and Perry's (1983) situation semantics is an excellent example of this approach, as is Jubien's (1997) theory of the attitudes. There is no clear consensus at this point on the correct way to explain the semantic properties of the attitudes.

Propositional Attitudes, the Ontology of Mind, and Methodology of Psychology

Taking propositional attitudes seriously as explanations of human behavior and cognition poses questions about how the attitudes are related to phenomena relevant to other levels of explanation relevant to behavior, such as the biological level. Some (e.g., functionalists or other identity theorists) argue that each propositional attitude is identical to some token neural event or process. Others argue that each type of mental state is identical to some type of physical state. So on a token-identity view, if Van believes that unicorns are mythical, there is some state or event in Van's brain which literally *is* that belief. On a type-identity view, there is some kind of brain state which, wherever it occurs, is the belief that unicorns are mythical. So that if Yolanda and Van share that state, they share that belief.

Identity theories are designed to account for the causal properties and explanatory force of the attitudes. If one adopts the view that all causation is physical and that all explanation at any but the most fundamental physical level must in turn be explained by more fundamental regularities and processes, it is natural to conclude that psychological processes must at bottom be physical processes and that the most plausible candidates are neural processes and states. Neural causation then is only psychological causation.

Moreover, to the extent that propositional attitudes are causally efficacious, representational, and systematic, the causal properties of the representations must track the properties that determine their compositional, productive, and systematic character. A good explanation for these properties is the presence of an underlying recursive system of representations. Thus, Fodor (1975) argues, there must be in the brain a physical system of symbols with a recursive syntax over which operations are performed whose causal properties map onto properties of inference and other forms of thought. In other words, the propositional attitudes are in fact relations to expressions in a language of thought. This also explains how infralingual organisms such as infants and nonhuman animals can stand in propositional attitudes despite having no language in which to express propositions. This hypothesis has proven fertile in cognitive science and has been mobilized to explain

early learning and first language learning as well as the possibility of causation by propositional attitudes.

The language of thought hypothesis has come under attack from a number of directions. Connectionist models of thought often implement superpositional representation in which no representation can be localized in a network, or models in which representations sustaining propositional interpretation are in fact activation vectors with no compositional or syntactic structure. To the extent that these models are correct and to the extent that they vindicate the use of propositional attitudes in psychological explanation, the language of thought hypothesis is dubious.

Philosophers concerned with the ontology of the attitudes have pointed out that the assumption that the reality and causal efficacy of the attitudes demands their neural realization, and hence some form of the identity theory, is not necessarily correct. Anti-individualists (Baker, 1988; Garfield, 1988) point out that the identity conditions of many representational phenomena are relational and that their ontological bases are broad. To be a token of an English word is not to be an ink mark of a particular shape but to play a certain role in a much larger pattern, and one must describe that entire pattern to specify what it is to be a token of a particular word. Similarly, these theorists argue, for Winnie to believe that beliefs are in the head may not require that there be any particular state or process going on in Winnie's head. Instead, it could well be that Winnie bears a complex set of relations to expressions in her own language, to inferences she is likely to make, and to lines of inquiry she is likely to pursue.

Most radically, eliminative materialists (Churchland, 1979) have argued that there really are no propositional attitudes, at least not if our standard of reality is that they actually play a role in the correct characterization and explanation of psychological processes. Eliminative materialists argue that our best models of brain processes make no reference to anything that satisfies the criteria for being a propositional attitude and that the best science of human behavior will be one grounded in brain theory. Moreover, eliminativists argue, a psychology based in the propositional attitudes would be incapable of explaining a large range of human behavior that is plausibly continuous with the remainder of our psychology, and incapable of explaining the behavior of infralinguals with whose psychology ours is also plausibly continuous. Finally, they argue, anti-individualists are probably correct in thinking that no identity theory can possibly be true of the propositional attitudes, but since any biological science of behavior must only advert to individualistically construed states of organisms, this circumstance merely shows that the propositional attitudes are not genuine causal determinants of behavior or cognition.

At present eliminativism is a minority position and has had little effect in empirical cognitive science, where theoretical discourse is still rich in propositional attitude language. If this is an unavoidable situation, we must face the challenge that the propositional attitudes pose for the reduction of psychology and other intentional sciences to sciences like neuroscience whose language is typically physicalistic and extensional. The problem is particularly acute if one thinks that higher-level sciences must be reducible to lower-level sciences *and* that reduction involves the definition of all terms in the higher-level science into the language of the lower-level science, together with the derivation of the laws of the higher-level theory from those of the lower. No such set of definitions will ever be forthcoming with respect to the propositional attitude terms, nor any derivations of the relevant regularities. This forces one either to abandon the view that all true theories must form part of a unified science, with sciences unified by intertheoretic reduction, or to adopt a somewhat weaker notion of reduction to guide the integration of cognitive science. Each approach can be and has been defended (Fodor, 1974; Churchland, 1979; Garfield, 1988).

A second methodological problem is posed by the need to integrate the psychology of language users with that of infralingual organisms. As we have seen, according to many of the plausible analyses of the propositional attitudes they are, *au fond*, relations to linguistic items. If this is the case, then it is hard to see how infralingual organisms could be subjects of propositional attitudes. But it seems equally plausible that there is no catastrophic gap between the psychology of infralinguals and language-users.

There are two principal strategies for resolving this problem. The first is to argue that indeed, appearances to the contrary notwithstanding, there *is* a catastrophic gap between language-users' and infralingual psychology, at least on some dimensions, and in fact part of that gap is to be accounted for by the fact that infralinguals do not have genuine propositional attitudes (Davidson, 1968; Garfield, 1988). This permits one to retain the language-directed analyses of the attitudes and harmonizes with results suggesting a dramatic change

in the quality of thought accompanying language acquisition (de Villiers and de Villiers, 2000). However, this view demands an alternative account of the obviously powerful representational capacities of such infralinguals as human infants and the great apes. The second strategy is to adopt the language of thought hypothesis. This allows one to have a uniform account of the attitudes and psychological processes of infralinguals and language-users. The problems with this strategy include the fact that it relies on a strong, unverified hypothesis about brain function, and it runs afoul of anti-individualist arguments. This debate remains unresolved.

The debate over individualism with respect to the propositional attitudes also raises methodological questions. If each propositional attitude is realized entirely in states within the body of its subject, we have a problem about how to individuate the attitudes. For if Xerxes believes that pigs can fly, there must be something about his state that makes it a belief (as opposed, say, to a fear) about pigs (not birds) and asserting of them that they fly (and not that they dig truffles). And it seems hard to imagine anything simply about Xerxes' brain or indeed the rest of his body, in isolation from his environment, that could fix the content and hence the identity of his belief. But if we have to go beyond Xerxes' body and examine the relation of his brain state to pigs and flying, we have lost individualism. But giving up individualism about the attitudes raises its own problems. How are we to develop a theory adverting to propositional attitudes if their boundaries are so vast and so vague? How, even if we allow them to extend beyond the body to the distal phenomena that determine their content, are we to know to what to turn in order to fix their identity?

These worries suggest another methodological option with regard to the attitudes. Cognitive science could treat them instrumentally and not be realistic about the attitudes. To do this would be to treat propositional attitude talk purely as a useful calculational device. The virtue of this position is that one can simply dismiss all of the metaphysical and methodological problems just identified as pseudo-problems relevant only to a science positing real propositional attitudes. The difficulty is the same as that afflicting eliminativism. It is at least implausible to say that nobody has ever really believed anything, desired anything, or feared anything, and certainly this is not something that a consistent instrumentalist can lead herself to believe!

Acquisition of Propositional Attitude Vocabulary

A great deal of research has been devoted to understanding the mechanisms by which human beings acquire the concepts of the propositional attitudes and the ability to ascribe attitudes to themselves and others and to explain and to predict behavior using the attitudes (Baron-Cohen, 1995; Lewis and Mitchell, 1994). Given that the attitudes are unobservable inner states, it is remarkable that by age 4 most normally developing children are quite competent in this domain. It is noteworthy that very few 3-year-olds are and that this pattern is remarkably consistent across cultures. On the other hand, there are specific disorders, such as autism, in which children never develop this set of abilities or concepts, or if they do, do so very late and without any of the fluency that characterizes normal human attribution of the attitudes. This discovery of a very consistent acquisition pattern, coupled with highly stereotyped disorders specifically disabling the representation of the attitudes, has led some (Baron-Cohen, 1995) to posit an innate cognitive faculty responsible for the representation of and reasoning about the attitudes. This explanation of these phenomena gains additional support from data concerning other aspects of psychological development, including the development of the ability to monitor and to exploit attention.

On the other hand, others (Gopnik and Meltzoff, 1997) have suggested that the development of this knowledge and skill is achieved through the deployment of children's general drive to theorize, with the propositional attitudes posited as theoretical constructs to explain and to predict behavior. It has also been proposed that the development of these capacities is driven by social and linguistic development (Garfield *et al*., 2001; Peterson and Siegal, 1999).

The hypothesis that language acquisition is central to the development of the ability to ascribe propositional attitudes is supported by a range of findings: deaf children of hearing parents who acquire language late, also acquire these abilities late, and not until they acquire linguistic fluency; whereas deaf children of deaf parents with normal language acquisition show normal acquisition of these abilities (Peterson and Siegal, 1999). Moreover, the best predictor of the development of the ability to reason using the attribution of propositional attitudes is the development of the ability to understand and to use complement constructions of the kind necessary to attribute propositional

attitudes (de Villiers and de Villiers, 2000). There is still a great deal of controversy regarding the correct explanation of these phenomena and the nature of our knowledge about the attitudes. But explorations of this question promise to yield a great deal of knowledge about the structure of the mind and the nature of development, and perhaps about the nature of the propositional attitudes themselves, their relation to language, and the degree to which propositional attitude discourse is an essential piece of our cognitive architecture.

Qualia

Intermediate article

Torin Alter, University of Alabama, Tuscaloosa, Alabama, USA

CONTENTS

Qualia are the subjective aspects, the characteristic properties, of conscious experience. There is extensive philosophical debate about how qualia relate to the physical world, and in what terms they can be characterized.

INTRODUCTION

Conscious experiences involve neural activity and information processing. They also feel a certain way. Consider your visual experience of reading these words, or the auditory and tactile sensations you had when you turned the previous page. There is something it is like to have those experiences. That is, the experiences have certain properties characterizing what it is like to have them. Those properties are known as *qualia* (singular: *quale*). C. I. Lewis coined the term in 1929. Common synonyms include 'phenomenal properties' and 'phenomenological properties', among others. Phenomenally conscious states, by definition, are states with qualia.

Recent decades have witnessed vigorous philosophical debate about qualia. Most of the controversy concerns whether qualia can be adequately characterized in physical or functional terms. If they cannot, then physicalism and functionalism, two leading theories of mind, are incomplete or false. Other issues include whether qualia exist, which mental states have qualia, how qualia relate to cognition, how physical systems such as brains give rise to qualia, how qualia can be scientifically studied, what the neural correlates of qualia are, which creatures have mental states with qualia, and how qualia are known. All of these issues have empirical components. In some cases, such as the neural correlates issue, scientific investigation is under way.

DO QUALIA EXIST?

'Qualia' is sometimes defined narrowly, in ways that give rise to substantive issues about their existence. For example, some reserve the term for properties that are nonphysical by definition. On that usage, the debate over whether conscious experiences have irreducibly nonphysical properties (discussed below) is a debate over whether qualia exist. And, to take a second example, Daniel Dennett (1988) reserves 'qualia' for properties that are by definition ineffable, intrinsic, private, and immediately apprehensible in consciousness. He attributes belief in their existence to various errors. For instance, he argues that conscious experiences seem to have ineffable properties because they have *practically* ineffable properties. Even the most detailed descriptions one can fathom might fall short of capturing what it is like to, say, taste a pomegranate. Nevertheless, on Dennett's view, a sufficiently detailed, accurate physical/functional description would leave nothing about such an experience unexplained. Thus, Dennett concludes, qualia do not exist.

But if qualia are defined broadly, as the properties characterizing what it is like to have conscious experiences, then their existence is hard to deny. Here 'qualia' should be understood in the broad sense.

QUALIA AND OTHER MENTAL PHENOMENA

Mental states with qualia include bodily sensations such as pains, itches, and orgasms, and perceptual experiences such as seeing, hearing, and hallucinating. Candidates for other states with qualia include at least: emotions such as lust, fear, and grief; moods such as depression, euphoria, and anxiety; thoughts one thinks silently but explicitly; perception of sentences of a language one understands; and cognitive attitudes such as desire, regret, and even belief.

Some use 'qualia' in such a way that by definition only sensory states can have qualia. On that usage,

even if there is something it is like to have a belief, beliefs do not have qualia. But on the most common usage, nonsensory states are not excluded from having qualia by definition. There may be a substantive issue about whether there is something it is like to have a belief, and therefore about whether beliefs have qualia.

Many believe that sensations have their qualia essentially. On that view, for example, no state that lacks pain qualia would count as pain. Opinions vary widely on whether the same should be said of emotions, moods, and other mental states. Disagreements over that issue tend to reflect divergent attitudes towards the overall relationship between qualia and cognition.

The assumption that qualia and cognition are closely linked has a distinguished history. It was more or less standard in seventeenth- and eighteenth-century Western philosophy, including especially (though not only) British empiricism and the Kantian tradition. In a different form, it pervades the writings of Brentano and other phenomenologists. (None of those figures used the term 'qualia', which was introduced in 1929. The preferred term was 'consciousness', and the assumption was usually implicit.)

Attitudes have since changed dramatically, due in part to the influence of behaviorism and the subsequent development of cognitive psychology. Many have come to believe that cognition and intentionality can and should be investigated without paying attention to qualia. Indeed, that opinion predominates in contemporary philosophy of mind and cognitive science, and has done so for more than half a century. But there are prominent dissenting opinions. John Searle argues that intentionality depends essentially on consciousness, which on his view entails qualia by definition. He writes:

> There is a conceptual connection between consciousness and intentionality that has the consequence that a complete theory of intentionality requires an account of consciousness (1992, p. 132).

ARE QUALIA IRREDUCIBLE?

How qualia relate to the physical world is controversial. Some doubt they can be explained in physical terms at all. The discussions usually centre on thought experiments, to which we now turn.

The Knowledge Argument

Perhaps the most widely discussed thought experiment about qualia is Frank Jackson's (1982) case of Mary, the brilliant scientist. Mary is raised in a black-and-white room, but learns all the physical information (all the physical facts) about human color vision by watching lectures on black-and-white television. That includes all the information in completed physics, chemistry, and biology, and everything that follows from that information (including functional information). Then she leaves the room and sees colors for the first time. Intuitively, it would seem that she thereby learns something new. For example, she learns what it is like to see red. So, Jackson concludes, there is nonphysical information about qualia. That is the knowledge argument against physicalism, the view that everything, mental and nonmental alike, is physical.

Physicalists have challenged each of the knowledge argument's assumptions. Some question whether one can learn all the physical information without experiencing color first-hand (e.g. Dennett, 1991). That objection is natural but unpopular; physical information as traditionally conceived is fully explicable in the objective language of science. Others (e.g. Lewis, 1988) argue that what Mary acquires when she leaves the room is not information but rather abilities: abilities to imagine, recognize, and remember color experiences. That objection is also relatively unpopular. As many note, what Mary gains when she finally sees red bears characteristic marks of informational knowledge. For example, the present author (Alter, 2001) argues that she might retain her new knowledge even if she loses the corresponding abilities, which is generally true of informational knowledge. A third objection to the knowledge argument runs as follows: when Mary leaves the room she acquires only new ways to represent information already in her possession. Before leaving the room, she uses physical concepts to represent the facts about color qualia. After leaving the room, she uses phenomenal concepts to represent those same facts (e.g. Loar, 1990). That objection is popular. But many remain unconvinced that phenomenal concepts pick out physical properties rather than distinctive properties of their own.

The knowledge argument has much in common with an argument advanced in Thomas Nagel's classic paper 'What is it like to be a bat?' (1974). Nagel argues that our inability to adopt the subjective viewpoint of echolocating bats prevents us from understanding essential aspects of their mental lives, and that no amount of objective, physical information would render our understanding complete. His reasoning is so similar to Jackson's that the knowledge argument is often attributed to both philosophers.

Absent Qualia

Another familiar thought experiment is usually discussed in connection with functionalism, the view that mental states consist in their causal relations to one another and to sensory stimuli and behavioral responses. The thought experiment is designed to show that the functional organization of a sentient creature could be realized in a system that has no mental states with qualia. In Ned Block's (1978) example, China's population organizes itself in a way that is isomorphic to the functional organization of a human brain. Individual citizens simulate the behavior of individual neurons, radio links correspond to synapses, and the system controls a robotic body. In Block's view, such a system might feel nothing, despite being a functional duplicate of a conscious human being. For example, it might feel no pain. If so, then qualia cannot be explained solely in functional terms.

David Chalmers (1996) argues that the absent-qualia hypothesis challenges not only functionalism but also any version of physicalism. Just as a qualia-free functional duplicate of a conscious human being seems possible, a qualia-free physical duplicate seems possible. Such creatures are known as phenomenal zombies (not to be confused with the Hollywood variety, which may have qualia and are functionally unlike ordinary humans).

Functionalists and physicalists sometimes respond by challenging the coherence of the absent-qualia hypothesis. For example, Shoemaker (1975) argues that a true functional duplicate of a conscious human must have introspective beliefs about its own sensory states, which on his view entails that some of its states have qualia. Another reply is to concede that the absent-qualia hypothesis is coherent, but deny that it undermines functionalism or physicalism. Here many invoke the Kripkean (Kripke, 1972) notion of *a posteriori* necessity, which may be explained as follows. That water is H_2O is a metaphysically necessary truth, which would obtain even if the laws of nature were different. Yet we know that truth only *a posteriori*; conceptual reflection alone cannot reveal the metaphysical impossibility of water existing without H_2O. Likewise, the argument runs, conceptual reflection cannot reveal whether absent-qualia cases are metaphysically possible. And, the argument continues, in fact they are not (e.g. Loar, 1990).

The latter response, though popular, has its problems. The Kripkean reasoning depends on the clear-cut distinction between the ordinary concept of water, which is given by its superficial features, and water itself, the essence of which consists in its molecular structure. Yet there appears to be no analogous distinction between the ordinary concept of pain and pain itself. There might be something, in some possible world, with the superficial appearance of water that is not H_2O. But, on most views, in any possible world if something feels like pain, then it is pain.

Inverted Qualia

A third familiar thought experiment, which Locke mentions (1690, bk II, chap. 32), involves inverted qualia. Imagine that your color experiences are inverted relative to mine. For example, ripe tomatoes look to me the color grass looks to you, and vice versa. We both call ripe tomatoes 'red' and grass 'green', but our qualia are inverted. There is empirical evidence that such cases may actually occur (Nida-Rumelin, 1996). The inverted-qualia hypothesis is that the whole range of one's color qualia could be inverted relative to a functionally identical twin.

The debate over inverted qualia parallels the debate over absent qualia in at least three respects. First, like the absent-qualia hypothesis, the inverted-qualia hypothesis is often used in arguments against functionalism. Second, some generalize the inverted-qualia hypothesis in the same way, arguing that physically indistinguishable creatures could have inverted qualia just as functionally indistinguishable creatures could. Third, reductionists reply in similar ways to the objections based on absent and inverted qualia; they argue that the cases are incoherent or metaphysically impossible.

It does not follow, however, that the absent-qualia and inverted-qualia hypotheses stand or fall together. On Shoemaker's view, the former is incoherent but the latter is not. Also, the two hypotheses raise different problems for reductive explanation. The absent-qualia hypothesis challenges reductive explanations of the existence of qualia (of having mental states with any qualia), whereas the inverted-qualia hypothesis challenges reductive explanations of the nature of specific qualia (of having red qualia as opposed to green qualia, for example).

Inverted Earth and Swampman

Recently, philosophers have been reflecting on two further thought experiments. One is the case of Inverted Earth (Block, 1990). Inverted Earth is just

like Earth, except the sky is yellow, grass is red, and so on. In the middle of the night, kidnappers drug you, transport you to Inverted Earth, and place you in your counterpart's bed. They also change your body pigments and put color-inverting lenses in your eyes, so that you are unaware of any difference (the two inversions cancel each other out).

According to Block, your new linguistic and physical environment will eventually produce changes in the intentional contents of your mental states. In time, your blue experiences will be about yellow things, your red experiences will be about green things, and so on, just like the other inhabitants of Inverted Earth. In Block's view, you will then be both intentionally and functionally inverted with respect to your former self, but your qualia will remain invariant. Inverted Earth thus creates another problem for functionalism.

Inverted Earth also challenges representationalism, the view that qualia are just representational or intentional properties. On that view, blue experiences are equated with perceptual states that represent blue things. Representationalism is popular among reductionists, who combine it with an appropriately reductionist account of mental representation (e.g. Tye, 1995). But if Block is right about Inverted Earth, then qualia can vary independently of, and thus fail to reduce to, intentional properties.

In response, some reductionists argue that the move to Inverted Earth affects qualia in ways that are not subjectively evident. And many deny that the move affects intentional content. The latter reply sometimes involves an appeal to a teleofunctional account of intentionality, on which the intentional content of color qualia is determined by the evolutionary history of one's species. Nature designed a certain type of human perceptual state to track blue things. That remains true even though, after enough time on Inverted Earth, that type of perceptual state is usually produced in you by seeing yellow objects. Therefore, the reply runs, your color experiences' intentional content never switches.

The idea that qualia are teleofunctional-representational properties encounters a difficulty from another thought experiment, devised by Donald Davidson (1986). In Davidson's story, lightning hits a dead tree in a swamp and creates Swampman, a molecule-for-molecule duplicate of a normal human being. Swampman has no evolutionary history. *A fortiori*, its experiences did not evolve for any biological purpose. Therefore, the teleofunctional-representation theory seems to lead to the conclusion that Swampman's states lack qualia, which many find counterintuitive.

QUALIA AND CAUSATION

The Hard Problem and the Explanatory Gap

The thought experiments discussed in the previous section relate closely to what Chalmers calls the hard problem of consciousness: how could a physical system such as the brain give rise to qualia? That problem has long seemed intractable, despite substantial progress in neuroscience and cognitive psychology. We are learning much about how the brain processes sensory stimulation, how it integrates information, and related matters. But why is such processing accompanied by qualia? There appears to be (in Joseph Levine's (1983) phrase) an explanatory gap: it seems that no amount of functional or physical information we might acquire about the brain would explain how it generates conscious experience.

Those who deny that qualia exist dismiss the explanatory gap as illusory. But, as noted earlier, those philosophers characteristically use 'qualia' in a narrow sense in which qualia are irreducible by definition. Even qualia eliminativists recognize that there is a problem, if only an empirical one, of how the brain generates conscious experience. Many qualia reductionists also regard the hard problem as unremarkable, according it the status of other unsolved problems in science. Eliminativists and reductionists sometimes compare the contrary inclination to the mindset of the vitalist, who puzzles over how life could emerge from mere physical processes and insists that nothing we could learn from biology or chemistry would remove the mystery (e.g. Dennett, 1988). Such comparisons may have value, but they can mislead. In the case of life, the phenomena requiring explanation are plainly complex functions, such as how a living system reproduces and how it adapts to its environment. But whether qualia can be explained functionally is a central point of controversy.

Other qualia reductionists agree that there is an explanatory gap, but attribute the problem to the distinctive character of phenomenal concepts. Those philosophers deny that the gap has strong metaphysical consequences. In particular, they argue, it does not undermine physicalism, because qualia can be identified *a posteriori* with physical properties (Loar, 1990).

Some are convinced that the hard problem is insoluble. For example, Colin McGinn (1989) argues

that, although there must be a naturalistic solution, we are constitutionally incapable of comprehending it – not because it is intrinsically difficult to grasp (though it might be), but rather because our distinctive cognitive capacities are ill suited to the task. Others are more optimistic. On Chalmers' view, a complete explanation will require psychophysical principles that connect physical processes and qualia. He proposes a framework for such principles, on which information is treated as basic and has both phenomenal and physical aspects. Nagel (1998) also suggests that qualia and physical properties may be manifestations of some deeper phenomenon, but he thinks our present concepts distort the underlying reality. He proposes that we try to develop new concepts to close the explanatory gap, modeled on Maxwell's development of the concept of a magnetic field, which enabled us to comprehend the relationship between electricity and magnetism.

Epiphenomenalism

The hard problem concerns how qualia are caused. There is also a problem concerning their effects. If qualia reduce to physical properties, then they have the effects of those properties. But what if qualia do not so reduce? How could they affect the physical world? Most agree that the physical world is causally closed, or nearly so; with the exception of some quantum indeterminacy, every physical event has a physical explanation. There would thus seem to be no room for qualia to do any independent causal work. Non-reductionism seems to imply epiphenomenalism, the view that qualia have physical causes but no physical effects. Many find that consequence unpalatable, and some consider it a strong argument for reductionism.

Some non-reductionists respond by defending epiphenomenalism, but more try to block the inference. One way to do that is to reject the assumption that the physical world is causally closed. Some interactionist dualists (e.g. Eccles, 1986) argue that qualia affect brain processes by filling in gaps resulting from quantum indeterminacy. But few contemporary philosophers or scientists accept interactionist dualism.

Many non-reductionists accept the causal closure of the physical, and argue that qualia nevertheless have physical effects. That strategy has been pursued in various ways. For example, some claim that certain physical events are causally overdetermined: that those events have both phenomenal and physical causes. By causal closure, any physical event has a sufficient physical cause. Therefore, any phenomenal cause it might also have would be causally redundant. That is an odd result, which some find as unacceptable as epiphenomenalism. But most non-reductionist strategies for avoiding epiphenomenalism involve substantive, sometimes surprising, views about causation.

Consider a second example. Chalmers describes a view, once proposed by Bertrand Russell (1927), on which the causal powers of qualia derive from intrinsic properties of the physical world. Physical theory characterizes its basic entities relationally. Basic particles, for example, are described in terms of how they interact with other particles and forces. Perhaps fundamental physical entities have intrinsic properties, which ultimately account for their relational properties. If so, then those intrinsic properties might be phenomenal properties. Or perhaps they are protophenomenal properties, from which both physical and phenomenal properties are constructed. Those ideas may sound strange, but either of them would explain how qualia could have physical effects.

Evolution

How did qualia come to exist? Many suspect that they provide organisms with evolutionary advantages. One hypothesis is that they supply an efficient way for organisms to acquire information about their bodies and environments. For example, pain qualia might help creatures capable of locomotion to avoid bodily damage, and olfactory qualia might help them distinguish nutritious food from poison.

Such hypotheses can be instructive (see below), but the extent to which they explain the origins of qualia is controversial. Phenomenal zombies, who lack qualia, have exactly the same informational sensitivities as their conscious counterparts. If phenomenal zombies are possible, then natural selection alone cannot explain why conscious creatures rather than phenomenal zombies evolved. Further principles may therefore be required to explain why qualia exist (Chalmers, 1996). Additionally, until more is understood about qualia and the brain, many will regard speculation on the evolutionary benefits of qualia as premature.

QUALIA AND COGNITIVE SCIENCE

Cognitive science often concerns qualia, or at least subjective reports of qualia, in some way. Consider three examples. First, studies of the splitting of auditory attention tend to rely on first-person reports of what the subject consciously experiences.

Second, consider the search for the neural correlates of consciousness. Some of that research concerns the neural correlates of the general state of being conscious, in a sense of 'conscious' that implies having qualia. And many studies concern the neural correlates of specific qualia. For example, experiments on rhesus macaques, trained to give bar-press reports, indicate strong correlations between specific kinds of visual sensation and activity in the inferior temporal cortex (Logothetis and Schall, 1989).

A third example is psychophysics. The Weber–Fechner law and Stevens's power law, typical results in the field, relate the intensity of percepts, or qualia, to the intensity of corresponding physical stimuli (e.g. luminance). Or consider studies of sensory illusions such as those produced by the Kanisza square, depicted in Figure 1. Normal subjects report seeing a square in the middle of the diagram, with a border as real as if it had been inscribed in ink. They also report perceiving the interior of the square as slightly brighter than the background, although there is no corresponding difference on the printed page. Many regard qualia such as those associated with such illusions as constituting a significant part of what psychophysics seeks to explain.

Studying qualia scientifically presents methodological difficulties. In general, we have only indirect access to a subject's conscious states. We have direct access to our own qualia, but introspective investigation also has well-known problems, which plagued the introspectionist tradition of the late nineteenth and early twentieth century. Further, first-person reports tend to employ coarse-grained and imprecise language such as 'an image of horizontal lines' or 'a high-pitched tone'. Substantial progress will presumably require developing more precise forms of expression. There may be principled limitations to any such endeavor; some claim, for example, that qualia are ineffable. But it may be possible to devise precise languages that capture at least the structural features of qualia. Indeed, there have been attempts along those lines, such as the quantitative techniques used in psychophysics.

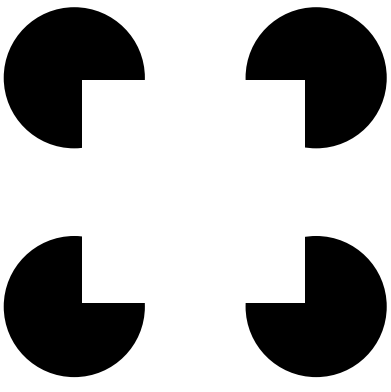

Figure 1. Kanisza square.

Many of the difficulties for the scientific investigation of qualia concern the phenomenal character of particular experiences, rather than the existence of qualia. Therefore, studying whether there is something it is like to be a bat is in certain respects more tractable than studying what it is like to be a bat (Allen and Bekoff, 1997). Here evolutionary hypotheses can be of use. For example, if we assume qualia evolved to allow adaptively flexible behavior, we may infer that adaptively flexible behavior provides evidence of qualia. Philosophical views can also help determine criteria for attributing qualia to other creatures. For example, functionalists might be more inclined than others to base attributions on the presence of certain functional properties.

KNOWLEDGE OF QUALIA

We have direct, first-person knowledge of our own qualia. That much is relatively uncontroversial. But what that knowledge consists in is unclear. Most accept that one can know about one's qualia noninferentially. For example, one need not infer one's qualia from one's behavior. Beyond that, opinions differ. In the early twentieth century, the heyday of sense-data theories, particularly strong epistemic claims about qualia were common. For example, three sentences after C. I. Lewis coins the term 'qualia' he writes: 'The quale is … not the subject of any possible error …' (1929, p. 121). One seldom finds such unqualified claims in contemporary philosophy, though philosophers continue to discuss attenuated variants.

Philosophical arguments sometimes rely on appeals to first-person knowledge of qualia. The knowledge argument (see above) provides one clear example. The literature on representationalism provides another. Some representationalists claim that experience is diaphanous: that when you attend introspectively to your experience of the color patch you perceive, you 'see right through' your qualia to the features of the patch itself, such as blueness and roundness. And that, they argue, suggests that qualia are just representational properties such as representing blue and representing roundness. But the legitimacy of such appeals to introspection is much disputed.

Rationality

Intermediate article

Richard Samuels, King's College London, London, UK
Stephen Stich, Rutgers University, New Brunswick, New Jersey, USA

CONTENTS

Rationality is a normative notion used to evaluate beliefs, inferences, decisions, goals, actions, and people.

INTRODUCTION

One of the most fundamental questions in philosophy concerns the *nature* of rationality: what conditions must be met for an inference or a decision to be rational? Disagreements over this issue have been a perennial theme in philosophy, but they also underlie many of the disputes about rationality in contemporary cognitive science. Another issue with a long philosophical history concerns the *extent* to which humans are rational. Aristotle famously held that rationality is an essential property of human beings, but other theorists have been less sanguine. Starting in the 1960s, a number of investigators have conducted experiments designed to explore how well the reasoning and decision-making abilities of ordinary human subjects accord with what the investigators take to be appropriate normative standards. The results in some of these experiments have been interpreted as showing that, on many sorts of problems, people exploit simple heuristics that violate normative principles and sometimes lead to solutions that are quite irrational. Moreover, some authors have gone on to suggest the rather pessimistic hypothesis that people use these heuristics because they have nothing better available. Because this work focuses on the use of *heuristics* that can lead to mistaken or *biased* results, it is often described as being in the 'heuristics and biases' tradition. In the next section, we sketch some of the more important experimental findings that have emerged from this tradition.

The heuristics and biases program, with its associated view of human rationality, has had a profound impact on cognitive science and related fields. It has, however, been challenged on both empirical and philosophical grounds. We will outline two important empirical challenges to the pessimistic view that, on many sorts of problems, people lack the cognitive competence to reason and decide rationally. One of these challenges comes from investigators influenced by evolutionary psychology; the other comes from investigators who have been looking at individual differences in performance on reasoning tasks.

While much of the contemporary debate over human rationality turns on empirical questions about the sorts of reasoning strategies that people possess, philosophical issues about the nature of rationality and the norms we ought to adopt in evaluating cognition, have also played an important role. These are the issues on which we will focus in the final section. One prominent view in this area is what Edward Stein has called the *Standard Picture*:

> According to this picture, to be rational is to reason in accordance with principles of reasoning that are based on rules of logic, probability theory and so forth. If the standard picture of reasoning is right, principles of reasoning that are based on such rules are normative principles of reasoning, namely they are the principles we ought to reason in accordance with. (Stein, 1996, p. 4)

Although the Standard Picture is widely accepted, we will see that it is far from clear how to apply it to specific cases. We will also review some of the considerations that have recently led a number of writers to challenge the Standard Picture's account of rationality.

EMPIRICAL EVIDENCE ON HUMAN RATIONALITY

The Selection Task

In 1966, Peter Wason published a highly influential study of a cluster of reasoning problems that

became known as the *selection task*. Figure 1 illustrates a typical example of a selection task problem.

Wason found that subjects typically perform very poorly on questions like this. Most subjects respond correctly that the E card must be turned over, but many also judge that the 5 card must be turned over, despite the fact that the 5 card could not falsify the claim no matter what is on the other side. Also, a majority of subjects judge that the 4 card need *not* be turned over, though without doing so there is no way of knowing whether it has a vowel on the other side. It is not the case that subjects do poorly on all selection task problems, however. A wide range of variations on the basic pattern has been tried, and on some versions a much larger percentage of subjects answer correctly. Figure 2 is an example from Griggs and Cox (1982): These results form a bewildering pattern, since there is no obvious feature or cluster of features that separates versions on which subjects do well from those on which they do poorly.

The Conjunction Fallacy

Much of the experimental literature on reasoning has focused on problems that require probabilistic judgment. Among the best-known experiments of this kind are those that involve so-called *conjunction problems*. In one quite famous experiment, Tversky and Kahneman (1982) presented subjects with the following task.

> Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.
>
> Please rank the following statements by their probability, using 1 for the most probable and 8 for the least probable.
>
> (a) Linda is a teacher in elementary school.
> (b) Linda works in a bookstore and takes Yoga classes.
> (c) Linda is active in the feminist movement.
> (d) Linda is a psychiatric social worker.
> (e) Linda is a member of the League of Women Voters.
> (f) Linda is a bank teller.
> (g) Linda is an insurance sales person.
> (h) Linda is a bank teller and is active in the feminist movement.

In a group of naive subjects with no background in probability and statistics, 89 per cent judged that statement (h) was more probable than statement (f) despite the fact that one cannot be a *feminist* bank teller unless one is a *bank teller*. When the same question was presented to sophisticated subjects – graduate students in the decision science program of the Stanford Business School – 85 per cent gave the same answer! Results of this sort, in which subjects judge that a compound event or state of affairs is more probable than one of the components of the compound, have been found repeatedly since Kahneman and Tversky's pioneering studies. This pattern of reasoning has been labeled *the conjunction fallacy*.

Base Rate Neglect

Another well-known group of studies explores the way in which people use base-rate information –

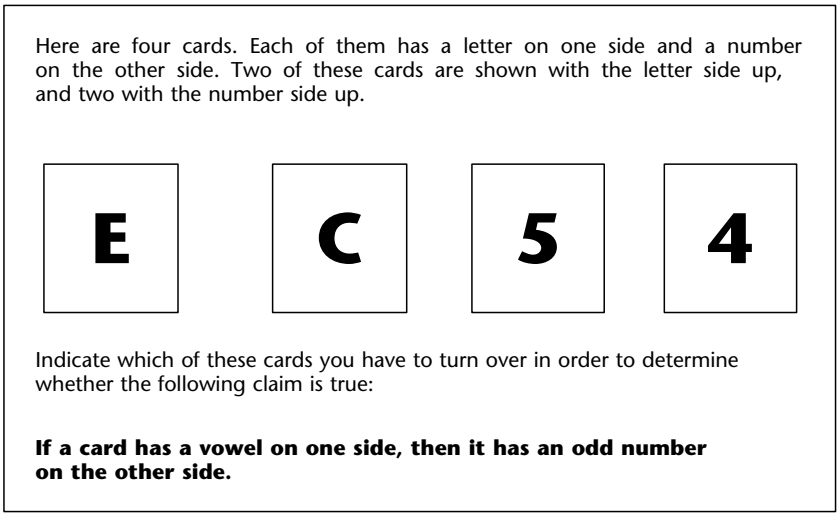

Figure 1.

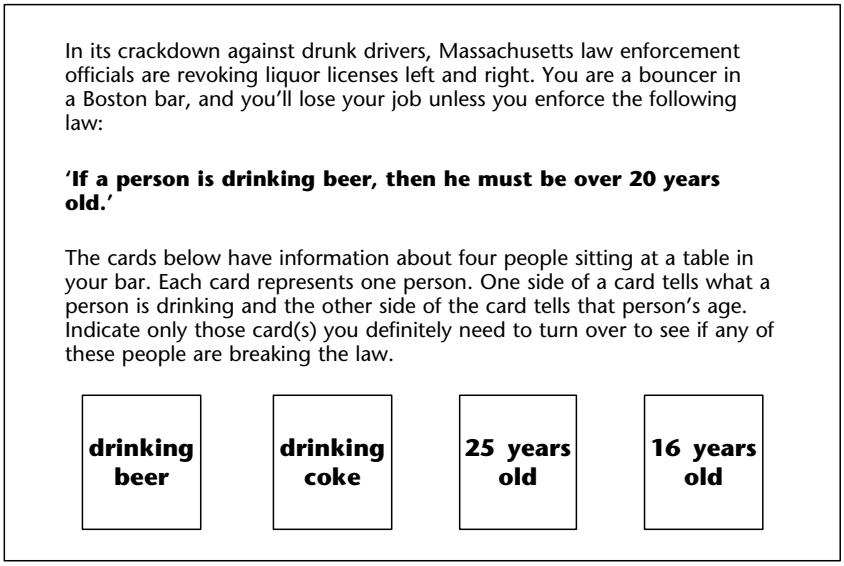

Figure 2.

roughly, background information about the proportion of a population that have a given characteristic – in making probabilistic judgments. According to the familiar Bayesian account, the probability of a hypothesis on a given body of evidence depends, in part, on the prior probability of the hypothesis. However, in a series of influential experiments, Kahneman and Tversky (1973) showed that subjects often seriously undervalue the importance of prior probabilities. One of these experiments presented half the subjects with the following 'cover story'.

> A panel of psychologists have interviewed and administered personality tests to 30 engineers and 70 lawyers, all successful in their respective fields. On the basis of this information, thumbnail descriptions of the 30 engineers and 70 lawyers have been written. You will find on your forms five descriptions, chosen at random from the 100 available descriptions. For each description, please indicate your probability that the person described is an engineer, on a scale from 0 to 100.

The other half of the subjects were presented with the same text, except the 'base rates' were reversed. They were told that the personality tests had been administered to 70 engineers and 30 lawyers. Some of the descriptions that were provided were designed to be compatible with the subjects' stereotypes of engineers, though not with their stereotypes of lawyers. Others were designed to fit the lawyer stereotype, but not the engineer stereotype. And one was intended to be quite neutral, giving subjects no information at all that would be of use in making their decision. Here are two examples, the first intended to sound like an engineer, the second intended to sound neutral:

> Jack is a 45-year-old man. He is married and has four children. He is generally conservative, careful and ambitious. He shows no interest in political and social issues and spends most of his free time on his many hobbies which include home carpentry, sailing, and mathematical puzzles.
>
> Dick is a 30-year-old man. He is married with no children. A man of high ability and high motivation, he promises to be quite successful in his field. He is well liked by his colleagues.

As expected, subjects in both groups thought that the probability that Jack is an engineer is quite high. Moreover, in what seems to be a clear violation of Bayesian principles, the difference in cover stories between the two groups of subjects had almost no effect at all. The neglect of base-rate information was even more striking in the case of Dick. That description was constructed to be totally uninformative with regard to Dick's profession. Thus, the only useful information that subjects had was the base-rate information that the test was administered to 30 engineers and 70 lawyers. But that information was entirely ignored. The median probability estimate in both groups of subjects was 50 per cent.

One further example of base rate neglect will illustrate the way in which the phenomenon might well have serious practical consequences. Here is a problem that was presented to a group

of faculty, staff, and fourth-year students at Harvard Medical School.

> If a test to detect a disease whose prevalence is 1/1000 has a false positive rate of 5%, what is the chance that a person found to have a positive result actually has the disease, assuming that you know nothing about the person's symptoms or signs? ____%

Under the most plausible interpretation of the problem, the correct Bayesian answer is 2 per cent. But only 18 per cent of the Harvard audience gave an answer close to 2 per cent. Forty-five per cent of this distinguished group completely ignored the base-rate information and said that the answer was 95 per cent.

Framing

In a study that is widely interpreted as illustrating a deeply irrational feature of human decision-making, Tversky and Kahneman (1981) presented a group of subjects with the following problem:

> Imagine that the U.S. is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimate of the consequences of the programs are as follows:
>
> If Program A is adopted, 200 people will be saved.
>
> If Program B is adopted, there is a 1/3 probability that 600 people will be saved, and a 2/3 probability that no people will be saved.

A second group of subjects was given an identical problem, except that the programs were described as follows:

> If Program C is adopted, 400 people will die.
>
> If Program D is adopted, there is a 1/3 probability that nobody will die and a 2/3 probability that 600 people will die.

On the first version of the problem most subjects chose Program A. But on the second version most chose Program D, despite the fact that the outcome described in A is *identical* to the one described in C. The disconcerting implication of this study is that the decisions we make are strongly influenced by the manner in which the options are described or *framed*.

A Pessimistic View of the Experimental Results

The results we've sketched are a small sample of the enormous literature on human reasoning and decision-making in the heuristics and biases tradition. (For detailed surveys see Nisbett and Ross, 1980; Kahneman *et al*., 1982; Piattelli-Palmarini, 1994; Baron, 2001.) What conclusions about human rationality should we draw from these findings? Though opinions are sharply divided, a cluster of claims often associated with the heuristics and biases tradition suggest a *pessimistic* view about the extent of human rationality. In one often-quoted comment, for example, two leading investigators claimed that the experimental results have 'bleak implications' for the rationality of ordinary people (Nisbett and Borgida, 1975). Other researchers have concluded that individuals are generally affected by 'systematic deviations from rationality' (Bazerman and Neale, 1986). And still others have suggested that the fault may be in our genes, or at least in our evolutionary history: 'people lack the correct programs for many important judgmental tasks … [because we] … have not had the opportunity to evolve an intellect capable of dealing conceptually with uncertainty' (Slovic *et al.*, 1976). But many other theorists have argued, on both empirical and philosophical grounds, that conclusions like these are unwarranted. In the remaining sections of this article, we consider briefly a number of such challenges. (For a more extensive review of the debate see Samuels *et al*., 2002a.)

EMPIRICAL CHALLENGES TO THE PESSIMISTIC VIEW OF HUMAN RATIONALITY

A Challenge from Evolutionary Psychology

One very influential challenge to the pessimistic interpretation of the heuristics and biases experiments has come from evolutionary psychologists who maintain that the human mind contains a number of specialized reasoning mechanisms that function in a normatively appropriate manner when presented with the sorts of problems that confronted our evolutionary forebears. Some of these theorists propose that the human mind contains a specialized reasoning mechanism designed by natural selection to solve problems in which probabilistic information is explicitly represented as frequencies. The ability to use probabilistic information effectively, they argue, would have been highly advantageous to our hominid forebears, and thus it would be surprising if we had not evolved mental mechanisms capable of using

this information rationally. But we should expect this capacity to manifest itself most clearly when probabilistic information is presented in a format that would have been common in ancestral environments. In those environments, probabilistic information would almost invariably have been presented in the form of information about frequencies, as opposed to single events. Thus we should expect people to do much better on probabilistic reasoning tasks if the problems are presented in a *frequency format*. And it appears that they do. In the 'feminist bank teller' problem, for example, if the description of Linda is followed by a question like this one:

> There are 100 people who fit the description above. How many of them are:
> …
> (f) bank tellers?
> …
> (h) bank tellers and active in the feminist movement?
> …

the number of subjects who commit the conjunction fallacy drops from over 90 per cent to only about 10 per cent.

Further evidence comes from Cosmides and Tooby's (1996) systematic exploration of the 'Harvard Medical School problem', in which they showed that subjects find it much easier to use base-rate information rationally on 'frequentist' versions of the problem, like the one that follows.

> 1 out of every 1000 Americans has disease X. A test has been developed to detect when a person has disease X. Every time the test is given to a person who has the disease, the test comes out positive. But sometimes the test also comes out positive when it is given to a person who is completely healthy. Specifically, out of every 1000 people who are perfectly healthy, 50 of them test positive for the disease.
>
> Imagine that we have assembled a random sample of 1000 Americans. They were selected by lottery. Those who conducted the lottery had no information about the health status of any of these people.
>
> Given the information above:
> on average,
> How many people who test positive for the disease will *actually* have the disease? _____ out of _____.

On this version of the problem, 76 per cent of subjects gave the correct Bayesian answer. Although these results are impressive, the hypothesis that we have evolved mental mechanisms designed to reason rationally about probability when problems are presented in a frequency format remains highly controversial and a number of competing hypotheses exist (Kahneman and Tversky, 1996).

Evolutionary psychologists have also argued that it would have been important for our forebears to have evolved cognitive mechanisms capable of subserving reciprocal exchanges, and that stable reciprocal exchange relationships require the capacity to detect *cheaters* – people who accept the benefits without paying the associated costs. A number of researchers have gone on to argue that the puzzling pattern of successes and failures in selection task problems can be explained by the hypothesis that the problems on which subjects do well are just the ones in which these reciprocal exchange and cheater detection capacities are deployed (Cosmides and Tooby, 1992; Gigerenzer and Hug, 1992). This hypothesis remains very controversial, however, and other authors have offered a variety of alternative explanations (Cheng and Holyoak, 1985; Oaksford and Chater, 1994; Manktelow and Over, 1995; Sperber *et al*., 1995).

A Challenge from the Study of Individual Differences

A different sort of challenge to the pessimistic interpretation of the heuristics and biases experiments comes from the study of individual differences. Stanovich and his colleagues (Stanovich, 1999) have shown that while the average performance on many heuristics and biases problems is quite poor, *some* subjects give the answer that the Standard Picture suggests is normatively correct on *many* of these problems. Moreover, subjects who are successful on these problems also get better scores on widely used measures of cognitive ability such as the Scholastic Aptitude Test (SAT). These researchers have also found significant correlations between success on reasoning tasks and various measures of 'cognitive style' and 'epistemic self regulation' which aim at assessing such things as how open-minded people are, how reflective they are, and how willing they are to consider evidence that contradicts their beliefs.

In light of these findings, a number of researchers have proposed *dual processing* theories which maintain that reasoning and decision-making are subserved by two quite different sorts of systems. One system is fast, holistic, automatic, largely unconscious, and requires relatively little cognitive capacity. The other is relatively slow, rule-based, more readily controlled, and requires significantly more cognitive capacity. Stanovich speculates that the former system is largely innate and that, as evolutionary psychologists suggest, it has been shaped by natural selection to do a good job on

problems like those that would have been important to our hominid forebears. The latter system, by contrast, is more heavily influenced by culture and formal education, and is more adept at dealing with many of the problems posed by a modern, technologically advanced, and highly bureaucratized society. Stanovich also argues that much of the individual variation seen in heuristics and biases tasks can be explained by differences in cognitive capacity (more of which is required for the second system), and by differences in cognitive style which lead to different levels of inclination to *use* the second system.

If Stanovich and the evolutionary psychologists are right, then the more pessimistic interpretations of the heuristics and biases experiments, according to which people typically do not have the correct 'programs' for many important reasoning tasks, are unwarranted, since everyone has the capacity to deal rationally with those reasoning problems that were important in the environment in which we evolved, and some of us also have considerable capacity to deal with a much wider range of problems. The extent to which education can improve the capacity to handle the kinds of problems that are important in a technological society, is, however, very much an open question.

PHILOSOPHICAL AND CONCEPTUAL ISSUES

On the Application and Interpretation of Standard Picture Norms

Though many investigators accept the Standard Picture account of rationality, a number of writers have challenged the way it has been applied to problems like those used in heuristics and biases experiments. So, for example, Gigerenzer (2000) and others have argued that in order to conclude that people are violating Bayesian normative principles, and thus being irrational, in the base rate neglect experiments, one must assume that the prior probability assignments which subjects make are identical to the base rates specified by the experimenters. But as Koehler (1996) observes: 'this assumption may not be reasonable in either the laboratory or the real world. Because they refer to subjective states of belief, prior probabilities may be influenced by base rates and any other information available to the decision-maker prior to the presentation of additional evidence. Thus, prior probabilities may be informed by base rates, but they need not be the same.' If this is right, and we think it is, then it is a genuine empirical possibility that some subjects are not violating Bayes' rule in these experiments but are merely assigning different prior probabilities from those that the experimenters expect.

In a more radical vein, Gigerenzer has noted that according to the influential 'frequentist' interpretation of probability theory, probabilistic statements make no sense unless they are relativized to a specific reference class, and thus claims about the probability of a single event are literally meaningless. Since many of the questions posed in heuristics and biases experiments ask subjects to judge the probabilities of single events (such as the probability that Linda is a bank teller), for a frequentist, no answer could possibly violate probability theory. Frequentism is a hotly contested view, but even if we grant that frequentism is correct, this argument is subject to serious objections. If statements about the probabilities of single events really are meaningless and hence do not violate the probability calculus, subjects are still guilty of making some sort of error in many heuristics and biases experiments. For if the questions are meaningless, then surely the correct response to a problem about the probability of a single event is not some numerical value or rank ordering, but rather: 'Huh?' or 'That's utter nonsense!' or 'What on earth are you talking about?' (For a more extended discussion of this point, see Samuels *et al*., 2002a.)

Objections to the Standard Picture

According to the Standard Picture, *what it is* to be rational – what is *constitutive* of good reasoning – is to reason in accord with rules or principles derived from formal theories, and where we fail to reason in this manner our cognitive processes are, at least to that extent, irrational. This view of rationality is sometimes called a *deontological* account. However, some philosophers have argued that a sharp distinction needs to be drawn between the principles governing *reasoning* and the formal principles of logic and probability theory. Harman (1986), for example, suggests that logic and probability theory are not directly relevant to reasoning at all.

Deontology is not the only conception of rationality that one might endorse. Another prominent view, called *consequentialism*, maintains that *what it is* to reason correctly is to reason in such a way that you are likely to attain certain goals or outcomes. Though the application of rules of reasoning may be a *means* to the attainment of certain ends, what is *constitutive* of being a rational reasoning process, on this view, is being an effective means of achieving some goal or range of goals. According to one

well-known form of consequentialism – *reliabilism* – a good reasoning process is one that tends to lead to true beliefs and the avoidance of false ones. Another form of consequentialism – sometimes called *pragmatism* – maintains that what it is for a reasoning process to be a good one is for it to be an efficient means of attaining the pragmatic objective of satisfying one's personal goals and desires. One reason for adopting a consequentialist rather than a deontological account of rationality is that it explains why it is worth worrying about rationality – why reasoning in a normatively correct fashion *matters.* If the deontological conception of rationality is rejected, however, then it is far from clear whether *any* of the experimental results in the heuristics and biases tradition really have 'bleak implications' for human rationality, since it is not clear which responses are rational on the consequentialist interpretation of rationality.

Another consideration that has led some to reject the Standard Picture is the principle that 'ought implies can'. This principle maintains that, just as in ethical matters where our obligations are constrained by what we can do, so too in the domain of reasoning and decision-making we are not obliged to satisfy standards that are beyond our capacities. But the Standard Picture requires us to perform reasoning tasks that are far beyond our abilities. For instance, it seems to be a principle of the Standard Picture that we ought to preserve the truth-functional consistency of our beliefs. Yet as Cherniak (1986) and others have argued, given even a conservative estimate of the number of beliefs we possess, this is a computationally intractable task – one that we *cannot* perform. Similar arguments have been developed against the claim, often associated with the Standard Picture, that we ought to revise our beliefs in such a way as to ensure *probabilistic coherence*. Here too considerations of computational complexity strongly suggest that we cannot satisfy this standard. And if we cannot satisfy the norms of the Standard Picture, then given that ought implies can, it follows that the Standard Picture is not the correct account of the norms of rationality.

Reduction

Intermediate article

Robert C Richardson, University of Cincinnati, Cincinnati, Ohio, USA

CONTENTS

Reduction is a relation between two theories, in which one captures or explains the other, usually with some gain in precision or scope. Reduction may involve theories at the same level of organization or at different levels of organization; and reduction may involve one theory explaining another theory or only its empirical domain. Empirical, historical, and methodological issues confront reductionism.

WHAT IS REDUCTION?

Reduction is an explanatory relation between two theories, models, or sciences in which one theory, model, or science captures or explains the other, with some gain in precision or scope. The former is the reducing theory and the latter is the reduced theory. Reduction may involve theories at the same level of organization or at different levels of organization; and reduction may involve one theory explaining another theory or explaining only the empirical phenomena captured by the reduced theory. Insofar as some range of empirical phenomena captured by one theory or model can be explained in terms of another theory or model, the empirical domain associated with the former is reduced within the latter reducing theory. Insofar as a theory or a model, and not merely the associated empirical phenomena, can be explained in terms of another, the reduced theory or model is reduced to the reducing theory or model. The reducing theory or model typically is more general or more exact: it captures a broader range of phenomena and/or explains them with greater precision. The empirical domain of the reduced theory becomes a subset of the empirical domain of the reducing theory. Increased generality or precision in the reducing theory creates an asymmetry between the two theories, giving priority to it over the reduced theory. The reducing theory explains more, or explains it more exactly, than the reduced theory. Reduction is thus an asymmetric relation between different models, theories, or sciences according priority to one, in which the explanatory potential of the reduced theory is captured within the reducing theory, and some explanatory purchase is gained by shifting to the reducing theory.

Examples can be drawn from a variety of domains, though all are controversial in one way or another. Chemical elements are ordered in a periodic table according to ratios in which they combine with other elements in chemical reactions. These chemical bonding properties are explicable in terms of the valence structures of atoms. Hydrogen has a valence of one and oxygen a valence of two, as reflected in the columns they occupy in the periodic table. They therefore combine in a ratio of two to one, resulting in molecules such as H_2O. J. J. Thomson explained the bonding ratios in terms of the number of electrons present in the outermost shells. During the early twentieth century, this was elaborated into the much more detailed theory of the covalent bond. This is a case in which a model of chemical interaction was explained in terms of a physical model at a lower level, concerned with atomic structure. In a similar way, cell biology depends on biochemistry. The behavior of organic systems is a function of constituent organ systems. Group behavior often needs to be understood in terms of local, individual, interactions. These are all commonly represented as cases of reduction at work in the sciences.

The most common paradigm within philosophy of science is the reduction of classical thermodynamics to statistical mechanics (Nagel, 1961; Bickle, 1998). Classical thermodynamics embodied a number of phenomenological laws describing the behavior of gases. The most important were Boyle's law and the law of Charles and Gay-Lussac. Boyle's law says that the product of the pressure and volume for a sample of gas is constant at a constant temperature. The law of Charles and Gay-Lussac says that the ratio of volume to temperature is

constant for a gas held at a constant pressure. The combined law is a straightforward consequence of these two principles. It says that the product of pressure and volume is a constant function of temperature. In a common form, with obvious abbreviations, this is the Boyle–Charles law: $PV = kT$.

Within statistical mechanics, we can derive an analogous result. Under a variety of simplifying assumptions, it is possible to show that the product of pressure and volume is a constant function of the aggregate kinetic energy of a gas. This is the Bernoulli formula: $PV = (2/3)e_t$.

The results bear obvious similarities so expressed. This motivates the conclusion that the thermal energy contained in a quantity of gas (T) is simply the aggregate kinetic energy of the particles constituting that gas (e_t), and that changes in the temperature of the gas are equivalent to changes in the aggregate kinetic energy of these particles. The Bernoulli formula allows us to explain what is explained by the Boyle–Charles law, and even to explain why the Boyle–Charles law holds as nearly as it does. It is also possible to explain why the Boyle–Charles law fails at extremes of temperature and density, though not in as direct a way as we can explain the law itself. The kinetic theory of gases is thus capable of explaining much of what is explained by classical thermodynamics, and can explain the behavior of gases with greater precision. Classical thermodynamics is therefore held to reduce to statistical mechanics.

Reduction can vary considerably in its goals. In some cases, the goal is overtly ontological, appealing to economy or parsimony; that is, the appeal of reduction is that it economizes on ontological commitments and eliminates any need to appeal to nonphysical entities such as vital forces, entelechies, or minds. For example, attempts to reduce number theory to mathematical logic at the beginning of the twentieth century were driven by the desire to undercut claims to any independent domain of mathematical entities, and thereby to synthetic a priori knowledge. In some cases, the goal of reduction is epistemological. For example, it was an important claim of logical positivism that all knowledge can be reduced to empirical knowledge. Early work, such as the work of Carnap on semantics, had this goal at the forefront. In yet other cases, the goal is methodological. It is sometimes easier to understand an effect if it is studied in isolation from other things that affect it. It is also sometimes easier to understand the behavior of a component in relative isolation from the system of which it is a part. The behavior of more complex entities can then, ideally, be understood in terms of component contributions (Bechtel and Richardson, 1993).

Reduction can also vary in form. First, we can distinguish between theoretical and empirical reductions. Theoretical reductions involve the explanation of one theory or model in terms of a second theory or model; by contrast, *empirical* reductions involve the explanation of the phenomena characteristic of one domain in terms of a second theory or model. In either case the predictions of one theory are captured by another, often more general, theory. In both cases, the reducing theory has explanatory priority because of its increased precision and generality. Second, we can distinguish between cases involving a single level of organization from those involving different levels of organization. There is no generally agreed way to distinguish levels of organization, though it is widely agreed that there is a useful distinction to be drawn; levels of organization can usefully be thought of, to a first approximation, as levels of aggregation, so that social groups constitute a level of organization higher than that of individuals, individuals a level of organization higher than that of organs, organs higher than that of cells, and so on (Wimsatt, 1976). Since these two distinctions are independent of one another, this leaves us with four general cases, as illustrated in Table 1.

In the first quadrant (on the upper left), the empirical phenomena captured by a theory or model at one level of organization are explained in terms of a theory or model at the same level. Geocentric models of the solar system explained with reasonable precision the observable behavior of stars and planets, including retrograde motion. Heliocentric models explained the same phenomena with quite different principles. The theories are nonetheless inconsistent, so one cannot be derived from the other. In the second quadrant (on the upper right), the phenomena captured by a theory or model at one level of organization are explained in terms of a theory or model at a deeper level of organization. Group selection was designed at one time to explain altruistic behavior, including cooperative behavior and the inclination sometimes shown to

Table 1. Four types of reduction

	Same level	*Different levels*
Empirical	Copernican astronomy and geocentric models	Group selection and kin (genic) selection
Theoretical	Newton mechanics and relativistic mechanics	Snell's Laws and electromagnetism

limit reproductive behavior to the apparent detriment of the individual. Models for kin selection and reciprocal altruism explained much of this apparently altruistic behavior in terms of selection acting below the level of the group. The behavior is explained at a lower level, without the benefits of group selection. Again, the theories are inconsistent, so kin selection explains the phenomena supposedly explained by group selection but does not reduce the theory of group selection. The third quadrant (at the lower left) includes explanations of theories or models in terms of theories or models at the same level of organization, generally with an increase in explanatory scope. Newtonian mechanics embodies laws that are limiting cases of relativistic mechanics, reasonable approximations at relatively low velocities. The laws characteristic of one theory are explained as limiting cases of laws characteristic of a later theory.

In the fourth quadrant (at the lower right), a theory or model at one level is explained in terms of a theory or model at a different level or organization. These are theoretical microreductions. They are the most common focus for discussions of reduction, and are often thought to be paradigmatic reductions, though there are few unproblematic examples. Snell's law describes the angles of light refraction in different media. Huygens showed that this could be explained in terms of a wave theory of light, and thus is an electromagnetic effect. Mendelian genetics provided a broad description of the patterns of transmission of genes. Some aspects of this theory were subsequently explained in terms of molecular mechanisms: for example, Mendelism during the first decades of the twentieth century involved linkage between genes and understood it as the probability of joint transmission. Molecular genetics gives us a mechanism for understanding linkage and why linkage is a function of distance between the genes coding for various characters. The case already outlined of thermodynamics and statistical mechanics is generally thought to be of this sort, though that characterization is problematic. It seems more likely that this is a theoretical reduction at the same level, explaining the macroscopic behavior of gases in terms of the statistical behavior of aggregates.

Any of the four reductive categories may be more or less conservative. The empirical phenomena within the scope of a reduced theory or its theoretical principles may be conserved to varying degrees. It is now common to treat the theoretical cases as ranging from cases of complete elimination to cases of nearly complete retention (Churchland, 1979; Bickle, 1998). At one extreme, Snell's law of refraction is almost wholly explained by Maxwell's equations describing electrical and magnetic fields, given suitable boundary conditions. Newtonian mechanics is at least approximately true, while phlogiston is not appealed to at all within modern chemistry. Empirical phenomena also are conserved to varying degrees. Conservatism is often high. Ptolemaic, Galilean, and Newtonian theories all needed to explain planetary motions. Some phenomena may be saved only to a limited degree. Independent assortment was an important part of early Mendelism, though it is a special case within molecular genetics. Dominance, likewise, was important for early Mendelism and is a limiting case for molecular genetics. At the other extreme, retention is minimal. Autonomy, or modularity, of development was an important part of early Mendelism, only to be abandoned subsequently in a wide range of cases; in fact, developmental phenomena that had been regarded as important were largely disregarded within the evolutionary synthesis for the first half of the twentieth century.

HISTORY

Empirical reduction has a long history within empiricism. There is a long tradition emphasizing the foundational nature of empirical knowledge, from Locke and Hume to Carnap. This involved reducing all knowledge to experiential knowledge, and all concepts to empirical concepts. British empiricists claimed that all ideas have their origins in the senses or impressions. Early in the twentieth century, this often meant showing that all concepts could be resolved as complexes of empirical concepts. The construction of more complex concepts based on simpler empirical ones was intended to support a radical empiricism. It was soon recognized that the project could not succeed, and this epistemological reductionism generally has been abandoned.

Ontological or methodological motivations for reduction have been more prominent in recent discussions. The most influential analysis is the synthesis by Ernst Nagel in *The Structure of Science* (1961), though many of the general ideas also can be found in other sources at about the same time. Nagel's account assumes that theories can be captured as axiomatic formal systems, with some finite number of primitive predicates expressing theoretical terms. Nagel then imposes two general conditions on reductions: (1) all the primitive terms appearing in the secondary (reduced) theory either appear in the primary (reducing) theory, or are

associated with terms in the primary theory by suitable 'reduction functions'; and (2) all the fundamental 'laws' of the secondary science can be explained from the primary science together with the 'bridge laws' given in the first condition. Many people assume the reduction functions under (1) are assumed to express identities, though that is not part of Nagel's account and is not typical of actual reductions. These two conditions have been modified in a number of ways. K. Schaffner (1967) offered a more general model according to which reduction requires only that what can be derived within the reducing science are laws 'strongly analogous' to those of the reduced science, thereby allowing for significant corrections to the reduced science. Presumably, the principles derived would be more accurate than those they supplant. More recently, others, including P. M. Churchland (1979) and J. Bickle (1998), have embraced similarly weakened conditions, requiring the reducing theory to incorporate principles analogous, or 'relevantly isomorphic', under limiting conditions to the principles in the reduced theory; insofar as the analogy fails, reduction fails and elimination is the result. (*See* **Eliminativism**)

The example of thermodynamics and statistical mechanics fits these weakened expectations reasonably well. The Bernoulli formula is formally analogous to the original Boyle–Charles law, at least in the form above, and the identification of heat with mean molecular motion serves as the relevant 'bridge law'. An equally common example, though involving intralevel reduction, comes from the special theory of relativity (STR). Newton's laws of motion hold not only from a standpoint of rest but for any inertial frames. Only relative motion is observable. The STR generalized and replaced the Galilean transformations to accommodate electromagnetic phenomena, and consequently required a reformulation of the laws of mechanics. Within this reformulation the values obtained from Newton's laws are approximately correct for velocities much below that of the speed of light. What is obtained within the STR is not precisely what can be derived within Newtonian mechanics, but it is a reasonable approximation under limiting assumptions and is arguably 'analogous' or 'relevantly isomorphic'.

One unresolved question confronting the weaker and more generalized models of reduction is whether they are not too generous. There is an 'analogy' to be had between the spread of rumors and the spread of diseases, as there is between economic growth and models within population genetics. Since these are not plausibly cases of reduction, some further constraints seem necessary. There is no broad consensus on additional constraints.

ARGUMENTS FOR REDUCTION

There are a variety of arguments for the importance of reduction. One general appeal is theoretical: nature appears to be hierarchically organized, and if our theories are somehow to reflect the structure we find in nature they too must be hierarchically organized. There are various levels of organization. Social groups consist of individuals. Individual organisms consist of a variety of organ systems, and those in turn of organs. These organs consist of specialized cells. This sort of decomposition can be continued to simpler and simpler entities until we reach fundamental particles. The order can be reversed. If we begin with a theory adequate for entities at any one level, then the behavior of more complex objects consisting of the simpler entities must be a function of the behavior of the simpler entities. If entities at higher levels are composed entirely of entities described at lower levels, and the behavior of these simpler entities can be adequately captured by theories tailored for those lower levels, then higher order behavior must depend only on the behavior of the entities at the lower level; and a theory adequate at the lower level should, in principle, be adequate for higher levels as well.

There is a general empirical appeal to reduction. The history of science shows the power of reduction, and progress in science often is the result of consolidation and unification, however these might be understood. Scientific progress is a matter of developing more and more general theories, and theories which unify more and more phenomena are preferable to those of narrower scope. Galilean mechanics found a more general and empirically more adequate formulation in Newton, just as Newtonian mechanics found a more general and empirically adequate formulation in Einstein. Similarly, the history of other sciences shows a succession of theories of increasing scope and comprehension, and when earlier theories were not wholly misguided, it is not surprising that the earlier theories are reasonable approximations to the truth. Likewise, history exhibits the development of theories of greater and greater scope. The recognition that electrical and magnetic forces are fundamentally the same was a triumph of reductionism, and the discovery of a unified theory encompassing electromagnetism and gravity would also be a reductionist triumph. We should therefore

expect that successful science leads to theories of increasing scope and power; theories at an earlier stage of development, or theories that are more specialized, should be reducible to those that are more developed and more fundamental.

There are also methodological appeals for reductionism. Much of the world is tremendously complex, and involves a variety of interactive processes. It is easier to understand a phenomenon we are studying if we can isolate it from other effects and causes, especially those with which it interacts (Bechtel and Richardson, 1993). If we want to predict the orbit of a planet, it is sufficient to know the several forces acting on it, though in some cases the analytical solutions may be prohibitively complex. If we can determine the effect an enzyme has in isolation from others in the protoplasm or the effect of a gene independently of other genes, then we should be able to use that information in explaining cellular behavior or organismic traits. If we can determine the effect of disabling a specific gene, then that gives us information concerning the role that gene plays in the larger cellular context. Observing deficits can provide the resources for understanding component function; and, correspondingly, component functions contribute to understanding systemic behavior. Reductionist methodology simplifies what would otherwise be an intractably complicated set of interactions, allowing an understanding of complex behavior in terms of individual components.

PROBLEMS FOR REDUCTION

There is a corresponding array of arguments against reduction. We can begin with the theoretical arguments. If nature is hierarchically organized, then our theories should reflect multiple levels of organization. Though there is no wholly satisfying account of what constitutes a level of organization, or therefore a level of explanation, there are clear reasons for recognizing hierarchical organization (Simon, 1969; Wimsatt, 1976). Hierarchies arise because the forces governing interactions between objects do not form an equally distributed continuum. The strongest forces govern interactions at the lowest level and give rise to reasonably stable units at a middle level. The forces responsible for atomic structure are an order of magnitude stronger than intermolecular forces, and those in turn are an order of magnitude stronger than those responsible for the three-dimensional structure of macromolecules. These lower-level forces may not determine which among a variety of complexes at the higher level will be realized. Moreover, there is often no explanatory gain in moving to a lower level and in some cases a substantial explanatory loss. In even the paradigm case for reduction, there would be no point in attempting to explain the behavior of a gas by turning to the behavior of individual molecules. In point of fact, we gain explanatory power by shifting to a higher level and considering the statistical properties of the aggregate without considering the details of structure.

The dominant arguments against reduction depend on multiplicity of realization and multiplicity of function. The thought is that Nagel's first condition on reduction above requires definitions of concepts at higher levels in terms of concepts at lower levels, and this minimally requires a one-to-one relation between levels. A one-to-many or many-to-one relation would violate this condition. The existence of one-to-many and many-to-one relations is widely thought to show that reduction is indefensible. That is, multiplicity of realization and multiplicity of function are both barriers to reduction. A gene, within Mendelian genetics, is a functional unit responsible for the production of phenotypic effects; it is also the case that a given phenotypic effect can be, and is, the effect of different molecular mechanisms (Wimsatt, 1976). The genetic code, to begin with, is redundant. Different molecular sequences code for the same set of amino acids. Different sequences of amino acids, furthermore, can be functionally equivalent, forming enzymes that catalyze the same reactions. The genetic code is also contingent. Though the code is universal, or nearly so, chemistry does not determine the code. The conclusion is that many molecular mechanisms result in the same amino acid sequence, many amino acid sequences constitute similar enzymes, and many enzymes catalyze the same reactions. This multiplicity of realization means that any bridge laws fall short of identities. This multiplicity of realization is common. There are, for example, isotopic variants of oxygen, differing only in the number of neutrons in the nucleus. They are indistinguishable except for a few reactions highly sensitive to atomic mass. Lacking the necessary identifications in the bridge laws, reductions cannot even get started. (*See* **Multiple Realizability**)

There are also historical problems for reduction. An argument nearly as pervasive as the more theoretical ones above is based on dramatic conceptual changes, and the resulting incommensurability (Kuhn, 1962; Feyerabend, 1962). Scientific change is often revolutionary. The ancients thought of planets as 'wanderers' moving with the heavenly

spheres. The spheres within which the planets were embedded were real, and circled about the Earth with definite periods. It was no small change to think of the planets as miniscule pieces of rock or gas orbiting about a minor star in the Milky Way, set no longer in a finite universe but in a largely empty space of vast proportions. The planets of the ancients are not our planets. Later changes are no less dramatic. Newton conceived of a universe infinite in space and time, with an absolute reference frame. Einstein changed our vision again. Within relativistic physics, mass is no longer conserved as it was for Newton, the universe is finite in extent, and space bends under gravitational distortions. There is, strictly, no concept in the theory of relativity capturing Newtonian mass, space, or time. The history shows radical conceptual change, rather than the reduction of one theory to another. Scientific change consists not in consolidation and unification but replacement and revolution.

From a methodological perspective, there also are flaws to reductionism. Though experimental manipulation can often isolate causes, the artificiality of the control can also induce artifacts. One experimental technique used to determine component function involves disabling or destroying some structure. The loss of function provides evidence concerning the functions of parts. A mutation in a gene, or a 'defective' gene, is often correlated with some loss of function, as, for example, a single gene is 'responsible for' the darkening of urine characteristic of alkaptonuria. The relatively simple change is induced by a recessive gene, and indicates a gene with a relatively specific catalytic effect. Likewise, the loss of a neural structure is often correlated with some loss of function, as in the classic results of Broca and Wernicke. The loss of a specific capacity indicates there is a neural 'organ' with a relatively specific cognitive function. However, this technique can also introduce artifacts. The behavior of an enzyme within a cell is not always the same as its behavior in a test tube. Genetic regulatory networks are known to be highly interactive: single genes typically have multiple effects, and multiple genes conspire to produce phenotypic effects. And as Hughlings-Jackson observed in the nineteenth century, loss of an organ does not explain any positive symptoms; what is important is how the person compensates for losses suffered. An analysis that ignores the systemic interactions is doomed to failure. Powerful computational techniques have only recently made it practical to deal with multiple variables simultaneously and to model multivariate systems. The interpretation of such results is controversial, but it is a method diverging significantly from reductionist methods. (*See* **Language and Brain**)

REDUCTION AND COGNITIVE SCIENCE

Within cognitive science, reduction has had an ambivalent status, for reasons analogous to those already outlined. From the mid-1950s through the mid-1980s, there was wide agreement concerning the general architecture of cognition, around a symbolic model or information processing accounts. Symbolic structures encoded representations within memory which were subject to various transformations. AI models were designed to simulate human intelligence, relying on rules and representations analogous to those characteristic of human cognition. These symbolic models constitute abstract models of cognition, with abstract representations. As such, they are compatible with varied physical realizations (Putnam, 1975; Fodor, 1975).

Multiplicity of physical realization has recently come under attack. However, plasticity of neural realization, and the variability of individual development, insure that there will be some differences in neural realization from person to person. Artificial intelligence promised even more radical prospects for differences in physical realization. Functional models abstract from physical details, offering an account of cognition which cuts across variability in physical realization. The abstractness promised a level of autonomy for cognitive psychology that moved it closer to work in AI and psycholinguistics than to neuroscience. Multiplicity of realization was thought to compromise any promise of reduction because it entailed that there would not be the required reduction functions to sustain a reduction of cognitive psychology to neuroscience; that is, it failed Nagel's conditions for reduction and especially the first condition. (*See* **Functionalism**; **Artificial Intelligence, Philosophy of**)

By the 1980s, theorists increasingly explored models of cognition that exploited alternative architectures. Neural networks, or connectionist/PDP models, yielded accounts of learning which differ significantly from symbolic models and promise a more realistic model of cognition. These models had a number of advantages, including enhanced flexibility. Mental representations came to be thought of as distributed rather than discrete. The appeal to distributed representations motivated some to reject cognitive models altogether, and many suggested that elimination rather than

reduction would be the fate of cognitive models (Churchland, 1979). (*See* **Connectionism**)

The emergence of cognitive neuroscience has since provided more support for a reductionist vision, fueled in large part by striking technological advances. Research on visual processing, for example, has revealed a number of processing pathways leading from the occipital lobe forward to temporal and parietal regions. Single cell responses show that cells respond preferentially to different types of information, a result confirmed in a wide range of cases. Coupled with lesion studies, and neuroimaging techniques (PET and fMRI), we are gaining an increasingly detailed understanding of visual processing. One of the classic results in neuropsychology is that language deficits follow from damage to regions anterior to the sylvan fissure known as Broca's area. Neuroimaging confirms the implication of Broca's area in speech production, and has led to a variety of more elaborate models involving other cortical areas. There are also now specific models of associative learning, based on a detailed knowledge of the structure and mechanisms in Aplysia. We also understand the involvement of the hippocampus in memory. It is far from clear how well any of this work fits traditional models of reduction, though it certainly does portend greater integration of neuroscience and psychology. (*See* **Neuroimaging**; **Golgi Staining**, **Aphasia**; **Hippocampus**)

Reference, Theories of

Intermediate article

Michael Devitt, City University of New York, New York, USA

CONTENTS

Theories of reference are about the relations between representations and the world that are thought to determine (at least partly) the meaning or content of those representations.

WHAT IS A THEORY OF REFERENCE?

Referential relations hold between representations and the world: in particular, between parts of sentences – words – and the world and between parts of thoughts – concepts – and the world. The most obvious example of such a relation is the naming relation, the sort that holds between 'Winston Churchill' and the famous statesman. However, it is usual to think of reference as covering a range of semantically significant relations: for example, between the word 'witty' and wittiness, and between the concept 'bachelor' and all bachelors. These relations are variously described by the terms 'designate', 'denote', 'signify', 'apply', 'satisfy', 'instantiate', 'fall under', and 'about'.

Reference is important because it is thought to be the core of meaning and content. Thus, the fact that 'Winston Churchill' refers to that famous statesman is the core of its meaning, and hence of its contribution to the meaning of any sentence – for example, 'Winston Churchill is witty' – that contains it. And the fact that the concept 'bachelor' refers to all bachelors is the core of its content and hence of its contribution to the content of any thought – for example, the thought 'Winston Churchill is not a bachelor' – that contains it. The usual view is that meaning determines reference.

The first question that arises about the reference of a term is: what does the term refer to? Sometimes the answer seems obvious. For example, 'Winston Churchill' refers to the famous statesman. Even this apparently obvious answer is rejected by those who take words to refer to ideas in the mind or to mental representations. But the received view in contemporary philosophy is that words refer to the world. This leaves room for different opinions about the reference of predicates. Some take 'witty' to refer to the property of wittiness, some to the set of all witty things, and some to each witty thing separately.

The central question about reference is: by virtue of what does a representation have its reference? A theory of reference answers this question by explaining the relation of the representation to its referent. It has proved surprisingly hard to provide these explanations. There was a surge of interest in theories of reference in the twentieth century.

VARIETIES OF THEORIES OF REFERENCE

According to 'description' theories of reference, the reference of a representation is determined by certain descriptions – other representations – inferentially associated with it by competent speakers: these descriptions identify the referent. The simplest form of description theory, derived from the work of Frege (1893) and Russell (1912), specifies a set of descriptions each of which is necessary and all of which are sufficient for reference determination: for example, the references of 'adult', 'unmarried' and 'male' might be jointly sufficient and individually necessary for the reference of 'bachelor'. According to another form of description theory, the reference is whatever is picked out by a (weighted) majority of certain descriptions associated with the representation. On this 'cluster' theory, no one description is necessary for reference fixing (Searle, 1958).

Around 1970, several criticisms were made of description theories of proper names, such as 'Winston Churchill' (Kripke, 1980; Donnellan, 1972), and 'natural kind' words, such as 'gold' and 'tiger' (Kripke, 1980; Putnam, 1975). One important criticism is that the theories yield unwanted necessities. The description we inferentially associate with 'tiger' is along the lines of 'large carnivorous quadrupedal feline, tawny yellow in color with blackish transverse stripes and white belly'. So the objects that 'tiger' refers to must be four-legged and

striped. Yet tigers need not be thus: a tiger might lose a leg; in a different environment tigers might not be striped. Another important criticism is that people who seem perfectly able to use words to refer are too ignorant to provide descriptions adequate to identify the referents. Thus, some who use 'elm' and 'beech' cannot supply descriptions that distinguish elms from beeches; many who use 'gold' cannot distinguish gold from fool's gold. Worse, speakers are often so wrong about the referent that the descriptions they would provide apply not to the referent but to other entities or to nothing at all. Sometimes the whole speech community is ignorant or wrong about the referent. Thus, it was once common to associate 'fish' with 'whale'. Description theories of these words seem to require too much knowledge, placing too great an epistemic burden on speakers.

Putnam added a further argument, built around the following fantasy. Imagine that somewhere in the galaxy there is a planet called Twin Earth. Twin Earth, as its name suggests, is very like Earth. In particular, each Earthian has a doppelgänger on Twin Earth who is a cell-for-cell duplicate of the Earthian. Twin Earth differs from Earth in one respect, however: the liquid that the Twin Earthians who appear to speak English call 'water' – liquid that is superficially indistinguishable from what we call 'water' – is not H_2O but a very different compound XYZ. So Oscar on Earth and Twin Oscar on Twin Earth refer to different liquids by 'water'. Yet Oscar and Twin Oscar are doppelgängers, associating exactly the same descriptions with 'water' (which is more plausible if we place Oscar and Twin Oscar in 1750, before the chemical composition of water was known). So those associations are not sufficient to determine reference, and the description theory must be wrong. Indeed, nothing going on in the head is sufficient to determine reference. As Putnam put it, 'meanings just ain't in the head': meanings require a relation to something external to the thinker.

This is not to say that description theories fail for all representations. They still seem plausible for 'bachelor', and perhaps even for 'pencil' and 'pediatrician' (cf. Putnam, 1975). But even where they work, description theories have a problem: they are essentially incomplete. Suppose that a theory claims that the reference of 'bachelor' is determined by the references of 'adult', 'unmarried' and 'male'. We then need to explain the references of those words to complete the explanation of the reference of 'bachelor'. Description theories might be offered again. But then the explanation will still be incomplete. At some point we must offer a theory of reference that does not make the reference of one word dependent on those of others. We need an 'ultimate' explanation of reference that relates some words directly to the world. Description theories 'pass the referential buck'. The buck must stop somewhere if there is to be any reference at all.

'Verificationist' theories of reference implicitly acknowledge this point. They take a broader view than description theories of the required identification: speakers refer to whatever objects they would identify as the referents, whether by description or by recognition. Speakers recognize a referent by pointing it out in a crowd saying, for example, 'that person'. But these theories still seem to place too great an epistemic burden on speakers: we can only dimly call to mind the appearances of many objects we refer to, and are often mistaken.

There has been disagreement over whether reference can be explained in non-semantic or non-mentalistic terms. Many think not: reference is, in a sense, irreducible. From a naturalistic perspective, this view is unacceptable: reference must be explained in scientifically acceptable terms, ultimately in physical terms. Attempted explanations have appealed to one or more of three causal relations between representations and reality. First, there is the historical cause of a particular token, a causal chain going back to the dubbing of the token's referent. Theorists interested in this have emphasized the 'reference borrowing' links in the chain: in acquiring a word or concept from others we borrow their capacity to refer, even if we are ignorant of the referent (Kripke, 1980; Donnellan, 1972; Putnam, 1975; Burge, 1979). Second, there is the reliable cause of tokens of that type: a token refers to objects of a certain sort because tokens of that type are reliably correlated with the presence of those objects. The token 'carries the information' that a certain situation holds, in much the same way that tree rings carry information about the age of a tree (Dretske, 1981; Fodor, 1990). Third, there is the teleological cause, or function, of tokens of that type, where the function is explained along Darwinian lines: the function is what tokens of that type do that explains why they exist, what the type has been 'selected for' (Millikan, 1984; Papineau, 1987).

What all these recent developments suggest is that the reference of any word or concept will be explained by some such 'ultimate' theory, or by a description theory, or by a theory that combines elements of both. And different sorts of representations may have different sorts of theories.

Finally, it should be noted that some have denied, in one way or another, the reality of reference (and hence the need for, or even possibility of, an explanation of it). Perhaps the most influential of these denials is the 'deflationary' theory of reference, which accompanies the deflationary theory of truth (Horwich, 1998).

THEORIES OF REFERENCE AND COGNITIVE SCIENCE

Cognitive science holds that humans (and some other things) have mental representations – concepts – the contents (meanings) of which determine behavior (Margolis and Laurence, 1999). The common view is that a concept (and the word that expresses it) typically refers, and its reference is central to its content and nature. So, on this view, theories of reference should bear importantly on theories of concepts. However, it is often not clear how they bear on a particular theory.

Many cognitive scientists take the inferential associations of a concept to constitute its content and nature. This could involve a rejection of the centrality of reference, but it usually does not. Most seem to hold the appealing Fregean view that a concept's inferential associations determine its reference, thus endorsing a description theory of reference. The bearing of theories of reference is then obvious. However, some may prefer a 'two-factor' theory of content according to which reference constitutes one factor and inferential associations constitute an independent factor which does not determine reference. Most of what is said about concepts would then concern that independent factor and so would have nothing to do with theories of reference.

Finally, although psychological research on concepts is usually presented as if it concerned the nature of concepts, it may really concern something very different: the 'structure of knowledge'. On this view, the research is not throwing light on what concepts are – on what constitutes their contents – but on what they do – on their cognitive role, in particular, their role in recognitive skills. Theories of reference have little bearing on this.

We can distinguish three particular implications of theories of reference for cognitive science.

First, it is common to have a holistic view of concepts: their contents are given by all or most of their inferential associations. When combined with the appealing Fregean view, this yields a holistic description theory of reference. A consequence of such a theory is that the mistaken views we tend to have about the putative referents of our concepts would lead to widespread reference failure: most of our concepts would not fit anything in the world. So the Fregean view counts against holism; and the holistic view encourages a two-factor theory of concepts.

Second, verificationism is common in psychology: a concept's content is thought to be constituted by those features that lead us to apply it to the world. This application is naturally taken as determining reference. So the concept 'bird' refers to the objects that those who have the concept identify as birds. The recent developments in the theory of reference, particularly the view that reference can be borrowed, cast considerable doubt on verificationism: a person may have the concept 'elm', not by virtue of any ability to identify elms, but by virtue of being appropriately linked with a linguistic community.

Third, the simple Frege–Russell description theory calls to mind the 'classical' theory of concepts in psychology, and the more modern cluster theory calls to mind 'family resemblance', 'prototype' and 'exemplar' theories (Smith and Medin, 1981). In so far as the psychological theories are rightly construed as analogous to description theories, the recent developments cast doubt on them, particularly where they concern natural kind concepts like 'bird'.

Still, this may well be the wrong construal of some of these psychological theories. Thus, prototype theory usually seems to claim, not that a concept refers to an object that has most of the prototypical features (the cluster theory), but rather that it refers to an object to the degree that it has those features. Thus, the concept 'bird' is said to refer to penguins to a lesser degree than to robins. But this could be so only if penguins were birds to a lesser degree than robins, not 'fully' birds. For clearly the concept 'bird' fully refers to birds, and so if penguins are fully birds then the concept 'bird' must 'fully' refer to them. So prototype theory clashes disastrously with a biology which tells us that penguins are indeed 'fully' birds, as much so as robins. In the light of this, perhaps prototype theory should not be taken as a theory of the nature and reference of concepts but rather of their roles in recognition.

In conclusion, it is proving hard to discover fully satisfactory theories of reference. This has led some to pessimism about reference. This pessimism has a price: either we must abandon the view that reference is central to meaning (content), or, more radically still, we must abandon the idea that we have meaningful representations at all.

Representation, Philosophical Issues about

Intermediate article

Dan Lloyd, Trinity College, Hartford, Connecticut, USA

CONTENTS

Representation, the relation between a symbol, sign, or other vehicle and its content, has historically been analyzed through resemblance and causality; both accounts are flawed. The connectionist idea of distributed representation opens a window into the algebraic structure of representational vehicles, improving the prospects for a scientific theory of representation.

INTRODUCTION

Humans are representing animals, and we have built a world filled with representations of many kinds. Consider, for example, the number and variety of pictorial representations: paintings, photographs, moving pictures, line drawings, caricatures, diagrams, icons, charts, graphs, and maps. Add the variety of linguistic representations, in signs, titles, texts of all kinds, and especially spoken words and sentences. Multiply by all of the forms of recording and storage, especially computer media with their many kinds of codes. Note that all of those external forms of representation can themselves be re-represented as 'meta-representations' (e.g. a book cover featuring a reproduction of a painting of an artist at work on a canvas depicting a musical score). Finally, add the representations in one's head, including sensation or perception, and one's store of beliefs, opinions, hopes, and fears, expressed in forms similar to words, images, or sensations. Human life is largely a cycle of making and interpreting representations. And yet, it is not clear that we have an adequate theory of representation: what they are (at the most general level) and how they work (again, at the most general level).

We also lack full theories of other essential parts of life, like love or justice, but representation plays an essential role not only in life but also in science. Along with the related notion of computation, representation is a foundation of cognitive science. According to cognitive science, the mind computes: it is a symbol manipulator, where symbols are physical tokens that are moved or manipulated according to their formal (syntactic) properties. The mind also represents: the symbols manipulated have meaning. Without computation, the brain would be inert, at best an archive of information. Without representation, the brain's machinations would be empty, without content or connection to the world. Even in broad outline, it is clear that ideas of computation and representation interact. However, it will be useful to look at representation in isolation first, and then examine its relations to ideas of computation.

Representation is usually understood as a relationship between something that represents, a 'vehicle' (e.g. a picture, sentence, or thought), and what it represents, its 'content' (e.g. an object, scene, or situation). The list of examples above begins to suggest the variety of vehicles. Potentially, the list is infinite. So is the potential range of content. Notably, content is not confined to present reality. It can reach out in time and space, and also embrace metaphor, pure fiction, paradox, and outright nonsense (as in Noam Chomsky's example, 'colorless green ideas sleep furiously'). But even at long physical and metaphysical range, representations nonetheless pinpoint their targets. Collecting the second biggest rock on the third largest planet in the Andromeda galaxy may be difficult, but representing it (as in this sentence) is easy.

CONSTRAINTS ON A THEORY OF REPRESENTATION

Representation is a potent multiform relationship. Any general theory of representation should accommodate the examples above, and more. From

the examples we can also abstract some basic properties of the relationship, pointing toward a theory. A theory of representation must account for the following:

- Concerning vehicles:
  Sign and medium. Signs are components of the vehicle which, if they change, lead to a change in the content of the representation. Media are changeable without changing the signs (content) they carry.
  Atomic and molecular signs. In many representational systems, signs combine to form complex signs whose content is not simply an aggregate of the contents of component signs.
  Adaptability. Any set of objects may be transformed, by various means, into a set of representations.
- Concerning content:
  Range. Representations can represent mundane present facts, but with equal ease they can represent counterfactual content. Erroneous representations are still representations, as are representations of mere possibilities, future and past events, and impossibilities.
  Focus. Representations have unlimited range, but express only certain specific contents, omitting a range of ancillary facts from representation. At one extreme, a representation may have no factual content at all. But even the most accurate representation is a narrow and partial window onto a potentially infinite set of factual conditions.
- Concerning the relationship:
  Asymmetry. The relation of representation is one-way, from vehicle to contents. Contents do not represent their vehicles.

MAIN TYPES OF THEORIES

Historically, there are two classes of theories of representation: those that hold that the relation is dyadic, between just the two main elements of vehicle and content; and those that hold that the relation is polyadic, involving third parties in addition to vehicles and content. But any valid theory must account for the constraints above. Several well-known theories fail to do so.

Dyadic Theories

Resemblance

Plato and Aristotle construed representation as *mimesis* or resemblance between vehicle and content, using pictorial art and tragedy as their main examples. In the *Republic*, for example, Socrates suggests that mirror images are the most perfect representations, and in *Cratylus* Plato raises the possibility that perfect representations, being perfect likenesses, might simply duplicate their objects. Resemblance theories have persisted in many forms ever since, sometimes covertly. Modern examples often restrict the domain and range of the resemblance relation, usually to certain formal properties of vehicle and content. For example, Shepard and Chipman (1970) propose that representations resemble objects by duplicating only the relations between them, rather than 'intrinsic' object properties (like color). (See also O'Brien and Opie, 2002.)

The problems with resemblance as the root of representation are well known. Resemblance fails to satisfy several of the listed constraints on representation. With respect to vehicles, it is too general, as any object is already similar to many other objects, in many respects. As a result, with respect to content, resemblance fails to focus on specific content but rather spans every resembling object or situation. At the same time, resemblance seems not general enough, in that counterfactual content seems fundamentally dissimilar from any real vehicle of representation. Moreover, for many representational systems, including spoken and written language, it is unclear how resemblance could hold at all between vehicle and content. Except in unusual circumstances, a sentence generally bears no resemblance to its content. Finally, resemblance, unlike representation, is symmetric: if A resembles B, then to the same extent B resembles A. Although restricting the domain of resemblance mitigates these problems, it does not dissolve them.

Causality

A second major type of dyadic theory of representation is the causal theory, which holds that the relation of content to vehicle is one of cause and effect. Whereas resemblance theories sprang from reflections on art, causal theories often begin with an account of perception. Descartes, for example, imagined the path from worldly stimulus to mental response as a causal one. Modern versions have usually acknowledged the primary problem with causal theories, strikingly like the problems faced by resemblance. Causality is everywhere, holding between many relata that are not at the same time related as vehicle and content. But at the same time, there is no obvious way that a counterfactual situation can cause anything at all. So causal theory entails representational vehicles that represent both too much (all their causal antecedents) and too little (omitting erroneous or other counterfactual content).

A modern variant on causal theory employs the concept of information, which originated in the work of Shannon and Weaver (1949) and was harnessed for cognitive science by Dretske (1981). The

information carried by a channel, in the traditional theory, is proportional to the degree to which the signals transmitted increase the receiver's confidence that particular conditions obtain at the signal's source. For Dretske, a sign carries the 'informational content' that (for example) the ball is red if it is certain that the ball is red, given that the sign has appeared (and also given certain background conditions). The strong accuracy demanded by Dretske's theory helps limit the generality of the standard informational relation (which can hold in some cases even where causality does not). But even as amended, the theory nonetheless requires additional apparatus to accommodate misrepresentation and focus. That is, it still labors to show how a representation picks out its content among a number of antecedent or intermediate 'sources' other than its proper object, and again when there is no real source at all.

Polyadic Theories

Dyadic theories acknowledge that between content and vehicle there will be diverse mediating processes, but they place no restrictions on these processes. Polyadic theories, in contrast, place restrictions on the processes that produce representations, or follow their production. While the dyadic theories faced their greatest difficulty in trimming a profusion of vehicle and content, the polyadic theories in general face the problem of subtly reintroducing 'representation' into their own explanations.

Intention

Since many representations are artifacts, one obvious theory of representation would simply govern the relation by the intentions of either the producers or receivers of representations. Thus, for example, to understand what an author means to represent, we appeal to the author's intentions. Similarly, a 3-year-old can elevate a smear of paint to a picture of Daddy with a simple declaration. These examples fix representationality and content with an appeal to the producer's intention. One could also assign these representational powers to receivers or interpreters.

In routine representational practice, both producers and receivers do seem to play a role in determining content. However, as a general theory of representation, intention theory faces an immediate problem, which is that the mental states of producers and receivers are themselves representations. Those mental states cannot derive their content from other producers or receivers, without leading to an infinite regress of intention bearers. Therefore, at best, intention theories help with artifactual representations, leaving untouched the problem of mental representations.

Some thinkers (e.g. Putnam, 1988) believe that the covert appeal to intention is inescapable in any theory of representation. Another response, however, is to seek polyadic theories that do not depend on an intelligence, in a way that begs the question, for conferring content. There are several possibilities.

Convention

A short step from the intentional is the conventional. Many familiar representational systems arose and evolved through convention, and several students of representation maintain that even the practices of pictorial mimesis are in fact conventions (Gombrich, 1969; Goodman, 1976). A convention, conceived as a set of orchestrated behaviors arising over time within a group, might escape the regress of intentions if 'orchestrated behavior' can be limited strictly to overt physical movement. Behaviorism itself labored for half a century to purge the mental from behavior, without ultimate success. But even were that problem to be solved, convention theory shares with intention theory the fundamental limitation to public representational systems. It is unclear how a convention could extend to psychological representations, without some appeal to a prior, non-conventional, form of native representation.

Functional role

'Native' or 'mental' representation thus emerges as the central issue not just for psychology but for every polyadic theory of representation. Here ideas of computation engage with ideas of representation. 'Functional role semantics' is one name for the representational theory arising within the general philosophy of functionalism. (It is also called conceptual role semantics, or causal role semantics.) Just as functionalism is the view that psychological states are to be differentiated and identified by their functions within a system of such states, so functional role semantics posits that the identity of a representation and its content depends on its functional role in a system of representations, each deriving its content from its role in the system.

The pocket calculator is a favorite example (Haugeland, 1985). To a Martian engineer, a calculator manipulates tokens whose meaning is unknown. Nonetheless, the tokens (shapes on the screen, or patterns of electron flow in the circuits) shift according to patterns. Looking over those

patterns, the Martian tries out various interpretations. Are the shapes pictures of herding animals? Is the flow a model of a river system? Eventually the engineer hits on the interpretation that the shapes are numerals, and the flow allows the numerals to evolve according to arithmetic laws. What makes the arithmetic interpretation unique is that it is truth-preserving. That is, the symbol sequence $2 + 3 =$ is reliably followed by a symbol which properly fits into many such sentences, but in general does not appear in places where the number 5 would be in error. Thus, the representational system attaches itself to a systematic interpretation all at once, and the most favored interpretation is the one that makes statements in the system most often true. Though devised as a theory of mental representation, this theory could apply to public representational systems as well.

Functional role semantics is not dependent on interpreting Martians or humans: their presence in the example above is merely illustrative, since 'interpretability' is a property of the system itself, in relation to the world. But the theory is dependent on another concept, truth, which is rather similar to our target, representation. The difficulties surrounding the concept of 'truth', even if they are different difficulties, do not encourage one to lean on it in a theory of representation. Nonetheless, functional role semantics has opened a path by regarding representation as a systemic property, rather than a property of individual tokens. This approach deserves closer examination, to see whether it can be developed in a way that avoids the problems faced by other theories.

One way to think of a representing system is as a single complex representation, further ramified by its orderly transformations from moment to moment. Of this vast and intricate vehicle we then ask, what relation could it hold to its equally intricate content? This takes us back to the beginning, looking at the dyadic possibilities of resemblance and causation. Now, however, the many components of the big vehicle all constrain the possibilities for its resembling object. It resembles (in some sense) the world overall. Misrepresentation, fiction, and other counterfactuals are then assigned content through their place in the system, rather than through any relation they may have to their content, since there is nothing real for them to be related to. The last task for the theory, then, would be to identify, somehow, the direction of representation, preserving the asymmetry of the relation.

This relation of complex resemblance has been tested by several thought experiments in which the complex vehicle and the world are held constant while the causal relations between system and world are altered. We will look at just two such experiments.

- *The Swampman* (Davidson, 1987). Imagine that some miraculous implosion of organic chemicals occurs in a chemical dump, resulting in the creation of something indiscernible from an ordinary adult human. So thorough is the coincidence that the Swampman has a full store of apparent beliefs and desires, comparable to those of any human. Are those internal states (its 'beliefs' and 'desires') real mental representations, or are they merely lucky simulations?
- *The brain in a vat* (Harrison, 1967; Putnam, 1981). Imagine that evil neuroscientists steal the sleeping brain of an ordinary human and install it in an aquarium, hooking it up to life support and duplicating all its neural connections. However, its previous connections via sense organs to the real world have now been replaced by an elaborate computer simulation concocted by the scientists. Would the mental states formed by the brain upon waking (for example, the computer-simulated percept of a morning cup of coffee), bear content as ordinary representations do?

The two fantasies are complementary. The Swampman gets to the present moment by an abnormal causal route, so its normal-seeming representational states are not generated by the normal causal processes. Henceforth, however, this individual will be in normal interactions with the world. The brain in a vat has the normal causal history, but at the present moment all of those normal relations have been terminated. Henceforth his or her interactions with the world will not be normal. Yet at every moment in both individuals there is something physically very similar to the representational system in our normal brains (we who presume that we are neither swamp people nor brains in vats). If either or both characters lack 'real' representations, then the thought experiments have revealed a commitment to an essential causal or informational link required for any representing system.

Philosophers have been divided in their intuitive responses to the two fantasies. Both characters, for example, have human moral standing, nor would we regard them as mentally impaired despite the myriad delusions that permeate their thought. This, along with the nagging awareness that we cannot tell from introspection that we are neither swamp people nor brains in vats, suggests that the right internal configuration may be all that matters, as suggested by functional role semantics. However, regardless of our intuitions, it seems that the systems approach has not fully answered the basic question. In part, this is the effect of the term 'complex' in 'complex internal configuration' and

'complex causal relations', which only evades certain questions.

CONTRIBUTIONS FROM COGNITIVE SCIENCE

Complexity, especially complexity evolving over time, has been the special expertise of cognitive science. If philosophy is at an impasse in understanding the intricate scenarios sketched above (and many others like them), then it may be useful to look for more concrete guidance from science. In this case, there is a promising lead in connectionism, variously known as parallel distributed processing or neural network modeling. The vehicle of distributed processing is widely termed 'distributed representation'.

Distributed representation refers to representations 'spread out' through a processing system (conceived as a network of neuron-like processors). Thus, no component of the system is dedicated to representing just one piece of content. Rather, each component contributes to many different representational states to many different degrees. It is the pattern of all the components that comprises a single representation. Different overall patterns involving those same components represent different contents.

This is not just an interesting idea. Many working models of distributed representations have been built. These models demonstrate that for a wide range of interesting human tasks, distributed processors could be doing the work. This 'existence proof' offered by parallel processing is similar to the existence proof offered by the digital computer in the early days of cognitive science, in its demonstration of the possibility of purely mechanical symbol processing. The possibility of parallel processing in the human brain has opened new research avenues in many areas of psychology and neuroscience.

In the appeal to distributed representation, connectionists have appropriated without analysis the notion of representation itself. Nonetheless, the properties of distributed representations offer a new view into the phenomena of 'complex resemblance' and 'complex causation'. With respect to resemblance, distributed representations offer principled methods for assessing similarity among sets of distributed patterns. These methods, borrowed from multivariate statistics, produce maps of the structure of a distributed representing system. They reveal that in various working systems, distributed processors generate internal states that track the external environment. At the same time (and with the same representations) they identify the conceptual or categorical membership of external stimuli, as well as tracking the temporal context of the stimuli and coding their precursors and anticipated consequents (e.g. Elman, 1990). All of this is possible, even easy, for distributed processors, because the many components of each representation allow for subtle variations of content. 'Same but slightly different' representations play specific roles in the processing system, with large or small differences in effect, according to the task at hand.

Complex causation emerges through a similar analysis. As connectionism opens a window onto complex patterns of activity in processing components, so also it opens a window onto the varying connections between the components. Although their analysis is in its infancy, these also afford a principled, mathematical treatment. Thus, through the connectionist lens, both resemblance and causation ultimately become matters of linear algebra.

A deep problem remains, however. In connectionism, both complex resemblance and complex causation can be mathematically defined between components of the representational vehicle (the system). But representation is a relationship between a system and the world. Extending the algebraic treatment to vehicle–world connections requires a step of 'preprocessing' the world to offer a systematic input, amenable to mathematical notation. Will there be a coding scheme for reality which does not ultimately trace (once again) to some intelligent interpreter or producer, whose own unanalyzed representations guide the parsing of the world? This uncertainty suggests that the question of representation is still unanswered. Complexity can be treated in systematic ways (by connectionists), but what kind of complexity is the mark of representation, and what kinds of complexity are 'mere' complexity?

IS REPRESENTATION MONADIC?

Every attempt to express the relation of representation in nonrepresentational terms has failed to meet the constraints of content, being either too short in range or too wide in focus. If neither dyadic nor polyadic relations are adequate for the task, then it is perhaps time for a proposal of last resort: what if representation is not a relational property at all, but rather a monadic, nonrelational property? One could retain the ideas of complex distributed representations discussed above, while escaping the difficulties of understanding the 'right' resemblance or the 'right' causation. What would remain is the

idea of content internal to the representation, content as a complex property without external reference of any sort. The analytical techniques applied to distributed representations would then afford direct displays of contents, again without the need for a further interpretive connection of vehicle to world.

The main advantage of this strategy is that it makes tractable the domain of representation, capturing it in the mathematics of distributed processing and distributed representation. So located, it may be possible to answer the question, what is the right sort of complexity for representation? For example, multivariate analyses generally abstract or simplify the complexity of the distributed representations under analysis. In doing so, these analyses compute how amenable the whole system of distributed patterns is to the analysis itself. A random pattern or random system cannot be analyzed smoothly: any attempt to describe it with fewer terms than there are components to the system results in distortion or inaccuracy (Dennett, 1991). Organized distributed systems, like those emerging from neural network research, on the other hand, analyze crisply into fewer terms. So, for all distributed systems, there is an objective measure of organization. This, or something like it, could be the new measure of representationality.

The main disadvantage of this strategy may be that it seems to abandon the fundamental idea of representation. Representation does seem to be a relation: it is the mind's way of making contact with the world and with other minds. Ignoring both the 'outside' and the 'other' seems tantamount to solipsism. At the end of this train of reasoning might be metaphysical dead-ends like Leibniz' *Monadology*.

Consider, however, that if the randomized network described above were turned loose in the world (even in a simulated 'toy' world), it could not meaningfully interact with the world. Brains are continually adjusted by pragmatic consequences, both on the evolutionary scale and in daily human cognizing. Thus, regardless of the metaphysical 'reach' of representation, something will always influence us from without. Complex systems that survive in life will as a matter of practical necessity develop an internal guidance system, which will be intricately responsive to environmental conditions. But this process (and all the real causal relations contained in it) need not be considered definitive of or necessary for representation. Limiting representation to a monadic property in no way removes the mind from nature.

THE FUTURE OF 'REPRESENTATION'

Cognitive science thus inherits a concept of representation that has resisted definitive analysis. Presumably, either a new analysis will clarify the concept, or 'representation' will disappear from the formal explanatory apparatus of cognitive science, to be replaced by a more direct language, perhaps from cognitive neuroscience. Either development would enhance and clarify the science of the mind. Such developments may possibly also oblige us to revise our way of thinking about human life.

Self, Philosophical Issues about

Intermediate article

Shaun Gallagher, Canisius College, Buffalo, New York, USA

CONTENTS

Multiple concepts of the self present a variety of philosophical problems, including questions about ontological and epistemological status, relations between self and consciousness, self-consciousness, memory, and body. These issues are related to the question of determining the proper methodological approach to the self.

THE CONCEPT OF THE SELF

Currently there is no philosophical definition of the self that has drawn consensus. The concept is characterized in a variety of ways throughout the literature. The disparity of conceptions can be glimpsed by considering an incomplete inventory of terms that have come to proliferate in philosophical and psychological accounts:

- material self, social self, spiritual self (James, 1890);
- ecological self, interpersonal self, extended self, private self, conceptual self (Neisser, 1988) (*See* **Perception: The Ecological Approach**); and
- autobiographical self, cognitive self, conceptual self, contextualized self, core self, dialogical self, embodied self, empirical self, fictional self, minimal self, neural self (see, e.g. Damasio, 1999; Strawson, 1999).

This disparity, which is both problematic and productive, is directly related to the variety of methodological approaches taken within philosophy and in related interdisciplinary studies of the self. These include introspection, phenomenological analysis, linguistic analysis, the use of thought experiments, empirical research in cognitive and brain sciences, and studies of exceptional and pathological behavior. In this light, one problem is whether different characterizations of self signify diverse aspects of a unitary concept of selfhood, or whether they identify different and unrelated concepts. This problem of 'inter-theoretical coherency' is addressed below. Regardless of how one responds to this problem, however, the variety of approaches and definitions found in studies of the self productively reinforces the idea that human cognition involves complex and varied aspects that are not easily reducible to one set of principles. (*See* **Self**)

HISTORICAL BACKGROUND

The modern set of problems concerning the self emerged in a definitive way in the seventeenth century from a background that involved theological controversies concerning immortality and the concept of multiple persons in a trinitarian god. The question of personal immortality, which stretches back to ancient times, is no less contentiously debated in contemporary, and mostly secular, discussions about the survival of the self. The question of the unity of the self, even across multiple persons, has been transformed in modern investigations of personal identity and psychopathology. The *locus classicus* of this transformation is to be found in the pages of John Locke's *Essay on Human Understanding*, where, for the first time, the problem of personal identity was defined. Locke reframed the problem by moving away from traditional ideas of a substantial self. Theorists from Plato to Descartes had answered questions about the self in terms of a soul or mind constituted as a separate or separable, non-physical substance. (*See* **Dualism**)

Although Locke's definition of the self moves away from the idea that it is a spiritual substance, it nonetheless remains perfectly consistent with the idea that the self is not essentially embodied. He considers it to be something that depends on cognitive function. The person or self is that which 'can consider itself as itself, the same thinking thing, in different times and places; which it does only by that consciousness which is inseparable from thinking, and, as it seems to me, essential to it … and by this every one is to himself that which he calls self …' (Locke, 1690) The self, then, is a psychological entity. Locke distinguishes this concept of self or person from the concept of human being

('man') defined as an entity that has a body characterized by a continuity of organization over time. In Locke's definition of the person as a psychologically continuous entity, memory plays the most important role. To the extent that I can remember my past actions, those actions constitute part of what I call my self.

One can see, already in Locke, a nest of related philosophical problems pertaining to the self. First, there are ontological problems about what constitutes self-identity in any present moment, and what constitutes the self's identity over time. Second, there is a complex set of epistemological problems related to the role of consciousness, reflection, memory, and other cognitive faculties in providing experiential or conceptual access to the self. Third, cutting across these problems, there are unresolved questions concerning what role the body might play in either constituting or providing epistemological access to the self.

Locke's account is often viewed as reducing ontological problems to epistemological ones. That is, self-identity is constituted precisely through the epistemological access we have to the self. The self is constituted by a psychological continuity that is more or less transparent to self-reflection. To the extent that we fail to be conscious of ourselves, or to remember past events in our life, such events are not part of who we are. This interpretation is the basis of the famous criticisms launched against Locke by Butler (1736) and Reid (1785), theorists who championed a return to the substantialist view of the self. The identity of the person, they argued, is presupposed by memory, not made by it. On the other hand, Locke's view leads directly to David Hume and to a basic question about the ontological status of the self. Is the self something real? The influential Humean answer is 'No'. (*See* **Hume, David**)

Hume supposes that what we mean by the term 'self' is some constant and invariable impression of which we are continually conscious. The problem is that he can find no such thing in his own experience. What Hume introspects is a succession of ever changing impressions, in effect, 'a bundle or collection of different perceptions, which succeed each other with an inconceivable rapidity, and are in a perpetual flux and movement' (Hume, 1739). According to his 'bundle' theory of the self, there is no real self in the manner defined. Nonetheless, we seem to be under the impression that a self is just what we are. To account for this common (folk psychological) conviction Hume proposes that the self is a false impression, a fiction produced by the imagination which in memory mistakes resemblance for identity, and extends that identity beyond what we can remember. To the extent that we imagine there to be causal relations among our mental or intentional states, Hume suggests, the self has the same kind of ontological status as a republic or nation. We attribute identity to such an entity only in a formal way. The reality is a diverse set of changing individuals (perceptions) and institutions. Furthermore, philosophical disputes about the self are merely grammatical or verbal problems. The question is not so much about identity or continuity of the self over time but about how we should talk about the fictional entity that we call 'the self'. (*See* **Self-consciousness**)

One way to deal with the Humean problem is to ask about the unity of the imaginative faculty. If imagination or memory produces a consistent representation of the empirical self, such consistency is likely due to the unity of the cognitive subject. Thus Immanuel Kant (1781) argues for a transcendental (that is, nonempirical) unity of apperception which he calls the transcendental ego – a self that, in principle, is not open to natural scientific investigation. (*See* **Consciousness, Unity of**)

A more naturalistic way to deal with the Humean problem is to accept the definition of the self as a bundle of impressions and to identity the proper criteria necessary to judge which impressions are to be bundled together. William James (1890), setting aside the ontological issues about what actually makes the self, proposes criteria that account for the sense of personal identity. He finds in the stream of consciousness an apparent constancy, characterized as a feeling of 'warmth and intimacy'. This is an impression produced by the physical processes of our own body, by 'faint physiological adjustments' including changes in heart rate, breathing, and so on. This uniform feeling, to whatever extent it pervades our experiences over time, provides an epistemological criterion that we may use to judge the continuity of self. An important objection to using something like a felt impression as the criterion for judging one's identity, however, is that it is regressive. In other words, use of the criterion depends on a subjective awareness of sameness or resemblance from one instance of the impression to another. It thus presupposes the identity of the experiencing subject of each individual state of awareness, which is precisely what one aims to establish through the use of the criterion. (*See* **James, William**)

CURRENT PHILOSOPHICAL THEORIES OF THE SELF

In contemporary philosophical theory there are two main approaches to the question of the self. They extend the traditional answers that distinguish between psychological and bodily continuity.

The Psychological Approach

The psychological approach is closely associated with philosophical functionalism and is often developed through the use of thought experiments that involve brain transplants or the transfer of neurocognitive information from one subject to another. Our informed intuitions concerning a hypothetical brain transplant from body A to body B suggest that personal identity follows the brain and does not remain with the original body. Split-brain experiments, and thought experiments based on these, suggest the possibility that the survival of the self does not depend on the entire brain but on only a sufficient part of the brain. Functionalist theory takes this one step further. What is important about the brain is not physical continuity, not even of some minimal part of the brain; rather, the only thing about the brain relevant to the survival of the self is the psychological information (or the syntactical functions) it instantiates. Even if information (or function) requires physical instantiation, it is still possible to think that it can be moved around from one physical system to another. Thus, the possibility that, in principle, memory information can be removed from one storage device (the brain) and stored in another (another brain or a machine) suggests that psychological rather than physical continuity is what counts in the constitution of the self. (*See* **Self, Psychology of**; **Thought Experiments**)

Locke's emphasis on memory does not provide an adequate concept of psychological continuity for several reasons. First, it is not just that episodic or autobiographical memory is untrustworthy. Rather, psychologically, I am more than just my memories. The concept of psychological continuity includes broader aspects of intentionality – my other cognitive states and dispositions, my behavioral peculiarities, my habitual ways of thinking, my intentions and plans etc. (*See* **False Memory**)

Second, the reliance on memory is further complicated by the possibility that, according to the terms of another thought experiment, I could end up with memories that actually belong to someone else. If one part of brain A (or information from brain A) is transferred to body B, and another part transferred to body C (and assuming that B and C end up as persons of sound mind), then it would be quite possible for B and C to remember certain events as having happened to each of them respectively, when in fact the events happened to their neurological or psychological ancestor, A. In such cases (referred to as cases of 'fission') the memories had by B and C are called 'quasi-memories' and are not sufficient to guarantee the identity of one self across time (Parfit, 1984, Shoemaker, 1984). (*See* **Memory, Philosophical Issues about**)

Third, solving the problem of personal identity presupposes some account of how self is discriminated from non-self. In this regard, a question arises when one considers whether memory can operate as a criterion of first-person identity. The use of a criterion depends on a comparative judgment. To judge whether some object X is in fact Y I need to compare what I know about X to whatever criterion I have for defining Y. If it satisfies the criterion, then I am justified in saying that X is Y. Is this how it works with memory? If I remember visiting a friend yesterday, and I want to use that memory as a criterion that allows me to judge that the person who visited my friend was in fact the same person as myself, then the memory that I use cannot be the memory '*I* visited my friend yesterday.' It would have to be something like the memory '*Someone* visited my friend yesterday.' I would then have to use some appropriate criterion (to compare some knowledge about myself with some knowledge about the 'someone') that would allow me to judge that the 'someone' was actually myself. Only on that basis, it seems, would I be justified in making the statement '*I* visited my friend yesterday.' In that case, however, the statement 'I visited my friend yesterday' would not be a memory statement but a conclusion drawn from the application of a criterion (Shoemaker, 1959). Clearly, if identification and memory worked this way, there would be no such thing as autobiographical memory. Memory would tell me only that someone did X and I would have to make sure that that person satisfied some criterion before I could say that it was I who did X. Such considerations lead Shoemaker to conclude that memory does not act as a criterion for first-person identity, but not because we use a different criterion. Rather, first-person ability to identify the self does not require the use of a criterion at all. Indeed, my ability to say 'I', or to be self-conscious in certain ways, does not depend on a process of identification in which I make a criterial judgment with the possibility that I could get it wrong.

One's first-person access to the self by introspective means is characterized by a direct and sure immediacy that is immune to misidentification (Shoemaker, 1984; Strawson, 1994). (*See* **Autobiographical Memory**)

The Bodily or Biological Approach

There are clear ways in which bodily continuity does *not* enter into the constitution of the self. If one loses a limb, for example, one's self is not necessarily diminished. It also seems obvious that a dead body is still a body in some sense but is no longer a self. Some thinkers have argued that a working brain, or at least some part of the brain, seems a necessary if not a sufficient condition for the existence of a self. Yet functionalist-inspired thought experiments about body (brain) exchange and information transfer have suggested the possibility, in principle, that the self could exist independently of the human body. To the extent that psychological information could be kept intact indefinitely (for example in a machine) this possibility has even suggested a new sense of immortality. Those who pursue the psychological approach have therefore found reason to dismiss the body as an important element for explaining the self.

Towards the end of the twentieth century, however, a variety of theorists in philosophy of mind, phenomenology, and neuroscience revived the notion that embodiment contributes in essential ways to the constitution of the self (e.g. Clark, 1997; Damasio, 1999; Varela *et al*., 1991). The strongest versions of this approach do not dismiss the importance of psychological continuity but provide a way to understand how embodiment shapes the constitution of the self as a psychological entity. Following this line of thought, the following points can be mentioned. (*See* **Embodiment**)

Aspects of embodiment directly shape mental experience and thereby contribute to the constitution of the self. Many thought experiments cited in support of the psychological approach ignore the fact that a person's character, mannerisms, and emotions, which in some way contribute to his or her identity, are embodied. An individual's disposition is instantiated in the performances of embodied processes; mood and emotional states, and appetitive states, are not divorced from but can dramatically shape cognitive states. If two persons are physically unlike one another – for example, if they were of the opposite sex – it would be difficult to imagine one individual's disposition or expressive mannerisms being instantiated in the performances of the second individual's body as the result of a memory transfer or brain transplant. Such dispositions are not simply the result of brain function. They depend both on *cultural factors* – for example those having to do with gender differences – which come to be inscribed in bodily mannerisms, posture and movement style, and *biological factors* such as autonomic regulations, or the effects of hormonal levels, the mix of neurotransmitters, and so forth. Most psychological-continuity theorists ignore these complications.

The embodied approach argues that the body's operations help to constitute affective and cognitive experience. The physical nature of the body, and how the body operates, completely conditions conscious activities. Disembodied experience is an impossible experience. With regard to perception, for example, the egocentric spatial framework of our experience is in fact a body-centric framework tied to the operations of the body. To see is not only *to see something* but also to see *from somewhere*, and under conditions defined by the position and postural situation of the perceiving body and by certain physical capacities of the body and its sense organs. The perceiving body provides a coherency to consciousness across individual perceptual events. That is, a certain coherency of experience is produced by the fact that it is one body doing the perceiving. Biological and emotional, as well as the sensory-motor aspects of embodiment, resonate in the disposition of experience and help to individuate that experience as one's own. Proprioceptive awareness (already operative in very young infants), for example, provides a mode of first-person access to the embodied self that cannot be mistaken in regard to identifying whose body it is that is being experienced (Bermúdez, 1998; Cassam, 1995). A proprioceptive sense of self, a form of bodily self-awareness, plays an important role in the differentiation between self and non-self that informs ecological perception and shapes our psychological identity on a very basic level.

OTHER PHILOSOPHICAL ISSUES ABOUT THE SELF

Other issues concerning the self are often discounted in the mainstream philosophical theories outlined above. Psychological and biological approaches frequently focus their analyses in ways that ignore or set aside the social dimensions that play an important role in the constitution of the self. Social construction theories understand the self as produced by its interpersonal relationships and the cultural practices and institutions that

surround it. The individual self is defined as the cross-section of the various roles it plays in its social milieu. This idea is further developed by narrative theories of the self that understand self-identity to be determined by the stories that are generated by individuals or groups. Dennett's (1988) concept of the self as a 'center of narrative gravity,' that is, an abstract intersection of the various stories that can be told about the individual, is one version of this theory. Other versions emphasize the notion of a self that may be relatively unified or disunified across the sum total of its life narratives and so include within itself equivocations, contradictions, and latent interpretations that find expression in different behavioral situations (Ricoeur, 1992). The view of the self extended across various social roles and across a rich set of diversified narratives permits an account of conflict, moral indecision and self-deception that would be difficult to work out in terms of either an abstract center or a perfectly unified self concept. (*See* **Culture and Cognitive Development**)

Methodological issues with respect to the self are also of concern to philosophers and cognitive scientists. Within philosophy there are debates about how best to approach the problem of the self. Since the time of Locke, for example, philosophers have appealed to thought experiments to outline the logical possibilities pertaining to the self. A variety of limitations and difficulties with this approach have motivated some theorists to turn to the study of pathological cases (e.g. Wilkes, 1988). Understanding the pathologies of the self involved in depersonalization, dissociation disorders, schizophrenia etc. may help to throw more realistic light on the self-structure of normal experience.

The problem of intertheoretical coherency may be more critical for the cognitive sciences. One important strategy for addressing problems as complex as consciousness and the self is to admit that no one method is adequate for a complete explanation. In the process of triangulation several methods are employed and attempts are made to discover a coherent explanation in the results. One issue that seems especially relevant in this case is whether the disparate concepts of self (listed at the beginning) are simply different but ultimately consistent portraits of one unitary thing, or whether different methods capture entirely different things that in each case we label 'self'. Does a neurological approach to the self explain the same thing that narrative theorists call 'the self'? Is it the same self that is material, social, spiritual, autobiographical, cognitive, contextualized, embodied, fictional, and neural? Or are we dealing with a range of phenomena that ultimately cannot be made consistent with each other?

RELEVANCE TO COGNITIVE SCIENCE

Whether the self is real or fictional, one thing or many, it is clearly something that needs explanation, for at least two reasons.

First, there is an undeniable sense of self that accompanies experience and action. One normally has both a sense of ownership and a sense of agency for one's body, actions, and thoughts, and in certain pathologies one or another of these senses can be disrupted (Gallagher, 2000). If this phenomenology points to something real, then a full explanation of cognition would require some account of the self. Even if the self has a fictional status, however, one needs to explain why the fiction arises. In this case we might appeal to psychology, as Hume did, or to accounts involving the neuromechanisms responsible for the implicit (ecological and proprioceptive) structures of perception and action, for autobiographical memory, and for the generation of narrative. It is possible, for example, that our sense of self is generated in a neural signature that originates in subcortical brain areas, and reiterates throughout various cortical processes so that it structures our experience and accompanies all of our thoughts (Panksepp, 1999). (*See* **Personal Identity**)

Second, self-structures play an important role in the way intelligent systems work. At very basic levels of sensory-motor processes it would be difficult to explain how an organism copes with its environment without employing a differentiation between self and non-self. If this distinction is built into intelligence from the very start, it is essential for the cognitive sciences to design a model to account for it, and to put it to work in fields such as artificial intelligence and robotics (see, e.g., Tani, 1998). (*See* **Consciousness, Machine**)

Interdisciplinary approaches that focus on a single aspect or dimension of the complex problems of self are more likely to mitigate problems of intertheoretical coherency. Neuroscientists, psychologists, psychiatrists and roboticists, as much as philosophers, have an interest in developing a neurocognitive model of the self. The neuropsychology of dissociative disorders and the neuroscience of the split brain, as well as the cognitive linguistics of narrative structure, may throw light on how narrative generates a seemingly unified self in normal humans. A variety of approaches, including the neuroscience of motor action, animal studies, and developmental

psychology, are needed to understand aspects of self-awareness, self-recognition, agency, and social interaction, and how such things contribute to the generation of self-identity. In the end, if good explanations of these various aspects of experience are developed, the cognitive sciences have the potential to recast the central philosophical questions about the self. (*See* **Split-brain Research**)

CONTENTS

Viewed from the perspective of cognitive science, the self is a knowledge structure representing one's declarative knowledge of oneself. This knowledge, in turn, may be classified as semantic knowledge of one's physical, personal, and sociocultural characteristics, episodic knowledge of one's past actions and experiences (and, perhaps, prospective memory of one's future actions and experiences as well), and metaknowledge of one's repertoire of mental and behavioral skills.

INTRODUCTION

Usually we think of cognition in third-person terms, in terms of how people (and other systems) acquire, represent, store, and use knowledge about the world outside themselves. This is also true for social cognition, which has to do with how we perceive, remember, and think about other people, their behaviors, and the situations in which we encounter them. At least for humans, however, cognition also turns inward, representing people's knowledge about themselves. A sense of self is critical to our status as persons. In fact, philosophers often use the terms *self* and *person* interchangeably: a capacity for self-awareness is necessary for full personhood. One has a sense of self if one is able to entertain first-person thoughts, and if one possesses first-person knowledge. The eye cannot see itself, but the self somehow knows itself: the simultaneous status of self as subject and object of awareness is one of the enduring problems of philosophy. (*See* **Social Cognition**)

In philosophy, self-awareness is often taken as a primitive, uninformed by reflection or any other form of conceptual thought. Self-awareness is also often taken as privileged. According to Sydney Shoemaker, first-person statements are immune to error through misidentification: they cannot be mistaken, and they cannot be contradicted; we cannot tell someone that he or she doesn't believe in God, feel depressed, or want a hamburger. Shaun Gallagher notes that there is a difference between the minimal self of immediate experience, and a more coherent narrative self that extends in time from the past through the present into the future. For example, amnesic patients will have a sense of their experiences in the immediate here and now, but no sense of their past experiences. In either case, the self is at the root of our sense of agency (i.e., that we are the causes of our actions) and our sense of ownership (i.e., that we are the ones who are having an experience). Further, as Kihlstrom has noted, the self is critical to both the monitoring and controlling functions of consciousness. In cognitive social psychology, the self is construed simply as one's mental representation of oneself – that is, one's idea or mental picture of one's physical, psychological, and sociocultural attributes, of one's own cognitive, affective, and conative states, and of one's own behavior. (*See* **Self, Psychology of**; **Consciousness, Philosophical Issues about**; **Consciousness and Higher-order Thought**; **Implicit Cognition**; **Consciousness, Function of**; **Consciousness and Attention**; **Consciousness, Cognitive Theories of**; **Consciousness, Sleep, and Dreaming**; **Consciousness, Stream of**; **Consciousness, Animal**; **Consciousness, Unity of**; **Self, Philosophical Issues About**; **Self-consciousness**)

MENTAL REPRESENTATIONS OF SELF

A central problem in cognitive science is knowledge representation. In general, we may distinguish between meaning-based knowledge representations, which store propositional knowledge about the semantic relations among objects, features, and events, and perception-based knowledge representations, which take the form of mental images representing the physical appear-

ance of objects, and the configuration of objects and features in space. Self-knowledge can be construed in both terms: the cognitive view of the self as a knowledge structure is anticipated in ordinary language when we refer to the self-concept and the self-image, and there is some value in taking such terms literally, and exploring their ramifications in cognitive theory. What does it mean to say that the self is a concept? That it is an image? (*See* **Imagery**; **Spatial Cognition, Psychology of**)

The Self as Concept

A concept is a mental representation of a category, a set of objects whose members share some features in common that are somehow distinct from objects in other categories. In the classical Aristotelian view, concepts are proper sets, defined by a list of features that are both singly necessary and jointly sufficient to identify an object as an instance of a category. From the classical point of view, then, the self-concept is identified by a set of features that are singly necessary and jointly sufficient to identify oneself as different from all others. The classical set view of the self as a set with only a single instance aptly recognizes our experience of ourselves as unique – that we are not the same as anyone else. Research by William McGuire and his colleagues has found that people who are in the minority with respect to age, birthplace, gender, ethnicity, and other physical, social, and demographic features are more likely to mention them when asked to describe themselves. Apparently, people notice aspects of themselves, and incorporate these attributes into their self-concepts, to the extent that these features render them distinctive. Along the same lines, Hazel Markus and her colleagues have suggested that the self-schema incorporates those features that are important to one's self-concept, not merely those that are descriptive of the self.

On the other hand, philosophers and cognitive scientists have identified a number of problems with the classical view of concepts as proper sets that have led to the progressive elaboration of a number of revisionist views. Chief among these alternatives is the probabilistic view of concepts as fuzzy sets represented by summary prototypes whose features are only imperfectly correlated with category membership. Instead of sharing some set of singly necessary and jointly sufficient defining features, instances of a concept are related to each other by a principle of family resemblance. This view of the self as a prototype has won wide acceptance within social cognition, but the notion of family resemblance suggests that there must be more than one self. Actually, the multiplicity of self makes sense from a social-psychological point of view. Despite our tendency to describe each other in terms of stable traits, human social behavior is widely variable across time and place, and our self-knowledge must represent this kind of variability. Perhaps, then, the self-as-prototype is abstracted from multiple, context-specific, mental representations of self. Clinical cases of multiple personality disorder (also known as dissociative identity disorder) bring the multiplicity of self into bold relief. In normals, autobiographical memory creates a continuity between the mental representation of self-in-one-situation and self-in-another that is destroyed by the amnesic barrier between multiple personalities. (*See* **Conceptual Representations in Psychology**; **Prototype Representations**)

Just as problems with the classical view of concepts led to the prototype view, so problems with the prototype view have led to further revisionist views. While the classical and prototype views construe concepts as some kind of summary of the features of category members, the exemplar view denies that we have any such summary at all. Instead, we represent concepts as a collection of instances. While the classical, prototype, and exemplar views are all based on a principle of similarity, the theory-based view holds that concepts are based on a theory of the domain in question. The instances of a category are not related by any kind of similarity but only through some theoretical explanation. Applied to the self-concept, the exemplar view would imply that there is no unitary self at any level of representation: all we have are context-specific selves. The theory view, in turn, would imply that our self-concept is a theory about ourselves – how we became what we are, and why we do what we do, rather than a list of features or instances. As yet, however, neither of these views of conceptual organization has been applied systematically to the self-concept.

The Self as Image

Perception-based representations have not been much studied in social cognition, but this is what the notion of 'self-image', taken literally, would entail. The rudiments of the self-image may be found in the body schema postulated by Henry Head to account for the ability of animals to maintain stability of posture and adjust to our physical surroundings. In addition to verbal knowledge about our characteristic features, then, we appear to possess analog representations of our own bodies

and their parts, independent of immediate sensory stimulation. Distortions and other aberrations of the self-image are often observed in cases of acute schizophrenia, anorexia, bulimia and other eating disorders, body dysmorphic disorder, and phantom limb pain. The neurological syndrome known as autotopagnosia is characterized by an inability to localize the parts of one's own body on demand; it is associated with focal lesions in the left parietal lobe. Outside the psychiatric and neurological clinic, experimental subjects prefer left–right reversals of photos of themselves, while they prefer unreversed photos of others. The fact that our picture preferences match the way we view ourselves in the mirror indicates that the self-image preserves both spatial relations and visual detail. (*See* **Schemas in Psychology**)

The Self as Memory

John Locke (1632–1704), the English philosopher, famously identified the self with memory: a person's identity, which is to say selfhood, extends to whatever of a person's past he or she can remember. Modern cognitive theories often distinguish between two forms of knowledge stored in memory. Declarative knowledge is our fund of factual knowledge about the world; it can be represented as sentence-like propositions. Procedural knowledge is our repertoire of rules and skills by which we manipulate and transform declarative knowledge; it can be represented as productions specifying the actions that will achieve some goal under specified conditions. Viewed as a memory, the self is usually thought of as declarative in nature, although certainly we can have declarative metaknowledge about our cognitive skills and abilities. Declarative memory, in turn, takes two basic forms. Episodic memory is autobiographical memory for the events and experiences of one's past, and its relevance to Locke's concept of the self is obvious. Our sense of self is very much tied up with the 'story' of how what we have experienced has made us who we are, and how who we are has led us to do what we have done. By contrast, semantic memory is more generic, context-free knowledge about the world. With respect to the self, semantic memory is tantamount to the self-concept and the self-image. (*See* **Skill Learning**; **Metacognition**)

Cognitive psychologists have only recently begun to study autobiographical memory, in the sense of people's memories for events and experiences occurring in the real world outside the laboratory. The simplest proposal for the organization of autobiographical memory is as a temporal sequence, running from birth to the present, with retrieval based on a serial backwards search. However, the serial record of autobiographical memory is more likely broken up into segments corresponding to the major phases of life: elementary school, high school, and college; first job, promotion, and retirement; first marriage and second. The fact that these phases overlap, and are defined subjectively and redefined retrospectively, makes the organization of autobiographical memory difficult to study except on an individual basis. The earliest years of life are covered by infantile and childhood amnesia: one's earliest recollection is typically dated between the third and fourth birthdays, and autobiographical memory does not typically achieve any kind of continuity before the 'five to seven shift' prominent in studies of child development. 'Flashbulb' memories occur where private and public history meet. Autobiographical memory is reconstructive in that our personal histories are shaped by our current theories of who we are and how we came to be that way. It is our 'story so far', a narrative that is constantly subject to revision.

In a generic associative network model of memory, the self (or each of a multiplicity of context-specific selves) can be represented as a node linked to other nodes representing corresponding knowledge about oneself. Considerable research has addressed the question of how episodic memory for one's past behaviors and semantic memory for one's characteristic traits can be represented in such a scheme. According to a conventional hierarchical model, nodes representing traits fan off the central node representing the self, and nodes representing behaviors fan off the traits they exemplify from nodes. An alternative model, related to 'self-perception' theories of social cognition, holds that memory contains only behavioral knowledge with traits known only by inference. A third model is that items of trait and behavioral information are represented by nodes that fan off independently from the 'self' node.

These models can be tested experimentally by means of a priming methodology. If the hierarchical model is correct, asking people questions about their traits should facilitate their answers to questions about their behaviors. If the self-perception model is correct, asking people questions about their behaviors should facilitate their answers to questions about their traits. A series of studies by Klein and his colleagues has revealed priming of neither sort, a consistent null result supporting the third model, of independence. The independence

model is also supported by neuropsychological evidence summarized below.

IS THE SELF A PERSON LIKE ANYONE ELSE?

Viewed as a concept, the self is a fuzzy set of context-specific selves, or perhaps a theory about oneself. Viewed as an image, the self represents both our perceptible features and their spatial configuration. Viewed as a memory, the self represents propositional knowledge about our abstract traits and specific behaviors, including a narrative record of our personal history. Lying behind all these models is the general idea that oneself is a person like anyone else and represented accordingly.

However, social psychological research has revealed a number of differences between cognition about oneself and cognition about others. While we tend to attribute others' behaviors to their internal traits, we are more likely to attribute our own actions to the demands of the situation (the self–other difference in causal attribution). We tend to perceive ourselves as more central to events than we really are (egocentricity), especially if the outcomes were positive (beneffectance). On the other hand, it is not yet clear that these biases are intrinsic to self-knowledge. Perhaps they apply to knowledge about others, as well, so long as we like them (as we tend to like ourselves) and/or know them well (as we think we know ourselves).

THE SELF AND ITS BRAIN

As philosophers and psychologists became interested in the biological substrates of mental life, and brain-imaging techniques have permitted us to watch the brain in action, many cognitive scientists have evolved into cognitive neuroscientists. Taking cognitive neuropsychology as a model, Klein and Kihlstrom have argued that neuropsychological studies of brain-injured patients, and brain-imaging studies of normal subjects, may provide new solutions to old problems and afford new theoretical insights for personality and social psychologists as well. Consider, for example, the relation between self and memory. If, as Locke argued, our sense of self is intimately tied up with our recollection of our past, what is the sense of self for an amnesic patient? H.M., the famous patient with the amnesic syndrome, cannot consciously remember anything that he did or experienced since the operation that destroyed his medial temporal lobes. H.M.'s anterograde amnesia is virtually complete, and hence his sense of self may be confined to whatever memories he has from before his surgery. Moreover, Locke did not fully appreciate the distinction between episodic and semantic memory. Amnesic patients retain some ability to acquire new semantic knowledge, and this dissociation may permit their self-concepts to be based on 'updated' semantic knowledge, even if they are lacking a complete record of autobiographical memory. (*See* **Amnesia**)

Such questions have not been asked of H.M. himself, but they have been asked of other patients. For example, the patient known as K.C., who suffered a severe head injury as a result of a motorcycle accident, has both a complete anterograde amnesia covering events since the accident, and a complete retrograde amnesia covering his life before the accident. K.C. has no autobiographical memory at all, but research by Endel Tulving reveals that he has a fairly accurate self-concept. The same accident that caused his amnesia also resulted in a profound personality change: the premorbid K.C. was quite extraverted, while the postmorbid K.C. is rather introverted. When asked to rate himself as he is now, K.C. rates himself as introverted, in agreement with his mother's ratings of him. Interestingly, his ratings of his premorbid personality do not agree with his mother's. K.C. has acquired semantic knowledge about himself, but he has not retained in episodic memory the experiences on which this self-knowledge is based; and his newly acquired semantic self-knowledge has effectively replaced that which he possessed before the accident.

Similar results were obtained by Klein and his colleagues in a study of W.J., a college freshman who suffered a temporary retrograde amnesia, covering the period since her high-school graduation, as a result of a concussive blow to the head. Asked to describe herself, W.J. showed a good appreciation of how she had changed since matriculating, as corroborated by her boyfriend's ratings of her. Findings such as these lend strength to the conclusion, based on experimental studies of priming, that semantic (trait) knowledge of the self is encoded independently of episodic (behavioral) knowledge.

Amnesic patients typically suffer damage to the hippocampus and related structures in the medial temporal lobes, leading to the conclusion that these structures constitute a module, or system, for encoding consciously accessible autobiographical memories. Is there a similar structure responsible for the sense of self? Recently, F. I. M. Craik and his

colleagues used positron emission tomography (PET) to image the brain while subjects rated themselves on a list of trait adjectives. As comparison tasks, subjects rated the prime minister of Canada on the same traits; they also judged the social desirability of each trait, and the number of syllables in each word. One analytic technique, statistical parametric mapping, revealed no differences in brain activation between the self- and other-ratings tasks. While this finding would be consistent with the proposition that the self is a person like any other, a partial least squares analysis showed significant self–other differences in the right and left medial frontal lobes, and the middle and inferior frontal gyri of the right hemisphere. Further studies of this sort are obviously in order. (*See* **Neuroimaging**)

So is the self in the right hemisphere? Probably not. Self-referent processing may be performed by a module or system localized in the right frontal lobe, but control is critical in these conditions, and it may well be that other-referent processing is performed by the same system, provided that the other is well liked and/or well known. Although cognitive neuroscience has generally embraced a doctrine of modularity, the neural representation of individual items of declarative knowledge is distributed widely across the cerebral cortex. Self-reference may be localized, but self-knowledge is widely distributed over the same neural structures that represent knowledge of others. (*See* **Modularity**; **Modularity in Neural Systems and Localization of Function**; **Learning and Memory, Models of**; **Memory Models**)

THE DEVELOPMENT OF SELFHOOD

Development can be viewed in two ways: ontogenetically, in terms of changes in individual organisms across the life cycle from birth to death; and phylogenetically, in terms of changes in species across evolutionary time.

Locke viewed a sense of self as essential for personhood, but nonhuman animals may also have a sense of self. In a classic study, Gordon Gallup painted an odorless, nontoxic red mark on the foreheads of anesthetized chimpanzees. In the absence of a mirror, the chimps showed no awareness that their appearance had been altered. When exposed to their reflections in a mirror, however, the animals often examined the spot in the mirror, touched the spot on their foreheads, and then inspected and smelled their fingers. They appeared to recognize a discrepancy between what they thought they looked like, and what they actually looked like – suggesting, in the process, that they possessed at least a rudimentary self-image. The same effect has been found in some orangutans and bonobos, but not in gorillas (except perhaps for the famous Koko), monkeys, and other primates, or in nonprimate species. However, it should be noted that not all chimpanzees pass the self-recognition test, and alternative means of testing may well reveal self-recognition in other species.

By the time they are 18–24 months old, most human infants also pass the mirror-recognition test. However, if the infants are shown a videotape of themselves after a delay as short as three minutes, most fail to recognize themselves on the monitor; most four-year-olds pass this more difficult test. By the age of two, then, human infants have at least a minimal sense of self, but it takes a while longer for them to develop a narrative sense of themselves as extended in time – that they are the same person now that they were a while ago. Similarly, children younger than four years old seem unable to recognize that their current knowledge and beliefs differ from those they held in the past. Interestingly, age four is about the time that children achieve a capacity for episodic memory – the ability to recognize that a current mental state is in fact a representation of a past mental state. (*See* **Theory of Mind**)

PATHOLOGIES OF SELFHOOD

Whatever the findings in infants and animals, a sense of self is part and parcel of the conscious experience of all normal human adults. However, a number of pathological conditions appear to involve disruptions in self-recognition and self-awareness. For example, some prosopagnosic patients fail to recognize their own faces as well as others, while some individuals with Capgras syndrome will identify themselves, as well as others, as imposters. Patients with frontal lobe damage often show a reduced capacity for self-reflection or impaired feelings of self-continuity. Frontal lobe damage can also impair episodic memory, in which self-reference is critical. (*See* **Prosopagnosia**; **Face Perception, Psychology of**; **Frontal Cortex**)

Within psychiatry, some theorists have suggested that schizophrenia involves a breakdown in the neural substrates of self-reflection and self-monitoring, while some dissociative disorders appear to involve a disruption of self and identity. While patients with psychogenic amnesia retain a sense of self (they simply cannot remember a period of their lives), patients with psychogenic

fugue lose their identity as well as their memories. In multiple personality disorder, both identity and autobiographical memory shift back and forth from one 'alter ego' to another. Children with autism, a pervasive developmental disorder, appear to have a limited capacity for self-reflection, personal agency, and personal ownership. Whether these deficits in social cognition are limited to the sense of self, or extend to other people as well, is a topic of much current investigation. (*See* **Disorders of Body Image**; **Autism**; **Autism, Psychology of**; **Williams Syndrome**)

SELF-KNOWLEDGE INTO ACTION

While cognitive psychology tends to study mind in the abstract, social psychology studies mind in action. Mental representations of self, others, and situations do not exist for themselves but as guides to social behavior. How we behave towards others depends not only on how we perceive them but also on how we perceive ourselves. Erving Goffman, E. E. Jones, and others have argued that people often engage in strategic self-presentation to shape others' impressions of them in an attempt to gain or retain control over the social situation. Many social interactions are characterized by what Robert K. Merton would call a 'self-fulfilling prophecy' – in which, for example, a person who believes that someone is aggressive may treat that person in a manner that evokes aggressive behavior that may not have occurred otherwise. A strong sense of self may promote strategic self-presentation, but it may also militate against others' self-fulfilling prophecies concerning oneself. If people do not define themselves as aggressive, perhaps they will be less likely to act aggressively, regardless of how they are treated. From a social-psychological perspective, then, the self is not just something that knows and is known; it is also something that one does. That is to say, the self is actively constructed and reconstructed, maintained, tested, and revised, presented and represented to others, in the course of ongoing social interaction.

Self-consciousness

Intermediate article

Jose Luis Bermúdez, University of Stirling, Stirling, UK

CONTENTS

Self-consciousness is deeply implicated in many aspects of cognition. To be self-conscious is to be aware of oneself through information that one cannot fail to recognize is about oneself.

INTRODUCTION

A creature is self-conscious to the extent that it is aware of its embodied self in such a way that it cannot fail to realize that it is itself the object of awareness. Philosophers have often discussed self-consciousness as if it were the unique property of language-using humans. There are powerful reasons for thinking that this is not the case, but whether self-consciousness is understood broadly or narrowly it remains a crucial cognitive capacity of central concern to cognitive science.

WHAT IS SELF-CONSCIOUSNESS?

Self-consciousness is primarily a cognitive, rather than an affective, state. Although the term 'self-consciousness' is often used in ordinary language to describe a particular state of hypersensitivity about certain features of one's character or appearance, in philosophy and cognitive science the expression is best reserved for a form of awareness of one's self. But what does it mean to be aware of one's self? Unsurprisingly everything depends on what one means by 'awareness' and what one takes the self to be. Let us take these two dimensions of variation in reverse order.

Historically philosophers have understood the nature of the self in many different ways. According to the various versions of dualism, the self is a purely psychological entity that is connected to a particular body but that could exist without that body. For dualists, therefore, self-consciousness consists in awareness of that psychological entity. Most contemporary philosophers and cognitive scientists are agreed that the self is an embodied person with both psychological and physical properties, although there are disagreements about the appropriate criteria of personal identity. Does the survival of the self require psychological continuity, physical continuity, or both? These disputes cut across the debate between dualists and anti-dualists, because one can hold that the survival of the self does not require physical continuity (the continued existence of the same body) without being committed to the dualist claim that the self need not be embodied at all. (*See* **Personal Identity**)

Turning now to the awareness component, we should start by distinguishing two different types of awareness – *direct awareness* and *propositional awareness*. One can be aware of something (as when I catch sight of someone walking up the garden path) or one can be aware that a particular state of affairs is the case (as when the sound of the doorbell alerts me to the fact that a visitor is at the door). In *direct awareness* the object of awareness is a particular thing. In *propositional awareness* the direct object of awareness is a proposition or state of affairs (a complex of particular things, properties, and/or relations). A further difference between direct awareness and propositional awareness is that the former is *extensional* while the latter is *intensional*. If 'JLB is directly aware of *x*' is a true report, then it will remain true whatever name referring to the same object is substituted for '*x*' in the report. Direct awareness is not sensitive to the mode of presentation of the object of awareness. Propositional awareness, however, *is* sensitive to the mode of presentation of the state of affairs that is the object of awareness. I can be aware that a state of affairs holds when it is conceptualized in one way, but be unaware that it holds under a different conceptualization. If 'JLB is propositionally aware that *x* is *F*' is a true report, it will not necessarily remain true if a co-referential name is substituted for '*x*' and/or a predicate true of the same objects for '*F*'.

Self-consciousness, therefore, can be understood either in terms of direct awareness of the self or in terms of propositional awareness that the self

has such-and-such a property, or stands in such-and-such relations. Some philosophers have maintained that there can be no such thing as self-consciousness at the level of direct awareness. David Hume maintained that the self could never be encountered in introspection:

> For my part, when I enter most intimately into what I call *myself*, I always stumble on some perception or other, of heat or cold, light or shade, love or hatred, pain or pleasure. I never catch *myself* at any time without a perception, and never can observe anything but the perception. (Hume, 1739–1740/1978, p. 252)

It is clear that this introspective report (Hume's thesis of the *elusiveness of the self*) will be telling if the self were a purely psychological entity, since introspection would then be the only possible source of direct awareness of the self. But philosophers who think that the self is essentially embodied will be untroubled by Hume's point. They will rightly point out that we do have direct awareness of the body through somatic proprioception.

In any case, it is clear that propositional awareness *about* the self does not require direct awareness *of* the self. I can be aware that a particular state of affairs holds without being directly aware of one of the constituent objects in that state of affairs, and so I can be aware that the self has certain properties without being directly aware of the self. So the truth or otherwise of the elusiveness thesis is not directly relevant to the possibility of propositional awareness of the self. Nor is it likely that propositional awareness concerning the self will be analyzable in terms of, or reducible to, direct awareness of the self. The intensional and cognitively mediated character of propositional awareness seems an insuperable obstacle to any such reductive or analytic project.

Propositional awareness of the self is in many ways more interesting than direct awareness of the self. Self-consciousness is important because of the role it plays in the cognitive economy. Self-conscious subjects think about, and react to, the world in distinctive and characteristic ways that are not available to non-self-conscious subjects. Self-consciousness makes possible certain types of inference and reflection, and it does this because of the distinctive types of proposition that it makes available.

But what are these distinctive types of proposition? Self-consciousness makes available to the subject thoughts that are about the thinker of that thought, but not all thoughts that are about the person thinking them qualify as self-conscious. A thought might be about its thinker without the thinker being aware of that fact. So, for example, I might think that the last person arriving at the party is ill-mannered without realizing that I am that person. A genuinely self-conscious thought is about the thinker of that thought in a way that does not leave any room for the thinker to fail to recognize that the thought concerns him. This is part and parcel of the distinctive functional role of self-consciousness. It is mirrored by the linguistic fact that any token of the first person pronoun 'I' always refers to its producer. Self-conscious thoughts would naturally be expressed with sentences involving the first person pronoun.

Self-conscious thoughts can be based on a range of different sources of information. Some of these sources can provide information *either* about the self *or* about other people. Testimony is a case in point. I can learn facts about myself by being told them by others, in the same way as I learn facts about anything else. But there are other sources of information about the self that provide information purely about the self. These sources of information are such that, if we know from them that somebody has a particular property, we *ipso facto* know that we ourselves have that property. Introspection is an example. If I know through introspection that someone is currently thinking about self-consciousness then I know that I myself am thinking about self-consciousness. Introspection cannot provide information about anybody other than me. This does not mean that introspection (and other comparable sources of information) cannot be mistaken. They certainly can, but they do not permit a certain type of error. Judgments made on the basis of them cannot be mistaken about who it is that has the property in question. Such judgments are *immune to error through misidentification relative to the first person pronoun* (Shoemaker, 1968), an epistemological property that they inherit from the information sources on which they are based.

Self-conscious thoughts that are immune to error in this sense (such as the thought that I am in pain, where this is based on information from pain receptors) are clearly more fundamental than those that are not. They reflect ways of finding out about ourselves that are exclusively about the self and that do not require identifying an object *as* the self. Self-conscious thoughts that are not immune to error through misidentification must be analyzed in terms of those that are immune, because they will involve identifying an object as the self, and any such identification must be immune to error through misidentification on pain of an

infinite regress. For this reason influential accounts of self-consciousness, such as those of Shoemaker (1963, 1968) and Evans (1982), have attributed a fundamental role to the phenomenon of immunity to error through misidentification.

PHILOSOPHICAL ISSUES CONCERNING SELF-CONSCIOUSNESS

The Scope of Awareness

There are four different ways in which a cognitive state properly describable as awareness can emerge. One can be aware of something (whether an object or a state of affairs): (1) by having information about it and acting accordingly; (2) by perceiving it; (3) by having beliefs about it; or (4) by having knowledge of it. How do these differ?

One can have information about something without perceiving it. There are many examples of this among neuropsychological disorders, including blindsight. The performance of blindsight patients on certain matching and other tasks shows that they are capable of performing certain perceptual discriminations in their blindfield, and hence that at some level they are picking up visual information about a portion of the distal environment that they are not perceiving. Similarly, one can perceive something without having beliefs about it. Most simply, one might not believe the content of one's perception. Finally, one can have beliefs about something without having knowledge of it. The belief might be mistaken, or fail to be securely enough grounded to qualify as knowledge. (*See* **Blindsight**; **Epistemology**)

Each of these different ways of understanding 'awareness' will yield a different conception of self-consciousness. The strictest and narrowest conception identifies it with self-knowledge (the knowledge of propositions about the self whose natural linguistic expression would involve the first person pronoun). Only slightly less strict would be the view that self-consciousness involves believing the appropriate sort of propositions about the self. Both of these views have the consequence that self-consciousness is only available to creatures who can have beliefs, and on many conceptions of belief this significantly narrows the field of self-conscious subjects. This has struck some philosophers as undesirable.

Understanding awareness in terms of either information pick-up or perception significantly broadens the scope of self-consciousness with respect to its emergence in human development and to where we might expect to find it in the animal kingdom. There are important questions, however, about how these types of awareness of the self should be understood. It is easy to see how they can support a form of direct awareness of the self. But do they admit propositional awareness of the self? If so, what is the content of that awareness? It presumably differs from the content of beliefs and/or knowledge about the self. But in what ways? At this point appeal might be made to the notion of *nonconceptual content*. Whereas the content of beliefs, and propositional attitudes in general, is conceptual (in the sense that it can only be attributed to creatures possessing the concepts required to specify it), some authors have found it helpful to postulate the possibility of representing the world in ways that are not constrained by the conceptual repertoire in this sense (Evans, 1982; Cussins, 1990; Peacocke, 1992; Bermúdez, 1998). (*See* **Mental Content, Nonconceptual**)

As a way of motivating a more inclusive conception of self-consciousness, consider that self-conscious thoughts play a distinctive functional role in the cognitive economy. They have, for example, immediate implications for action (Castañeda, 1969; Perry, 1979). Whereas I may contemplate with equanimity the thought that the worst-performing philosopher in the department will shortly be ejected from the department, as soon as I realize that *I* am the person whose job is on the line I will be galvanized into action. One might wonder, therefore, whether all motivated action might not require some form of self-conscious thought. Let us call this the *thesis of essential self-consciousness*. If motivated action really does require some form of self-conscious thought, then *either* only creatures who are capable of knowledge and/or belief are capable of motivated action, *or* the domain of self-consciousness must be extended until it is co-extensive with the domain of agents. The perceived need to accommodate the second of these options is a prime motivation for taking one of the broad readings of self-consciousness outlined above.

It is natural to point out that what is shown by the above example and the many others like it is that it is not possible for me to act on the basis of knowledge or belief that 'a is F' where 'a' is a term or expression that refers to me but when I do not know that it does. But it does not follow from this that all motivated action requires knowledge or belief that would be expressed in the (genuinely self-conscious) form 'I am F'. If I am hungry and see food then I will act accordingly. But it is hard to see where the self-conscious thought comes in. What is see is what I desire, namely, the food over there.

Defenders of the thesis of essential self-consciousness will suggest that this misrepresents the nature of perception, since perception of the external world has an irreducible first-person component (Gibson, 1979; Bermúdez, 1998). Perception is essentially perspectival and egocentric, most obviously in vision but also in the sense of touch. The world is not presented in perception as an abstract arrangement of objects, but rather as an array of objects that stand in certain spatial relations to the perceiver. The world is perceived from a point of view, where a perceiver's point of view is tied to his possibilities for acting upon the distal environment.

It is important for both the philosophy of self-consciousness and the philosophy of perception to provide an account of the content of visual perception that reflects its perspectival and egocentric nature. Such an account will stress the differences between the content of perception and the content of propositional attitudes such as belief, such as: the unit-free way in which distances are presented in visual perception; the fact that the spatiality of the distal environment is perceived on an egocentric frame of reference; and the way in which the embodied self actually appears in the field of vision and the content of tactile perception. Nonetheless, although we should not expect the contents of visual perception to be propositions of the sort that serve as contents of propositional attitudes, the status of exteroceptive perception as a form of propositional awareness of the self emerges when one remembers that it essentially provides information about the relations between the embodied self and objects in the distal environment. (*See* **Mental Content, Nonconceptual**)

Can we broaden the scope of self-consciousness even further? Can the appropriate type of awareness be derived from nonperceptual information pick-up? Somatic proprioception seems the most plausible place to look. Many of the sources of proprioception, such as the information about limb position and movement provided by joint position sense and the information about the body's orientation and state of balance derived from the vestibular system, have seemed to many to be better described at the level of information pick-up, rather than at the level of perceptual awareness – not least because there does not seem to be a sensory dimension to the information they provide. Yet they also seem to be providing information about properties of the embodied self – intrinsic properties in the case of joint position sense and relational in the case of the vestibular system. It may be, however, that these two information sources are best understood, not in isolation, but rather as embedded within somatic proprioception as a whole, and it has been argued that somatic proprioception does indeed provide a form of perceptual awareness of the body (see the essays in Bermúdez *et al*., 1995 for various perspectives on this issue).

Awareness of Self and Awareness of the World

As has emerged above, the functional role of self-conscious thoughts is both distinctive and important. We have so far concentrated on just two aspects of that functional role – the role of information sources that are immune to error through misidentification in generating first-person thoughts, and the immediate implications that such thoughts have for action. But the functional role of a given type of thought also includes its relations to other types of thought. They will be the subject of this section.

Self-consciousness is essentially a contrastive notion. Subjects are aware of themselves relative to, and as distinct from, other members of a contrast class of either other physical objects or other psychological subjects. In view of this it is natural to adopt what I shall term the Interdependence Thesis, according to which a creature's capacity for self-consciousness is directly proportional to his capacity to represent the external world.

A classic expression of the Interdependence Thesis is Kant's claim, defended in the section of the *Critique of Pure Reason* entitled 'The Transcendental Deduction of the Categories', that self-consciousness both depends upon and makes possible the perception of a spatio-temporal world composed of continuously existing objects causally interacting in law-like ways. The form of self-consciousness he is discussing (the unity of apperception that he describes in terms of the 'I think' being able to accompany all my representations) is largely formal – essentially the awareness, with respect to each member of a series of thoughts and experiences, that it is one's own. The interdependence emerges from the two-way links between the unity of apperception and the possibility of applying the categorial concepts whose applicability Kant took to define the objectivity of the world. In this sense, Kant's version of the Interdependence Thesis is closely linked to his distinctive version of transcendental idealism. (*See* **Kant, Immanuel**)

Philosophers such as P. F. Strawson (1966) and Gareth Evans (1982) have more recently attempted

to defend a version of the Interdependence Thesis that is not committed to a Kantian transcendental idealism. Like Kant, however, they adopt what I earlier described as a narrow conception of self-consciousness – that is, the thesis that self-consciousness involves and requires beliefs and/or knowledge about the self. For Strawson and Evans the Interdependence Thesis holds because the capacity to have a suitably generalized understanding of the first person pronoun (Evans) or to conceptualize the distinction between experience and what it is experience of (Strawson) requires the ability to formulate judgments reflecting a conception of the embodied self as located within an objective world possessing certain very general features. For Evans, possessing a mastery of the first-person concept that is integrated with thought about the rest of the world in a suitably productive and systematic way requires the ability to conceive of oneself 'from the third-person point of view' as an objective particular in a unified spatio-temporal world. For Strawson, the ability to distinguish appearance from reality within the realm of experience requires the ability to ascribe experiences to oneself as a continuously existing particular.

Whether these arguments are sound or not, an important question emerges for those who have sought to defend a broader conception of self-consciousness. How, if at all, can a version of the Interdependence Thesis be motivated once we move below the level of self-knowledge and beliefs/knowledge about the world? Clearly, at the level of perceptual awareness and information pick-up it is not appropriate to construe the Interdependence Thesis in terms of connections between *judgments* about the self and *judgments* about the world. Yet unless some version of the Interdependence Thesis holds at these more primitive levels, it is unclear how they can support genuine forms of self-consciousness at all, given that the Interdependence Thesis reflects the essentially contrastive nature of self-consciousness.

Some materials for answering this challenge are offered in Bermúdez (1998), where it is shown how primitive nonconceptual and prelinguistic forms of self-consciousness can be appropriately contrastive. Analyzing visual perception following the ecological approach of J. J. Gibson (1979) reveals the exterospecific and propriospecific dimensions of visual perception and how the dynamism of visual perception emerges from their interaction. Similarly, somatic proprioception provides a broadly perceptual awareness of the limits of the body as a physical object responsive to the will, and hence as clearly demarcated from all other physical objects. By the same token, it is possible for a creature to have a sense of itself as following a single path through space-time, and hence to possess a (nonconceptual) point of view on the world, as manifested in its memories and navigational understanding of space, rather than in high-level beliefs and judgments.

SELF-CONSCIOUSNESS AND THE COGNITIVE SCIENCES

Many discussions of cognitive science make a distinction between central and peripheral processes. This is often tied to the distinction between modular and nonmodular processes. Central processes are not encapsulated, domain-specific, mandatory, and fast in the manner of peripheral processes such as those responsible for early vision and phonological analysis. On what I have been calling the narrow conception of self-consciousness, according to which self-consciousness is at root a matter of having certain distinctive types of thought about oneself, self-consciousness will have to be analyzed at the level of central processing. Those who follow Fodor (1985) in thinking that cognitive science can have little to say about central processes will draw appropriately pessimistic conclusions. More plausibly, it seems natural to think that the capacity to entertain self-conscious beliefs will depend upon some form of metarepresentational capacity, and hence should be analysed as an element in what is often termed theory of mind. (*See* **Modularity**)

There exists a rich cognitive scientific literature in this area, which one might expect to be highly informative on the ontogenesis of higher-level self-consciousness, as well as on what happens when the mechanisms that subserve higher-level self-consciousness break down. With respect to the former of these, one might expect the capacity for higher-level self-consciousness to emerge as part of the overall 'theory of mind' package at more or less the age of four. As far as pathology is concerned, Christopher Frith's influential analysis suggests that schizophrenia should be understood as a breakdown in the mechanisms that permit awareness of oneself as the author of one's thoughts and beliefs – and hence that it is, at least in part, a deficit of higher-order self-consciousness (Frith, 1992).

The scope for dialogue between philosophy and the cognitive sciences with respect to self-consciousness becomes much greater on what I have termed the broader conception of self-consciousness. Most straightforwardly, the different areas of cognitive science can be expected to

play a crucial role in exploring the more primitive dimensions of self-consciousness (Neisser, 1993). We have already briefly seen how Gibson's ecological approach to visual perception can be of great help in understanding the way in which visual perception incorporates an element of self-awareness. One would also expect the cognitive sciences to provide much-needed clarification of the different information systems and channels subserving somatic proprioception.

There is also scope for influence in the other direction. Accounts within cognitive science need to be sensitive to phenomenological factors revealed by philosophical accounts of the nature of self-consciousness. A single example will make the point. I suggested above that one way in which the Interdependence Thesis might be understood at the level of perceptual awareness and information pick-up is through a creature's possessing a (non-conceptual) point of view on the world in virtue of having certain navigational abilities. It seems plausible to stress the role of the following capacities in underwriting a creature's grasp of the spatial organization of its environment and its location within that environment: (1) the capacity to think about different routes to the same place; (2) the capacity to keep track of changes in spatial relations between objects caused by its own movements relative to those objects; and (3) the capacity to think about places independently of the objects or features located at those places. Recognizing the centrality of these cognitive capacities influences how we interpret some important recent work on animal representations of space and their neurophysiological coding. Chapters 5 and 6 of Gallistel (1990) defend the thesis that all animals from insects upwards deploy cognitive maps with the same formal characteristics in navigating around the environment. Gallistel argues that the cognitive maps that control movement in animals all preserve the same set of geometric relations within a system of earth-centred (*geocentric*) coordinates. These relations are metric relations. The distinctive feature of a metric geometry is that it preserves all the geometric relations between the points in the coordinate system. Gallistel's thesis is that, although the cognitive maps of lower animals have far fewer places on them, they record the same geometrical relations between those points as do humans and other higher animals.

Without, of course, wishing to challenge Gallistel's central thesis that all animal cognitive maps from insects up preserve geometric relations, it none the less seems wrong to draw the conclusion that all animals represent space in the same way. Just as important as how animals represent spatial relations between objects is how they represent their own position within the object-space thus defined. And it is here, in what we should think of as not just their awareness of space but also their self-conscious awareness of themselves as spatially located entities, that we see the major variations and the scale of gradations that the theorists whom Gallistel is criticizing have previously located at the level of the cognitive map.

Sense and Reference

Intermediate article

Margaret Reimer, University of Arizona, Tucson, Arizona, USA

CONTENTS

Many philosophers of language believe that sense and reference are two essential components of linguistic meaning. The reference of an expression is (roughly) that which the expression is used to talk about; the sense of an expression is (roughly) the criterion an entity must satisfy in order to be the reference of that expression. The intuitive, nontechnical notion coming closest to the notion of 'sense' is that of meaning.

WHAT ARE SENSE AND REFERENCE?

What, if anything, can we say about words that is uncontroversial? Probably nothing – at least if one is to judge by the relevant philosophical literature. Virtually everyone, however, would agree that words have meanings – in *some* sense of 'meanings'. But in what does the meaning of a word consist? Is the meaning of a word nothing more than what it refers to? Is the meaning of the expression 'water' simply water? Or is there something more to linguistic meaning? Those who answer the latter question affirmatively, often claim that what Frege (1892) called 'sense' is this 'something more'. Because reference is generally considered to be the more fundamental of the two notions, let us begin our discussion of sense and reference with a few introductory remarks on reference.

It seems clear that words, at least some of them, *refer*: they somehow attach to the particular objects and individuals that we use them to talk about. Indeed, how else would talk about the world be possible? When a word refers, what it refers to is called its 'reference'. Reference is thus a property of words, at least of certain words. Thus, for example, the reference of the proper name 'George W. Bush' is George W. Bush; the reference of the definite description 'the tallest person ever to live' is that very person – whoever he or she may be; the reference of the natural kind term 'tiger' is the class of all tigers; the reference of the artifactual kind term 'pencil' is the class of all pencils. The basic idea is not particularly deep or subtle, but there are some tricky points to bear in mind.

First, there are words that seem to refer *when we use them*, yet fail to refer when considered in the abstract, as it were. What, for instance, does the demonstrative 'that' refer to? What about the pronoun 'she'? What about the expressions 'here' and 'there'? These sorts of expressions, known in the literature as 'indexicals', are expressions whose reference depends upon the particular context in which they are used, where context is construed as including speaker, hearer, time, and place. (See Kaplan, 1989.) Thus, I may, while pointing to my sister, say 'She is a vet' and, while pointing to my daughter, say 'She is my daughter'. In both cases, the pronoun 'she' refers – but to whom it refers to depends upon the particular context in which it is used. (Some have argued that natural kind terms are also indexical expressions. See Putnam, 1975.)

Second, one must be careful to distinguish between what a word(s) refers to and what a speaker uses a word(s) to refer to. Often the two coincide, but sometimes they come apart. Suppose, for instance, that I see in the distance what I take to be a man in a gray jacket, though in fact the individual I perceive is a woman in a mauve jacket, behind whom is a man in a gray jacket. Suppose further that I an unable to see the man in the gray jacket. Then, when I say to you 'The man in the gray jacket is coming this way', I am referring to the woman (provided my intention is to draw your attention to her). My words, however, arguably refer to the man if indeed they refer to anything at all. (See Kripke, 1977.) The distinction between speaker reference and word reference leads to the question: which kind of reference is primary? Do words refer primarily and speakers only derivatively – or is it the other way around? To ask this question is to ask whether speaker reference is to be analyzed in terms of word reference, or the other

way around. While many philosophers of language appear to have assumed the primacy of word reference, others (Strawson, 1950; Donnellan, 1966) have argued for the primacy of speaker reference.

At any rate, if there are words that refer (even if only derivatively), we are going to need an explanation of how this is possible. One might initially think: that's easy. A word, at least a word of the referring sort, refers to whatever speakers in the relevant linguistic community use that word to refer to. Thus, for instance, the word 'telephone' refers to … yes, *telephones*, and it refers to such things because that is what speakers of the relevant linguistic community (here, English) use that word to refer to. But there is a problem with this view: although correct, it is either circular or woefully incomplete. The view is circular if the notion of reference is the same in the definition as in the term to be defined. And, in that case, it is no more informative than the claim that calculators are things we use to do calculations. The view is incomplete if the notion of reference in the definition is distinct from the notion of reference being defined; for although the definition appears to offer an explanation of word reference in terms of speaker reference, it does not say in what speaker reference consists. One question is thus answered at the expense of generating another, equally interesting and important, question that remains unanswered.

This brings us to the notion of sense. Sense corresponds at least roughly to the intuitive, nontechnical notion of meaning, according to which competent speakers of the language know the meanings of the words in that language. So construed, sense is thought by some philosophers to play a variety of different theoretical roles. Indeed, according to Frege (1892) and his followers, the notion of sense plays four distinct roles. First, it serves as the bearer of 'cognitive significance', and thus explains the difference in 'cognitive value' between sentences like (1) and (2):

Hesperus is Hesperus. (1)

Hesperus is Phosphorus. (2)

(The names 'Hesperus' and 'Phosphorus' are co-referring, both referring to the planet Venus.) Intuitively, while (1) is trivial, (2) is informative. The informativeness of (2) is to be explained by the hypothesis that the expressions 'Hesperus' and 'Phosphorus', though identical in reference, are different in sense or 'cognitive significance'. (The sense of the former might be something like brightest heavenly body in the evening sky; the sense of the latter might be something like brightest heavenly body in the morning sky.) Second, the sense of an expression determines its reference. An expression refers to whatever somehow satisfies its sense. The sense of an expression might thus be thought of as providing a criterion for reference: a set of conditions that an object/individual must satisfy in order to emerge as the expression's referent. Third, senses are the objects of thought: the sense of a declarative sentence simply is the thought it expresses. And fourth, senses are identified as the referents of embedded sentences. Thus, in a sentence like 'Fred believes that Bush is president', the referent of the embedded sentence 'Bush is president' is identical to the sense of the unembedded sentence. Obviously, then, Frege expected senses to do a great deal of theoretical work – according to some, more than could reasonably be expected by a single notion. (See Schiffer, 1990)

Because the topic at hand is sense *and reference*, let us look more closely at the distinction between these two notions.

THE SENSE/REFERENCE DISTINCTION

Frege (1892) is certainly the most famous exponent of the sense/reference distinction. Indeed, he is arguably its original proponent – though others before him proposed similar distinctions. Mill (1843), for instance, argued for a distinction between expressions that merely denote and those that both denote and connote. What an expression denotes is what it refers to, what it signifies; what an expression connotes is what it means, what it implies. But Mill was certainly not the first to appreciate this basic distinction between what a word refers to and what it means. Indeed, Mill attributes the original distinction to the schoolmen of the Middle Ages.

To understand the sense/reference distinction as conceived by Frege, one must understand its initial motivation. It is relatively uncontroversial that words, at least some words, refer to things, and that the reference of a word is somehow relevant to its meaning. Indeed, according to what is often called the 'naive' theory of meaning, the meaning of a word *just is* what it refers to. But there appear to be some fairly obvious problems with this view. Consider the following two sentences:

Jack the Ripper is Jack the Ripper. (3)

Jack the Ripper is Prince Albert Victor. (4)

Suppose that we adopt the view that meaning is nothing more than reference. On such a view, an

expression gets its meaning from the fact that it refers. Then, given that 'Jack the Ripper' and 'Prince Albert Victor' are co-referring, they mean the same thing, and we thus seem forced to conclude that sentences (3) and (4) mean the same thing – that they express the same 'proposition'. But do they? Surely, they do not appear to. After all, while the first is trivially true (analytic or tautologous), the second is anything but. While Queen Victoria would have been unfazed by the putative truth of (3), she might have vehemently denied the putative truth of (4). How can we explain the intuitive difference between such sentences – sentences of the form $a = a$ and those of the form $a = b$?

Such considerations, considerations having to do with the difference in cognitive significance (roughly, informativeness) between sentence pairs like (1)/(2) and (3)/(4), led Frege to the view that all so-called singular terms, terms that refer – or purport to refer to definite objects – invariably have senses. (This is true of 'Santa Claus' and 'Sasquatch', both of which arguably only purport to refer.) For Frege, the distinction between sense and reference is crucial. Thus, although the senses associated with the names 'Jack the Ripper' and 'Prince Albert Victor' may determine the same reference (Queen Victoria's eldest son), they have different senses: they present (or represent) that individual in distinct ways. While the sense of the first might be expressed by the description 'slayer of assorted London prostitutes in the late 1880s', that of the second might be expressed by the description 'the eldest son of Queen Victoria'. This is not, however, generally thought to be an essential feature of senses – they that be expressible via some sort of linguistic expression, like a definite description. It is just that sometimes they are so expressible, and in such cases it is especially easy to see that the senses are indeed distinct. (See, for instance, Evans, 1983 and Searle, 1983.) At any rate, since it is the sense of an expression that enters into the proposition expressed, the hypothesis that 'Jack the Ripper' and 'Prince Albert Victor' have different senses explains the difference in cognitive significance between the propositions expressed by sentences (3) and (4). For senses are generally thought to be compositional, in so far as the sense of a complex expression (such as a sentence) is going to be determined by the senses of the simple expressions out of which it is formed. Thus, since the subject terms of (3) and (4) have different senses, the senses of the sentences themselves will be different – those sentences will (in other words) express different propositions; they will express (in Fregean terms) different thoughts.

Frege's sense/reference distinction enables us to solve the puzzle posed by sentences pairs like (1)/(2) and (3)/(4): that is, it explains why these sentences differ in terms of cognitive significance. It also allows us to solve puzzles associated with other sorts of sentences, as we are about to see.

ARGUMENTS FOR THE DISTINCTION

The usual arguments for the sense/reference distinction are of two basic sorts. According to one, words refer and so we need something to explain how this happens. Sense provides such an answer – an expression refers to whatever satisfies the sense that it expresses. I suppose this might be construed by some as a sort of 'argument to the best explanation'. (Although of course not everyone thinks that senses *are* the best explanation – see below.) A second type of argument is what might be called a 'puzzle' argument. Various logical puzzles arise on the 'naive' view that reference – which seems crucial to meaning – is *all* that there is to meaning. By positing senses, the puzzles are effectively solved. In addition to the problem posed by pairs of identity sentences like (1)/(2) and (3)/(4), there are others, typically divided into three groups: (i) propositional attitude ascriptions, (ii) sentences containing empty names, and (iii) true negative existentials, which constitute a special subclass of (ii). Consider the following three sentences:

Fred believes Cicero, but not Tully, was Roman. (5)

Sasquatch was last sighted in Tucson, Arizona. (6)

The Easter Bunny does not exist. (7)

Intuitively, (5) seems to attribute noncontradictory beliefs to Fred, (6) seems to be meaningful, and (7) seems to be true. But suppose that meaning is no more than reference – that the meaning of an expression is simply what it refers to. Then, all of these intuitions are misleading. For on the meaning = reference view, (5) does ascribe contradictory beliefs to Fred – he believes of one and the same individual that he is both Roman and not Roman; (6) is meaningless, assuming that a sentence with a meaningless part cannot itself be meaningful, and (7) – if meaningful – must be false. For in order to be meaningful, the subject term must refer; but if it refers, then presumably its referent (the Easter Bunny) does exist. If, on the other hand, we suppose that expressions like 'Cicero', 'Tully', 'Sasquatch' and 'the Easter Bunny' have senses that are distinct from their references (if any), then we

can explain the intuitions without much difficulty. For it is the sense of an expression – as opposed to its reference – that enters into the proposition expressed, into what is said.

PROBLEMS WITH THE DISTINCTION

Although the sense/reference distinction seems to be an intuitive one, and the arguments for it have considerable force, some have argued that it is an ill-conceived distinction. The best-known objections to the distinction are those of Kripke (1980) and Putnam (1975).

Both Kripke and Putnam take issue with the idea that sense determines reference. Kripke's objections focus on proper names, while Putnam's focus on natural kind terms. Kripke argues, in effect, that if the sense of a proper name is identical to the property or properties the user of the name associates with that name, then sense is not what determines reference. Thus, for instance, if I declare that Einstein was a brilliant man then I refer to the famous German physicist, even if the (only) property I associate with that name – say, the inventor of the atomic bomb – picks out someone else (Oppenheimer). Kripke of course realizes that he is going to need to provide some alternative explanation of how proper names refer, and he does: he proposes his so-called Causal Theory of Reference, according to which users of a name are able to refer to the name's referent in virtue of their membership in a causal chain of communication, originating in an act of reference-fixing – a baptism of sorts. On this view, conceptual information (or misinformation) about a name's referent is irrelevant to the determination of nominal reference. (For some criticisms of this view, see Evans, 1973 and Searle, 1983.)

Putnam makes a similar point but applies it to natural kind terms. Suppose that sense determines reference, and that senses are (as Frege supposed) abstract conceptual entities grasped by competent speakers of the language. Now consider the natural kind terms 'puma' and 'jaguar'. I can use both of these terms to refer and, in so doing, I refer to pumas and jaguars respectively. But not knowing much about such felines, the concepts that I associate with each of the two expressions are not sufficient to distinguish pumas from jaguars. Indeed, perhaps I associate with both terms the same concept – something like *ferocious, sleek-bodied feline with a short glossy coat*. Thus, if senses are construed à la Frege as abstract conceptual entities grasped by competent speakers of the language, then they are not what determine reference. For if that were so, then 'puma' and 'jaguar', as I use those terms, would not refer (as they in fact do) to different kinds of feline; they would refer to the same kind of feline, if they referred at all. What, then, does determine reference – the reference of natural kind terms in particular? Putnam claims that two factors are relevant to such determination: the way the world is and social features captured by what he calls a 'division of linguistic labor', according to which, in using a natural kind term, speakers defer to the relevant experts (zoologists, in the case of felines), saying in effect that the term refers to whatever the experts would say that it refers to.

RELATION OF SENSE AND REFERENCE TO COGNITIVE SCIENCE

Sense is clearly going to be relevant to issues in cognitive science, while reference is not. The reasons for this are fairly obvious. Sense is supposed to explain cognitive significance; in particular, it is supposed to explain why it is that certain sentences express the particular thoughts they appear to express. Sense thus explains, at least indirectly, our linguistic behavior as well as our reactions to the linguistic behavior of others. Thus, for instance, sense might be invoked to explain why Queen Victoria would have been unfazed (though perhaps perplexed) by an utterance of (3), though outraged by an utterance of (4). And sense might also be invoked to explain why an utterance of (3) would, in most circumstances, seem pointless. Any philosopher of mind who thinks of thought as language-like is going to have to face the same puzzles that Frege did, and is going to have to respond to the challenges that Kripke and Putnam have posed to the Fregean distinction between sense and reference. (See Fodor, 1994 for an idea of how these puzzles might be treated by a philosopher of mind who thinks that thought is linguistic.)

Simulation Theory

Intermediate article

Joe Cruz, Williams College, Williamstown, Massachusetts, USA
Robert M Gordon, University of Missouri, St Louis, Missouri, USA

CONTENTS

The simulation theory is an account of our everyday ability to attribute mental states and predict and explain human behavior. It has been developed both as an empirical hypothesis in cognitive science and as an account of mental concepts in the philosophy of mind.

WHAT IS THE SIMULATION THEORY?

The simulation theory (ST) is an account of our everyday ability to make sense of the behavior of others. One crucial element of this ability is the identification and attribution of inner mental states that generate action, especially propositional attitudes such as beliefs or desires. The successful 'mindreading' of mental states allows us to predict and to explain what others do, and makes possible the rich social dynamic that pervades human life.

Conceived most broadly, ST maintains that one represents the mental activities and processes of others by mental simulation, i.e., by generating similar activities and processes in oneself. For example, one anticipates the product of another's theoretical or practical inferences from given premises by making inferences from the same premises oneself. In more complex simulations, one imaginatively adopts the circumstances of the target and then uses one's own mental apparatus to generate mental states and decisions. Computationally, this exercise of imagination is usually represented as feeding pretend inputs into one's own decision-making processes, taking these processes 'offline' so that they do not issue forth in real behaviors.

Some proponents of ST go further and claim that many of the concepts of mental states that we deploy in understanding other human beings are fundamentally linked to our possession of those same mental states. Some prominent accounts attempt to shed light on the conceptual transformation involved in refashioning our first-person concepts in such a way that they can be deployed in the third person.

While ST is related to the empathetic or *verstehen* approaches to explanation in the social sciences that were prominent in the twentieth century, most researchers who currently work on ST do not operate directly within that theoretical framework. In its contemporary forms, ST has often been developed with its principal rival, the theory theory (TT), as an explicit foil. TT maintains that the mental terms and concepts used in understanding, predicting and explaining human behavior derive from a folk theory of the mind. A closer historical source for contemporary ST was the debate in the philosophy of mind over the status of this putative theory. According to one view, known as eliminativism: (1) mental states like beliefs and desires are the posits of a folk theory of the mind; and (2) this theory is radically false. The conclusion drawn by the eliminativist is that the faulty folk theory ought to be rejected in favour of some more scientifically respectable theory such as one derived from neuroscience.

Before the advent of ST, most critics of eliminativism focused on the defensibility of its second tenet. Important articles by Jane Heal (1986), Robert Gordon (1986) and Alvin Goldman (1989) challenged the first tenet by setting out the ST alternative to TT. If it could be shown that mental terms did not derive their intelligibility from their role in a folk theory, then the eliminativist's conclusion would become suspect. Since this important impetus, ST has attracted interest in its own right and has become somewhat independent of concerns over eliminativism.

Some philosophers believe that ST sheds light on traditional topics such as the problem of other minds, referential opacity, broad and narrow content, and the peculiarities of self-knowledge. ST has

had a substantial impact on research into 'theory of mind' in developmental psychology, as well as on branches of philosophy outside the philosophy of mind, especially aesthetics and the philosophy of the social sciences.

SIMULATION THEORY VERSUS THEORY THEORY

One of the dominant explanatory patterns within cognitive science and the philosophy of mind has been to construe a mental capacity as subsumed by a theory of the domain of the capacity. The idea is that domains such as folk physics, folk biology, and intuitive statistics are treated as areas of knowledge in which the layperson's judgments are the results of applying a theory. The results of the application of the theory constitute our spontaneous conscious judgments about cases that seem amenable to the theory. Such theories are usually thought to be representations of law-like generalizations. In some domains, at least, they may be characterized as a set of 'platitudes' tacitly deployed in thinking about problems and circumstances in our world. The layperson need not be aware of using a theory to make a judgment, but, presumably, could generate at least some of the platitudes that inform his or her judgments.

In keeping with this widely endorsed strategy in cognitive science, theory theorists claim that we possess a body of tacit knowledge that governs our judgments about the mental states of others. The theoretical posits of this theory will be mental states like beliefs and desires, and the transitions between the mental states will be described by the theory as mental processes such as inference.

There is a diversity of opinion among theory theorists on the nature and origin of the putative common-sense theory. Some claim that the theory is learned; others that it is innate. Theory theorists also face a question regarding the modularity of the common-sense 'theory of mind'. Some claim that the theory is a distinct cognitive module; others that it is continuous with the system of representations that constitute theories of other, non-mental domains. What unifies theory theorists is the view that attributing inner states and making sense of the behavior of others is carried out by a capacity that deploys knowledge encoded in a theory.

The most straightforward sense in which ST is opposed to TT is that simulation theorists deny that our capacity to attribute mental states is subsumed by a body of knowledge about the minds of others. Rather, our own mental processes are treated as a manipulable model of other minds. Such simulation would typically require indexical adjustments, such as shifts in spatial, temporal, and personal points of view, to place oneself in the other's physical and epistemic situation in so far as it differs from one's own. One may also compensate for the other's reasoning capacity and level of expertise, if possible, or modify one's character and outlook as an actor might, to fit the other's background and behavioral history. With these adjustments, the attributer might enter mental states that differ from those he or she would have in the target's situation. Even when simulation is insufficient for making decisions in the role of the other, it might allow one to discriminate between those options likely to be attractive to the target and those likely to be unattractive. Accordingly one would be prepared for the former actions and surprised by the latter.

Moreover, most simulationists are happy to grant that, in some cases, we will develop general rules of thumb or heuristics for attributing mental states. These may be called on to generalize the results of a simulation to cover the same target at future times, or a class of targets, such as those who share the conventions of a particular culture, who 'as a rule' behave in a certain way in certain circumstances. Still, simulationists deny that general, 'theoretical' considerations play a fundamental part in attributing mental states. ST is often characterized as 'process driven', because it is a cognitive process that is generating the output of the simulation, with little or no influence from general information about minds.

An analogy may be helpful here. If we wished to predict a future state of the solar system, we might appeal to a theory that expresses law-like generalizations about the motions of the planets. So, we might appeal to the theories articulated in a contemporary textbook on astronomy, or, more in keeping with our interest here in folk theories, we might appeal to a set of platitudes about the motions of celestial objects of the kind articulated by the ancients. This would be a sensible approach, but it is not the only way we could successfully carry out the prediction. If we could build a reasonably accurate physical model (an orrery), we could advance this model the correct number of cycles and read from it a future state of the solar system. Depending on how versatile our model was, we might even be able to experiment with counterfactual starting states; or, with a still more sophisticated model, or a digital simulation, we might even adjust the orbits of planets, and their number, to model a range of planetary systems quite unlike our own.

This analogy gives us some insight into the difference between theory-driven and process-driven accounts of a domain. ST can be viewed as the proposal that we use our own mental states and processes – our perceptual, cognitive, motivational and emotional systems – as a model like an orrery.

VERSIONS OF SIMULATION THEORY

It is obviously desirable that any relevant disparities between simulator and target should be removed or offset in some way. If the behavior to be predicted or explained is crucially dependent on beliefs, desires or emotions not shared by the simulator, then the simulator must either adopt the appropriate pretend-beliefs, pretend-desires or pretend-emotions, or compensate by a heuristic rule. However, this proviso says nothing about the nature of belief, desire or emotion. For instance, it is consistent with (but certainly does not imply) a functionalist account of belief. In a well-known box diagram, Stich and Nichols (1992) portray ST as the empirical hypothesis that the same belief–desire system that generates one's own decisions and actions also generates our predictions of the decisions and actions of others, adding for this purpose a pretend-belief generator and a pretend-desire generator. Some simulationists find this portrayal too restrictive, claiming that it commits ST to a questionable conception of mental states and possibly also a mistaken understanding of the dependence of actions on these states. These proponents of ST conceive our everyday ascriptions of belief and other mental states as part of an explanatory enterprise quite unlike the attempt to fill in the 'boxes' of a functional theory like those commonly developed in cognitive science. Our ascriptions specify the 'internal states' of a system only in the sense of attempting an essentially first-person glimpse into a subject looking out on the world.

There is also disagreement among simulationists on another front. Some hold that to ascribe mental states to others by simulation, one must already be able to ascribe mental states to oneself by introspection, and that to do this one must already possess the relevant mental state concepts. On this view, simulation is understood as essentially an application of the argument from analogy. Others attempt to build on the 'subject looking out on the world' idea of mental state ascription. They hold that in such ascriptions, whether concerning oneself or another, one is saying something about the world, albeit in a way that is relativized to a particular 'point of view'. Rather than resting on an analogy between what lies 'inside' two individuals, this account assumes that, unless there is evidence to the contrary, all subjects look out on one and the same world.

ARGUMENTS FOR SIMULATION THEORY

A number of arguments have been put forward in favour of the simulation theory, three of which are outlined below.

Parsimony

The most important distinguishing feature of folk psychology, according to many writers, is the central and essential role it gives to the semantic content of the states it posits, particularly the propositional or sentential 'objects' of propositional attitudes such as beliefs, desires, and intentions. Most theory theorists try to accommodate this feature with the hypothesis that folk psychology comprises laws or principles that quantify over this content, connecting, for example, what someone believes and desires to what that person chooses to do. Moreover, the connections are said generally to mirror the semantic relations that hold among these contents, particularly relations that can be represented abstractly by rules of logic and rational argument such as modus ponens and the practical syllogism. Thus the theory theory posits an internal store of causal laws corresponding to these rules.

However, in so far as the store of causal generalizations mirrors the set of rules to which our own thinking typically conforms, ST appears to render it otiose. For whatever those rules are, our thinking continues to conform to them within the context of simulation, unless, of course, adjustments are made to accommodate evident differences. In short, we can use our own reasoning as a model of the reasoning of beings that reason the way we do. In the light of this alternative, it is argued, the hypothesis that people must be endowed with a special stock of laws corresponding to rules of logic and reason appears unmotivated and unparsimonious.

Other Uses of Simulation

The procedure that ST posits as essential to the common-sense methodology for predicting and explaining behavior also appears to be – with modifications – essential to emotional empathy, and important if not essential to ethical evaluation. Even if one didn't think simulation essential to common-sense explanation and prediction, one would probably have to posit such a procedure

anyway to account for empathy and ethical evaluation.

Explanation of Children's Errors in Predicting Behavior in 'False Belief' Situations

According to ST, the mature capacity for explaining and predicting the behavior of others requires capacities for imaginative pretense of at least three kinds: counterindexical pretending, which recenters the egocentric map (I am spatially or temporally somewhere else in the world, or I am someone else); counterfactual or propositional pretending, in which the world itself is altered in imagination (for example, this banana is a telephone, or dinosaurs roam the boulevards of Paris); and what might be called purposive pretending, in which alternative goals are adopted (for example, the putative goals of a mother, or the goals of an opponent in a game). These capacities are clearly evident in most children before their third birthday, and they are typically combined in role play.

To explain and predict a great deal of the human behavior they are likely to encounter in real life or in stories, young children can probably get by with a relatively simple employment of these and similar imaginative abilities. For example: while Sally and Anne are playing together, Anne grabs the marble in Sally's box and places it in her basket. Taking the role of Sally in this simple scenario, a child should have no trouble deciding where to look for her marble: in Anne's basket. However, suppose that in the story (or in a scene witnessed in real life) Sally is away when Anne takes her marble. When she returns, where does she look for her marble? Taking the role of Sally and deciding where to look, the child would be misled by a simple use of pretense. To get the correct prediction (she will look in her box, where she left it), and at the same time to maintain 'objectivity' (for example, to recognize that she won't actually find the marble there), the child would have to feed contrary premises into two distinct lines of reasoning: 'objectively', the marble has been moved to Anne's basket and therefore can be found there, not in Sally's box; 'subjectively' – and for the purpose of deciding what to do in the role of Sally – it hasn't been moved from Sally's box, and therefore can still be found there. According to ST, until children are capable of such compartmentalized reasoning – and of knowing when to use it – they can be expected to make incorrect predictions in complex scenarios in which behavior is likely to be based on a false belief.

Numerous experimental studies (beginning with Wimmer and Perner (1983)) have confirmed that in fact children do generally make these incorrect predictions until about the age of four. Although ST is not unique in offering an explanation of such errors, its explanation appears more compelling than typical 'theory' explanations, such as the hypothesis that children lack the 'belief' part of the theory of mind until the age of four (Gopnik, 1993; Wellman, 1990; Gopnik and Meltzoff, 1997).

SIMULATION THEORY AND COGNITIVE SCIENCE

The simulation theory has a bearing on a range of disciplines and methods in the cognitive sciences. Consequently, there has been significant research on ST within artificial intelligence (AI), neuroscience, and cognitive psychology. In order to show how ST has been pursued in these fields, it is useful to develop further the 'process driven' conception of ST introduced earlier. One way of refining the claim that simulations are process-driven is to take ST as the hypothesis that essentially the same set of mechanisms is called upon to provide two different competences. One of these competences is the intelligent control of behavior. This would include, among other things, the capacity to make inferences from beliefs to new beliefs and the capacity to make decisions on the basis of beliefs. The second competence is the anticipation and comprehension of intelligently controlled behavior, by predicting the underlying inferential and decision-making processes.

There are thought to be testable consequences of this 'double-duty mechanism' construal of ST. Researchers in AI have claimed that the same models that provide an account of practical reasoning (and of other dynamics between propositional attitudes) can efficiently be adapted to perform mental state attribution. These computational efficiency arguments have in turn sometimes been used as arguments in favour of ST. Both traditional AI programming methods and neural network techniques have been employed in research on ST along these lines.

In AI research, the double-duty hypothesis is a functional claim. The idea is that the same mental program is implicated both in practical reasoning and in mental state attribution, with changes allowed for taking the system 'offline' or feeding in pretend states. So, even if it turned out that different parts of the physical computational system were responsible for practical reasoning and mental

state attribution, the AI approach to ST would remain valid.

If, on the other hand, the double-duty conception of ST is not just understood functionally, but includes a commitment to the commonality of the underlying neural substrate, we arrive at another avenue of cognitive science research on ST. Such research would seek to show that there was a shared neuronal mechanism that is responsible for practical reasoning and mental state attribution. This approach is analogous to a fruitful line of research on vision and visual imagery. These two capacities appear to share substantial portions of the underlying neural substrate.

There is emerging evidence for the existence of 'mirror neurons' in humans and other primates (Fadiga *et al*., 1995; Rizzolatti *et al*., 1996). Single-cell recordings in macaque monkeys and magnetic stimulation techniques in humans show that these mirror neurons exhibit increased activity when another primate is observed performing some characteristic action, such as grasping an object. This is relevant for ST because these are the same neurons that show increased activity in the first-person performance of that action. This research is far from showing that sophisticated cognition is subsumed by double-duty mechanisms, but it is suggestive. Some simulation theorists maintain that this research reveals an evolutionary precursor to the capacity of assuming a different perspective that ST requires (Gallese and Goldman, 1998).

Evolutionary considerations have been lurking in the background of much empirical research in this domain. Thus, elements of cognitive ethology have been thought to bear on ST, and vice versa. Indeed, it was in their research on primate behavior that Premack and Woodruff (1978) introduced the term 'theory of mind'. Though efforts to develop ST within cognitive ethology have been limited, it does present another potential source of data.

A POSSIBLE TEST OF THE SIMULATION THEORY

If it can be shown that incorrect mental state attributions are in some cases best explained by claiming that the attributer lacks some specific and perhaps surprising background information about mental agents, then it seems less plausible to think that the attributer is simulating. Some critics of ST claim to have uncovered experimental evidence for just this.

The logic of such experiments is thought to be as follows. In order for a simulation to be successful, the operation of the attributer's mental processes must be substantially similar to the operation of the target's mental processes. The attributer does not need to know about the vagaries of human psychology because, by hypothesis, his or her own mental mechanism is subject to those same vagaries. One test of ST, according to this line of reasoning, would be to select some surprising feature of our mental life to see whether subjects can successfully attribute mental states to others where the mental processes in question exploit the surprising feature. If the attribution fails, this suggests that either the attributer's mind does not share the surprising feature, or that it is the specific lack of information about the surprising feature that is generating the failure to attribute a correct mental state. Neither of these results would be friendly to ST. The first possibility is against the very spirit of ST, while the second possibility implicates a theory of mental states.

In one attempt to pursue this line of criticism, researchers explored the counterintuitive effect (reported by Langer (1975)) whereby subjects demand more money in exchange for a lottery ticket that they have chosen than for a ticket that has just been given to them. Although there has been some concern about the reproducibility of Langer's initial results, the experiment is thought to show something unexpected about human psychology, namely, that subjects are more attached to items that they have chosen than they are to identical items that they have not chosen. Nichols *et al*. (1996) asked naive subjects to predict the outcome of the Langer experiment without actually putting them under the experimental conditions themselves. It was assumed that if, in making the prediction, the subjects simulated making a decision themselves under each of the two experimental conditions, they would be prone to the same surprising effect, valuing the ticket they had chosen themselves more than the one they had not. Thus, they would predict correctly. However, the subjects did not predict correctly, and Nichols *et al*. concluded that they were not simulating. Several problems have been noted with the experiment conducted by Nichols *et al*. A more discriminating set of experiments has been reported, with mixed results for ST (Perner *et al*., 1999).

One general objection concerns the logic of such tests. The account presented above neglects the following possibility: the experimental effect in question, such as the higher value placed on items one has chosen, may be partially due to aspects of processing that merely imagining does not, or perhaps even cannot, capture. Consider the two lines in the Mueller–Lyer illusion: remove the

arrowheads, and you are likely to judge the lines to be of equal length; merely *imagine* the arrowheads removed, and you are still likely to judge them unequal. Analogously, one may predict what people will do in situation S by simulation, in the sense of imagining being in S and deciding what to do, and yet fail to replicate all the processing that would occur if one actually were in S. If the analogy holds, then tests of ST should take account of a possible gap between imagining and replicating at a subpersonal level.

Speech Acts

Intermediate article

Robert M Harnish, University of Arizona, Tucson, Arizona, USA

CONTENTS

Speech acts are acts performed in or by speaking (or more generally, in or by using language).

INTRODUCTION

The theory of speech acts lies at the intersection of the theory of action and the theory of language, and historically the developers of speech act theory have tried to relate these two aspects. More recently, cognitive science has provided an opportunity, if not a framework, for unifying some of this work. Cognitive science is commonly viewed as the interdisciplinary study of cognition, the relevant disciplines being neuroscience, psychology, computer science, philosophy, linguistics and anthropology. Speech acts have been studied from the perspective of each of these disciplines, especially the last five.

PHILOSOPHY

The modern theory of speech acts begins with the work of J. L. Austin in the 1950s (Austin, 1962), although before this time important and interesting (albeit fragmentary) work had been done by Frege and Wittgenstein. Frege argued that sentences of natural language contain two kinds of information: information about what he called the 'force' of the sentence, and information about what he called the 'sense' of the sentence. The sense of a sentence is (roughly) the condition the world must meet for the sentence to be true. The sense of a complex expression is derived from the senses of its constituents by fitting argument names to function names – in the simplest case, singular terms to predicates. Frege did not give a general characterization of force, but he connected it with grammatical mood, and to speaking 'with requisite seriousness'. The three kinds of force he focused on were: assertive, interrogative (questions), and directive (requests and commands) (Harnish, 2001). One consequence of this view is that sense cannot be identified with linguistic meaning, because assertions, such as 'It is raining', and interrogatives, such as 'Is it raining?', have the same sense, but differ in force (and so meaning). To understand a sentence it is necessary to grasp both its sense and its force. Because Russell and the early Wittgenstein were almost exclusively concerned with logical form, they tended to neglect the non-assertive uses of language. A good example of this was Wittgenstein's early 'picture' theory of meaning. Later Wittgenstein exchanged the picture metaphor for the tool metaphor: like tools, words have many different uses, and these uses are organized in systems of what he called 'language games' (Wittgenstein, 1958). Speaking a language is like making moves in, and so following the rules of, language games. Frege's non-assertive uses of language had been rediscovered, but not systematically investigated or connected to the structure of sentences. Wittgenstein's antitheoretical stance left the study of language use fragmented until the 1950s when Austin noted that there were many uses of language which had the superficial appearance of stating facts, but really did something different: 'I do', 'I quit', 'I promise I will be there' (Austin, 1961). These are 'performatives' and their job in the language is to do something, not just to say something. As acts they have characteristic ways of succeeding and failing. Austin's famous 'doctrine of infelicities' distinguished two kinds of failure 'misfire' (the act is purported, but void, i.e. no act gets performed – this may be due, for example, to misinvocation, misexecution, misapplication of procedures, or flaws and hitches in the procedures) and 'abuse' (the act is performed, but defective – this may be due, for example, to insincerity or breaches of procedure).

Austin soon came to believe, in the face of examples such as 'I state that flounders snore', that the distinction between saying and doing

could not be rigidly maintained (but see (Recanati, 1987)), and that every sentential utterance has a performative aspect, and in the William James Lectures of 1955–1956 he moved from the special theory of performatives to the general theory of speech acts (Austin, 1962). In this theory, 'locutionary' acts are acts of 'saying something in the full normal sense', i.e. with a certain sense and reference. 'Perlocutionary' acts are acts of affecting the hearer's thought or action in some way (persuading). Austin only characterized 'illocutionary' acts, the third and most important category (which includes acts of stating, questioning, commanding, promising, etc.) by examples and by citing certain of their general features, such as being governed by conventions beyond those of grammar, sense and reference, and being capable of being made explicit by a performative prefix. He did, however, develop a preliminary taxonomy of illocutionary acts which has served as the basis for subsequent taxonomies in philosophy:

Verdictive: An act that delivers a finding based on evidence (e.g. an acquittal or estimate).
Exercitive: A decision for or against something, or a decision that something is to be so (e.g. an order or recommendation).
Commissive: An act that commits the speaker to a certain course of action (e.g. a promise or vow).
Expositive: An exposition of views (e.g. an affirmation or emphasis).
Behabitive: A reaction to other people's behavior (e.g. an apology or expression of thanks).

A theoretical breakthrough came with J. R. Searle's constitutive rule theory of speech acts (Searle, 1969), in which Austin's doctrine of infelicities was integrated with Wittgenstein's notion of language games and rule following and Frege's distinctions between force, reference and predication. Searle criticized Austin's notion of a locutionary act, and replaced it with a more abstract 'propositional' act, which allowed him to factor illocutionary acts with content into an illocutionary force (*F*) and a propositional content (*P*). Searle proposed that the illocutionary force component of a (nondefective) illocutionary act, for example a promise, can be analyzed into four kinds of condition:

1. Propositional content: A future act of the promiser.
2. Preparatory: The promiser can do the act, and the promisee would prefer the promiser to do it than not to do it.
3. Sincerity: The promiser intends to do the future act.
4. Essential: The utterance declares an obligation to do the future act.

These act-specific conditions were supplemented by general background ('input-output') conditions for linguistic communication, as well as by a more controversial Gricean condition (see below) on saying something and meaning it, thereby also capturing Frege's idea that force is connected with 'requisite seriousness'. If these conditions are met in uttering an expression, such as 'I promise I will be there', then the speaker has promised. And if the speaker has (nondefectively) promised, then he or she must have met these conditions. Moreover, sentences of a natural language can typically be semantically analyzed into a device which indicates the illocutionary force of the sentence and a device which indicates the (propositional) content of the sentence. In the above example, 'I promise' is the device for indicating a promise (*Pr*), and 'I will be there' is the device for indicating what is promised (*P*). The constitutive rules for the use of the device *Pr* are derived from the above conditions. For instance, the associated rules say: (1) utter *Pr* only if conditions 1–3 are met (these are 'regulative' rules, which regulate preexisting forms of behavior), and (2) the utterance of *Pr* counts as meeting condition 4 (this is a 'counts-as' rule, which defines a new form of behavior). Searle also follows Frege in viewing the semantics of sentences as compositionally determined by the semantics of their constituents, and proposes propositional acts of referring and predicating governed by constitutive rules similar to 1–4 above. We have arrived full circle at Frege's idea that sentences are analyzable into force and content; and we now have an articulated theory of illocutionary force, requisite seriousness, reference and predication. Searle criticized Austin's taxonomy of illocutionary acts for being unprincipled and failing to distinguish illocutionary acts from illocutionary verbs (see (Wierzbicka, 1987)), and he offered his own alternative taxonomy of illocutionary acts (Searle, 1979):

Assertive: An act that commits the speaker to something being the case (e.g. a statement or claim).
Directive: An attempt to get the hearer to do something (e.g. a request or command).
Commissive: An undertaking to do something (e.g. a promise or vow).
Expressive: An expression of a psychological state of the speaker (e.g. a congratulation or apology).
Declaration: An act that brings about the state of affairs mentioned in the propositional content (e.g. adjourning a meeting or resigning a position).

Unlike Austin, but following Grice (see below), Searle also systematically investigated indirect and nonliteral uses of language, such as: 'Want to go to the movies tonight?' 'I have an exam

tomorrow' (indirect: 'No, I can't'); or 'Sally is a block of ice' (nonliteral: 'Sally is cold and unresponsive'). Searle and Vanderveken have also investigated aspects of illocutionary logic (Searle and Vanderveken, 1985) (see also Vanderveken, 1990). Although Searle describes the above rules as 'semantic' rules, he did not formulate a general theory of how they could confer meaning on expressions. W. Alston has modified Searle's theory of illocutionary acts using the notion of 'taking responsibility for satisfying a condition' as central in such a way that it can form the foundation for a use theory of meaning (Alston, 2000).

At the same time as Austin and Searle were developing the theory of speech acts in terms of conventions and rules of language use, H. P. Grice was developing a theory of language based primarily on the notions of a speaker's beliefs, desires, and reflexive communicative intentions (Grice, 1989). Grice analyzed 'meaning something' (by uttering something) as intending to produce some effect in a hearer by means of the hearer's recognition of that intention. Furthermore, what the speaker means is specified by the intended effect: either a belief, for transfers of information (e.g. assertions), or an intention to act, for attempts to get people to do things (e.g. commands). Finally, what an expression means in the language is related to what speakers mean in uttering it. Grice briefly discussed how these two central categories of meaning and speech acts might be related to sentential mood (declarative, imperative, interrogative), but his main interest was in analyzing the 'total signification of an utterance', and here he drew the distinction between what is 'said' (related to Austin's 'locutionary' act and Searle's 'propositional' act) and what is conventionally and conversationally 'implicated':

> Conventional: 'She's poor but she's honest.' (Implicature: poverty contrasts with honesty.)
> Conversational (particular to the situation): 'He likes his colleagues at the bank and hasn't been to prison yet.' (Implicature: he might be tempted to take some money.)
> Conversational (general, usually implied by the form of words): 'He's meeting a woman.' (Implicature: she's not his mother, sister or close 'Platonic' friend.)

Conversational implicatures depend on spoken exchanges being 'cooperative' ventures between speaker and hearer, where cooperation often amounts to conforming to various 'maxims of conversation', such as: *quantity* (make your contribution just as informative as is required for the current purposes of the exchange); *quality* (do not say what you believe to be false or what you lack adequate evidence for); *relation* (be relevant); and *manner* (be perspicuous, brief and orderly, and avoid obscurity and ambiguity).

Speakers conversationally implicate something (*Q*) in saying something (*P*) by 'flouting' a maxim, i.e. by causing the hearer to reason as follows: the speaker is obeying the maxims, but in order for this to be true something must be being communicated that is not what is being said (*P*), and the likely candidate for this is *Q*. Davis (1998) has examined the explanatory adequacy of Grice's theory of implicature. Others have questioned Grice's suggestion that what is meant consists only of what is said and what is implicated. The utterance 'I've had breakfast' generally communicates that I've had breakfast *today*, but that information does not seem to be a part of the semantics of the sentence, nor does it seem to be implied by any flouting of the maxims. So where does it come from and what is its status? Sperber and Wilson (Sperber and Wilson, 1986) and Recanati (Recanati, 1989) opt for including it in an expanded conception of what is said (and an expanded role for pragmatics in determining it), whereas Bach opts for a narrower Gricean conception of what is said (Bach, 1994). All agree that mechanisms of 'completion' and 'expansion' are required to supplement Grice's account. Finally, Grice's theory of generalized implicature has recently been refined (Levinson, 2000). Grice envisaged a unified theory of meaning, saying, speech acts and communication, but, like Austin, did not live to complete it himself.

In one direction, Grice's ideas about meaning and speech acts were modified and developed by S. Schiffer, who first argued for an alternative analysis of speaker meaning, then, modifying D. Lewis (Lewis, 1969), worked out an analysis of convention, and connected it to speaker meaning by analyzing what it is to be the conventional meaning of a linguistic expression. Finally, building on his characterization of speaker meaning, as well as ideas of P. Strawson (Strawson, 1964), he proposed a taxonomy of illocutionary acts which divided them into an 'assertive' class and an 'imperative' class. Each of these classes was divided into three subclasses which were defined in terms of the form of the belief or desire, and the reasons being offered to form that belief or desire.

In another direction, Grice's ideas about speech acts and communication were developed by Bach and Harnish, who extended and schematized the inference pattern behind conversational implicatures and extended it to speech acts in general (Bach and Harnish, 1979). They studied inferential

strategies for direct, literal, nonliteral and indirect communication, along with the presumptions which drive such inferences. They proposed a taxonomy which divided illocutionary acts into two major categories, conventional (acts performed by satisfying a convention) and communicative (acts performed by having a reflexive intention recognized). Each of these categories was further subdivided as follows:

Conventional

Effective: An act that effects changes in institutional status (e.g. vetoing a bill).

Verdictive: A judgment that has official consequences (e.g. calling a runner out).

Communicative

Constative: An expression of belief (e.g. an assertion).

Directive: An expression of desire (e.g. a request).

Commissive: An expression of intention to undertake an obligation (e.g. a promise).

Acknowledgment: An expression of feelings or compliance with social expectations (e.g. an apology).

LINGUISTICS

In the 1970s linguistics and philosophy were closely related: philosophers of language were making regular appeals to the work of Chomsky and transformational grammar; while linguists, especially those involved in the 'generative semantics' movement, were appealing to work in logic and the philosophy of language, in particular to Austin's notions of performatives and felicity conditions. J. Katz and P. Postal argued, on the basis of linguistic data, for the Fregean idea that information concerning (illocutionary) force is coded into the mood structure of sentences (Katz and Postal, 1964). They proposed that this coding takes the form of abstract morphemes, with semantic interpretations, which trigger syntactic transformations and related lexical and phonological changes characteristic of moods. Declarative sentences are the unmarked case, but interrogative sentences share an abstract question morpheme *Q* which indicates a question, and imperative sentences share an abstract imperatival morpheme *I* with roughly the sense of 'the speaker requests'. J. R. Ross argued, in effect, that these markers are actually higher embedding clauses in the deepest structure of the sentence, which usually remain unspoken and unwritten, and have the form of Austin's performative prefixes (such as 'I promise') (Ross, 1970). Consequently, the seemingly simple sentence 'Floyd sucks eggs' actually has the structure of a complex sentence: 'I assert to you that Floyd sucks eggs.' Similar proposals were made for interrogatives and imperatives (Sadock, 1974); but the 'higher performative' analysis of force had serious problems (Gazdar, 1979), and was abandoned with generative semantics in the 1980s, though much of their data remains unaccounted for to this date.

Katz proposed to incorporate force into the alternative 'interpretive semantics' framework (Katz, 1977). Like Frege, he thought that sentences contain speech act information (which he called 'propositional type') and propositional content. The propositional content is divided into referential information and predicative information (which Katz calls the 'condition'). When the type of the sentence is assertive, it converts the condition into a truth condition, thus correctly connecting assertion with truth. When the type of the sentence is requestive, it converts the condition into a compliance condition, thereby correctly connecting request with compliance. Katz proposes a provisional alternative categorization of illocutionary forces as encoded into the meanings of sentences. These include: requestives, advisives, expressives, permissives, obligatives, expositives and stipulatives. In the 1980s, linguistics, inspired by Chomsky's 'government-binding' framework, turned to comparative studies, especially in syntax. The search for linguistic universals spread naturally to illocutionary force, and the question arose: how similar are languages in the way they encode speech act information? J. Sadock and A. Zwicky, working with a conception of mood that involves the conventional pairing of sentence structures with speech acts, surveyed 23 languages from a variety of families and found a number of general similarities for the major moods (declarative, imperative, interrogative), but very few for the minor moods (tags, exclamations, optatives, etc.) (Sadock and Zwicky, 1985). Generalizing on their work, Harnish proposed a theory of the major moods in terms of sentence structure (including intonation), direction of fit, and speech act potential (Harnish, 1994).

PSYCHOLOGY

Psycholinguistics blossomed with the ascendancy of Chomsky's idea that a linguist's grammar records facts of linguistic 'competence', which itself plays a role in linguistic 'performance', but until the 1970s most of this work was concentrated on speech, words and syntax. With the rise of interest in semantics and speech act theory, some psychologists began to investigate these aspects of language processing and acquisition. Psycholinguistic methodology typically uses reaction times and error

measures to study underlying psychological mechanisms and representations, and the aspects of the theory of speech acts most amenable to these methods were the inferences underlying indirect and nonliteral communication, and conversational implicature. H. Clark and his colleagues have conducted a number of experiments to test whether the stages of inference proposed by speech act theorists are psychologically realistic. In one study, Clark and Schunk (1980) noted, following Brown and Levinson (Brown and Levinson, 1978), that one reason for speaking indirectly is politeness, and they proposed to treat requests as polite to the extent that the cost to the hearer of complying with the request diminishes or the benefit to the hearer increases. On the hearer's side, Clark and Schunk suggested the 'attentiveness hypothesis' (AH): The more attentive the hearer is to all aspects of the speaker's remark, within limits, the more polite it is. In a pair of experiments it was found that AH could account for a significant amount of the correlation in these rankings, and to that extent these experiments support the view that the literal meaning is being processed in such cases. Much of this research is reviewed in (Clark, 1992). In another pair of experiments, Gibbs gave subjects sentences such as 'Must you open the window?' embedded in two different contexts: one that biased their understanding towards the literal and direct interpretation, and one that biased their understanding towards the indirect message (Gibbs, 1979). Puzzlingly, it was found that subjects took less or equal time to judge the indirect interpretations in context compared with the time they took to judge the literal ones. Gibbs has also conducted experiments on figurative language and metaphor (Gibbs, 1994), and others to determine how pragmatic processes determine what is said versus what is implicated (Gibbs and Moise, 1997).

COMPUTER SCIENCE

Winograd's work was a landmark not only in artificial intelligence, but in computational linguistics (Winograd, 1972). Although limited to a microworld of blocks and surfaces, it successfully processed fluent, flexible natural language dialogue in all the major moods. This work led to a bifurcation in the goals of natural language processing studies: building a natural language interface to communicate with computational systems, and building a computational model of human language processing. To achieve either of these goals would require speech act information to be expressed, and recognized, in language (Allen, 1987). The most common and influential approaches to this have been 'plan based'. Cohen and Perrault proposed that a theory of speech acts might be achieved by modeling requests, assertions and questions in a general planning system using operators with associated preconditions and effects defined in terms of the speaker's and hearer's beliefs and wants (goals) (Cohen and Perrault, 1979). Plans are sequences of operators for achieving goals, given certain preconditions, and speakers (agents) achieve goals by constructing and executing these plans. Searle's analysis of illocutionary acts (see above) was the starting point of their investigation, but constraints on compositionality and point of view analysis eventually moved the theory in a more Gricean direction (see above). Perrault and Allen modified and extended this analysis of (direct) illocutionary acts to indirect acts of requesting, including questions as a special case, using Gricean principles of cooperation (plan inference) and rationality (plan construction) (Perrault and Allen, 1980). (*See* **SHRDLU**)

ANTHROPOLOGY

One of the distinctive contributions of anthropology (and other social sciences) to cognitive science is the cross-cultural perspective. One interesting and ambitious research program was the Cross-cultural Speech Act Realization Project (Blum-Kulka, House and Casper, 1988). In these studies a 'discourse completion test' was given to speakers of a variety of languages (Danish, English, French, German, Hebrew, Spanish), belonging to a variety of cultures (American, Argentinian, Australian, Canadian, Danish, English, Israeli), who had to complete a dialogue involving characters of varying social distance (e.g. friends, strangers) and relative status (e.g. professor and student) either requesting or apologizing. These completed dialogues were then scored and analyzed to assess the connections between, for example, the indirectness and politeness of the request, the social roles of the characters, and the language or culture of the person completing the dialogue. In general, politeness was correlated with indirection, but different languages and cultures responded to the dialogue situations quite differently, in ways that are difficult at present to explain.

EXTENSIONS AND CRITIQUES OF SPEECH ACT THEORY

It is characteristic of, though not required by, speech act theory that individual speech acts,

however analyzed or categorized, are regarded as being performed in the utterance of single sentences (or fragments of sentences functioning as sentences). But we normally speak in connected series of sentences which form discourses or conversations. Speech act theory has been extended to include discourse and conversation as structured series of individual speech acts (Labov and Fanshel, 1977). Greetings invite greetings; questions invite answers; apologies, requests and offers invite acceptance (or denial); statements invite agreement (or disagreement); accusations invite denial (or acceptance); goodbyes invite goodbyes. But the idea that speech acts are useful categories of analysis for naturally occurring speech, discourse and conversation has been seriously questioned (Levinson, 1981; Schegloff, 1988). There are two main objections, which are related. First, speech act categories are too coarse and rigid to capture the fluid context-dependence of most conversational moves. Second, there is no principled correspondence between speech acts and individual sentences. The alternative proposal is that naturally occurring speech must be analyzed at a lower level, using a different vocabulary from that of high-level speech act theory. Some speech act theorists think that these objections are not essential to the speech act perspective, which was never intended to be exhaustive (Searle, Parret and Verschueren, 1992). Geis has attempted to combine speech act theory with conversational analysis and related work on computational speech acts (Geis, 1995).

Split Brains, Philosophical Issues about

Intermediate article

Grant Gillett, University of Otago, Dunedin, New Zealand

CONTENTS

A split brain is a brain in which the large bundle of fibres called the corpus callosum is divided. In such brains, information flows separately into the right and left hemispheres.

CLINICAL FINDINGS

The split brain syndrome results from a commissurotomy: an operation in which the large bundle of fibres connecting the two cerebral hemispheres is divided. A number of such operations were done in the 1960s and 1970s to relieve intractable epilepsy (Gazzaniga, 1970). There were two reasons why it was thought acceptable to undertake such a major procedure: first, it was an intervention of last resort for some severely affected epileptic patients; and second, it was difficult to detect any neuropsychological deficits following the operation. So subtle were the effects that it was widely believed that a section of the corpus callosum had no adverse effects on behavior (Parkin, 1996, p. 111). Indeed, most patients, after recovery from surgery, are untroubled in their everyday lives, and even now the literature on split brain patients confirms that 'a typical medical examination would not reveal anything unusual in their behavior, and their scores on standard tests are normal' (Kolb and Whishaw, 1990, p. 808). The most usual indication for this operation – the presence of intractable epilepsy arising from one or other hemisphere which can be limited in its effects by preventing the other hemisphere from being recruited in the course of a seizure – usually entailed that one side or other of the brain was abnormal because of the damage causing the epilepsy. Although such patients often had pre-existing damage in one hemisphere, they typically experienced no adverse events from the surgery itself. However, interesting patterns of behavior emerged on neuropsychological testing for cognitive disconnection.

Most of the experimental work used tachistoscopic exposure of visual stimuli so that they were confined to one or other half of the visual field (Gazzaniga, 1970). A number of different tests showed that a commissurotomy patient's response depended on whether it was controlled by the right hemisphere (e.g. picking out an object with the left hand) or the left hemisphere (e.g. verbal report). The typical disconnection syndrome resulting from commissurotomy is a combination of right-handed apraxia (defective visuospatial abilities at least in relation to complex tasks) and left-handed agraphia (inability to write). Such findings lead some to claim that commissurotomy patients develop different streams of consciousness, one located in each hemisphere: 'Each hemisphere can be shown to have its own sensations, thoughts, percepts, and memories that are not accessible to the other hemisphere' (Kolb and Whishaw, 1990, p. 808). And the problems are not confined to the experimental setting.

Disconnection is also revealed by confabulation when anomalies occur (Gardner, 1974, p. 361). For instance, a picture of a door may be shown 'to the left hemisphere', and a picture of a hammer 'to the right hemisphere'; when asked why the left hand is picking out a nail, the subject may say that you build doors with nails. Here each hemisphere deals with the information it has as best it can and the subject deals with discrepancies by using a technique – confabulation – often seen in amnesic or other cognitively impaired subjects. A further puzzling and bizarre manifestation of commissurotomy is 'manual conflict' or 'alien hand', where one hand interferes with the actions of the

other: 'the patient once grabbed his wife with his left hand and shook her violently while, with his right hand, he sought to rescue her and bring the violent left hand under control' (Gardner, 1974, p. 359). This is deeply problematic for traditional approaches to the philosophy of mind.

The problems become still more complex when we look at the way that subjects admonish and correct themselves, and also cheat, in order to overcome their problems (Weiscrantz, 1997). For instance, if information is delivered to one hemisphere and the parts of the body controlled by the other have to respond (e.g. by report, when the object is projected in the left visual field, or by picking out the object from an array with the hand ipsilateral to the visual field in which the picture of the object was presented), a common form of 'cheating' is to use facial expressions such as smiles and frowns to let the 'ignorant hemisphere' know what the right answer should be. This works because emotional expressions are bilaterally innervated (by sensorimotor systems).

PHILOSOPHICAL INTERPRETATIONS

A number of philosophers, including Nagel, Wiggins, and Parfit, have developed theses about the nature of conscious mental life and its unity or otherwise. These divide into three groups:

- There is a normal unity of conscious identity which is mental rather than physical but which is subserved by the hardware (or wetware) of the brain.
- There is no more to mental unity than a unity of diverse functions, each supervenient on localized brain processes (Nagel, 1979).
- There is no essential unity even in the mental life of a person. What matters to any of us are the relations of continuity and connectedness between mental states, which are the real basis of survival (rather than an enduring locus of personal identity) (Parfit, 1984).

It is problematic for dualists that certain mental acts are subject to profound disruption by an operation on the brain. Robinson (1976) calls such effects 'epistemic contradictions' and so places them among those functions associated with a 'mind, or intelligence, or intellect, or reason' (to quote Descartes in his *Fifth Meditation*). But Descartes also remarked, in his *Sixth Meditation*, that an essential feature of the mind as distinct from the body was its indivisibility. Thus if the mind is divided in split brain cases then Cartesian metaphysics is wrong. The remaining – monist – views are nonreductive only if we can suggest some reading of 'mental identity' that does not amount to the view that the mind is merely a set of functions supervenient on (or reducible to) neural functions.

Monist supervenient or reductive views clearly receive support from the split brain cases. It looks as if properties of mind such as the capacity to reason, form beliefs, perceive what is going on in the world, and act with intention are dissociated by commissurotomy into two sets, one per hemisphere. That is the conclusion reached by Nagel (1979), who claims that 'the numerically single subject is an illusion'. Parfit (1984, p. 251) remarks that 'the existence of a thinker just involves the existence of his brain and body, the doing of his deeds, the thinking of his thoughts and the occurrence of other physical and mental events'. Parfit denies that there is anything corresponding to Descartes' 'necessary unity of consciousness'. He concludes that all there is to mental unity is a set of relations (of connectedness and continuity) between mental states and events.

However, there is a difficulty with this position. In the experiments themselves, the subjects attempted to overcome their epistemic problems. They did this in a variety of ways, including self-correction and self-cueing (for instance by facial expression), and with such success that, even in the test situations, after a time the original neuropsychological problems cannot be demonstrated (Weiscrantz, 1997).

There are two important philosophical implications of this finding. First, each subject noted something amiss in his or her cognitive processes and interpreted it as an internal disruption of information flow. This led to a coordinated behavioral strategy aimed at correcting a perceived disability or departure from normal cognitive function. Thus, to all intents and purposes, the subject exhibits (verbally and practically) the belief (or attitude) that he or she is a single subject with cognitive problems.

Second, some argue that this attitude, and the coordinated strategy it calls forth, entails that there is something which the split brain patient is still 'one of'. This 'something' clearly exhibits reason, perception, and (perhaps impaired, but gradually reintegrated) action. Thus the subject, although temporarily 'fragmented' by cognitive defects, works, during his recovery, on the project of reintegration.

We therefore need a philosophical account of identity and consciousness that accommodates these phenomena.

IDENTITY AND CONSCIOUSNESS

The reductive view would be undermined if we could show that the constitution of thoughts,

perceptions and actions as 'contentful mental acts' requires an underlying unity of consciousness. Such an argument would have widespread implications for ascriptions of mental content in the context of brain damage.

Kant (1789) argued that every representation results from an act of judgment and implies a unitary 'I think' or a unified locus of conscious activity comprising the requisite cognitive skills. The thesis is that, in forming any mental representation, the subject judges that a number of presentations can be unified by being subsumed under a concept which then confers content on that representation. Thus a thinker confronting a small grey furry animal might judge that it is a possum. That judgment assimilates the present set of conditions to those conditions (experienced at other times) that justify the judgment 'possum'. This logically entails a mental unity between the epistemic subject now making the judgment and the subject who has mastered the requisite technique of judgment. This purely transcendental requirement (of Kant and the phenomenological tradition) can be developed further in a naturalistic approach to the mind.

The mental subject who judges in accordance with rules governing the use of concepts learns from those who impart the concept to him. His activity must be manifest so that others can converge in their judgments and participate in the application of consistent norms. The norms require the teaching of correct intentional responses to conditions which are public and are thereby incorporated into the structure of the subject's epistemic repertoire (Macdonald, 1998). On the basis of this activity, the subject develops as a locus of mental activity.

This practice is the basis of what we might call, after Wittgenstein, the grammar of self-ascription and self-reference: the application to oneself of mental predicates. Thus the mental subject is constituted as a unitary locus of those mental properties comprising consciousness. This creates a prerequisite for coherent mental content and therefore a normative influence favoring the reintegration of self after any disruption to it. These considerations lead to the philosophical position on mental ascriptions where the brain is damaged summarized below.

1. One's own conceptual relation to oneself shares truth conditions with judgments embedding mental concepts as used by coreferential others.
2. The relevant truth conditions are one's own manifest intentional activity.
3. One's own access to that activity is not the same as any other person's, and neither is one's access to the mental content informing it.
4. First- and third-person content attributions can fail because of imperfect knowledge on the part of the third or less commonly the first, person.
5. One situation in which first-person content attributions can fail is when a subject's broken brain affects knowledge and may disrupt the pattern of intentional activity that forms the basis of mental ascriptions.
6. One always tries to make sense of a single person's behavior as a tolerably coherent stream of intentional activity. This normatively driven exercise plays a central role in human activities. It underpins many of the things we do and think and it helps to bind the social enterprise of human survival.
7. The narrative self is a norm that cannot be discarded, but its application may be problematic if the brain is broken.
8. A subject always tries to get a narrative coherence into his or her conscious life. Hence even a fragmented brain will attempt to construct a unitary self as the emergent locus of mental activity on the basis of a holistic pattern of behavior.

Although this argument is based on the idea of mental content, it might be argued that what we have in the split brain case is not a single conscious subject but rather a pair of subsystems each exposed to the relevant norms but only partially equipped with the cognitive equipment to comply with them. It remains to be seen which is the best way to account for the clinical and neuropsychological data.

EMERGENT IDENTITY

The argument about the necessary unity of consciousness suggests that the split brain data reveal a single subject who is driven to give a unified account of his or her conscious experience, and sees himself or herself as laboring under epistemic difficulties arising from a commissurotomy. However, some would argue that the conscious subject is just a bundle of mental states and events loosely held together by a material substrate, or even a set of cognitive subsystems working together to provide a relatively coherent behavioral output. Reductionism, in either one of its forms, seems like a strong contender for the metaphysics of people where the mind is seen as being supervenient on a base physical level of reality. To some philosophers this has seemed like the only viable monist alternative, but the possibility of emergence suggests another naturalistic possibility.

The person, according to the anti-reductive or emergent view, is a single embodied subjective

and rational being who does the best he or she can using cognitive mechanisms which are designed to pick up information from the environment and produce a coherent stream of behavior. The person, on this view, holistically fashions an individual story based in a shared natural history, and usually has the cognitive resources to meet the demand that one should lead a unified conscious life as a being among others. This view, traceable back to the metaphysics of philosophers such as Strawson (1959) and Hampshire (1959), identifies the mind with a facet of a living, functioning human being taken as an individual. The naturalism inherent in this anti-reductive approach is appealing when we look at recent findings in subjects with a commissurotomy.

HOW FRAGMENTED NEUROCOGNITIVE FUNCTION MIGHT BE INTEGRATED

Traditionally, 'how' questions have been regarded as the province of science rather than philosophy. But there are areas of cognitive science where philosophical approaches to the mind can be illuminated by empirical data.

The reintegration of the mind after the splitting of its neural substrate is an area where philosophers can both learn and contribute. Neuropsychologists have tended to concentrate on internal neurocognitive mechanisms and the direct transfer of information between hemispheres using existing brain pathways, but there may be other mechanisms involved.

The ongoing activity shaping a human brain as an organ of cognitive adaptation to the environment is bodily activity. The behavior of any subject is the activity of an intentional agent with continuity of identity over time and a (more or less) coherent narrative about that activity. Therefore if there is no stable representation without neurocognitive change, it follows that a normative set of expectations that influence a subject's representation of self and world will induce the plastic brain to realize certain processing patterns. One would therefore expect the brain to find means of cognitive reintegration after commissurotomy. The two hemispheres do not have many ways of communicating; and yet the task is so central in human adaptation that any pathway or potential pathway will surely be used, even if they do not function as well as the neural pathways that are provided by our evolutionary history and strengthened by a lifetime of experience.

Weiscrantz (1997, p. 34) reported: 'Indeed those split-brain patients that I later studied no longer denied seeing stimuli projecting to the right hemisphere – they could give accurate descriptions and approximate dimensions of them.' Weiscrantz mentions neural plasticity and 'indirect bodily signaling stratagems' to account for this recovery. Few pathways are available for hemispheric reintegration once the major commissure with its 200 to 800 million fibres is severed (Kolb and Wishaw, 1990, pp. 504–506). But an interesting possibility is suggested by the fact that some of the patients cheated (one of Weiscrantz' 'indirect bodily signaling stratagems'). Not only does this indicate that the patient still behaves as if he or she is one self, albeit prone to certain kinds of errors, but also that direct transfer of information in the brain is not the only way to reintegrate cognition. The persistent psychological tendency to act as one subject – something that should not happen if the fragmentation of the system entails a fragmenting of the self (because of a strong supervenience of the mental on the physical) – might arise from public norms operating on the subject. But how can the brain achieve this reintegration given the poor resources available after commissurotomy?

According to the holistic view (and considering that a person resorts to indirect strategies), we can remark that the question is flawed – it is the person who achieves this and overcomes the fracture in the brain. We have noted the arguments based on mental content and the demand for reintegration in discussing what we might call the logical requirements of self- and other-ascription. On the view of mental ascription outlined above, a subject requires a body to manifest mental content and to provide a focus for mental ascriptions. Therefore the body is another resource to use in solving cognitive problems. This raises the possibility that, just as the body (or more correctly the embodied person) is the focus of the normative practices which impel towards reunification of the cognitive apparatus, so it might be the medium of neurocognitive reintegration.

All thinking is accompanied by, and even facilitated by, covert neuromuscular activity, involving either the movements that would be involved in the situation being thought about or the subvocal utterance of the words that would be said if the representation were articulated. McGuigan (1997) and others have provided persuasive evidence that cognitions are 'covert reactions' forming 'components of neuromuscular circuits governed by

cybernetic principles' and that 'where the striated musculature is totally inactive, cognitions are inactive'. If this is true, then the whole body is a massive display which exhibits cognitive processes; and it is subject to real-time proprioceptive monitoring. We know that connections between the brain and the body are very rich, two-way, and significantly bilateral. Ordinarily, the dominant traffic is between either half of the brain and the opposite side of the body – though there is also extensive ipsilateral information flow. Thus it is possible that cognitive reintegration is achieved by the brain using the body to talk to its other half rather than via the surviving direct connections. This would be a subliminal version of what often goes on in the so-called 'indirect cueing' of split brain patients during neuropsychological tests.

The implication is that, in cognition, it may be that 'meaning is use'. In other words, cognitive representation may be, at least in part, subliminally 'acting out' the responses that the subject has developed for dealing with a particular set of conditions. Furthermore, the subject might use such 'acting out' to determine what he or she thinks. We may need to reconsider the problem of mental ascriptions in split brain patients and the related ideas concerning the unity of consciousness and the nature of the self.

The dynamic nature of the problems following commissurotomy suggest a reassessment of the mental ascriptions to split brain patients, in much the same way as the phenomenon of blindsight has forced us to reassess visual perception. It is difficult to ascribe conscious intentional content in a split brain case. Our common practices of mental ascription do not apply, because the subjects have only partial cognitive access to the contents in question. The work of Block (1995) and others on theories of consciousness focusing on cognitive access seems to be highly relevant to the split brain data. It is clear that the split brain subject can only do certain things with the information gathered from the environment, and, to the extent that the subject has disconnected conscious access to that information, mental ascriptions are made for which the normal causes do not exist and which do not carry their normal entailments. Thus it is unclear the extent to which we can say that the subject is conscious (*simpliciter*) of, say, the object presented to the left visual field, despite the fact that some of the intentional responses to such data would, in a normal subject, justify ascriptions of conscious mental states.

This is consistent with a Wittgensteinian or even Dennettian view of conscious cognitive life (Gillett, 1999, pp. 102 ff.). Wittgenstein locates consciousness and thought in general in our normal practices of dealing with one another using language as a set of tools to understand and facilitate that interaction. Dennett regards conscious mental life as a 'lived narrative' or discursive articulation of what is happening in a seamless neuro-environmental interaction (1991). The narrative so constructed is jointly shaped by automatic responses and information gathering patterns, habits, well-rehearsed strategies for representation, the links between words and their truth conditions, and the intentional or voluntary direction of one's activity (using discursive techniques). A constant part of that neuro-environmental stream is, it seems from McGuigan's work, covert neuromuscular responses which mirror or reproduce (as it were in miniature) the subject's ways of responding to things. The conscious self is a holistic product of this stream as articulated using both linguistic and nonlinguistic techniques developed during the engagement of a person in his or her complex (natural and cultural) environment.

Therefore to try and find a 'self' in some part of the brain is as futile as Hume believed it to be on the basis of introspection and Kant argued that it was on the basis of transcendental analysis of consciousness and reason. The person who comes to think of himself or herself as a unified center of consciousness is a holistic or emergent unity born of environmental pressure on a physical focus (the body). The self as subject of thought and experience (as the reference of an integrated set of self-ascriptions) is a locus of purposive activity with intentional relations to its environment through the body. Thus the self, we might say, is necessarily embodied and therefore necessarily subject to disruptions of its internal causal structure in certain ways. But that is not to say that the subject can be reduced to a collection of physical processes or functions.

SUMMARY

We might view the philosophical implications of the split brain as follows.

1. The brain's functions can be split by commissurotomy into a set subserved by the left brain and a different set subserved by the right brain.
2. This does not bring about a fragmentation of the self: in fact, the self tries to overcome the problems caused by the damaged brain.
3. The self as integrated subject of mental ascriptions is a precondition for the ascription of 'conscious mental content' as we typically understand it.

4. The grasp of mental content is rooted in a public or shared world in which an embodied subject adapts to norms governing the conditions in which the content is properly exhibited.
5. The norms governing the causes and entailments of mental content are violated in the case of a split brain patient.
6. The relevant truth conditions for the judgments we normally make about mental content therefore rest on the bodily integrity of the subject and his or her more or less coherent human activity in relation to objects in the environment (so that the subject's states are intentional in the phenomenological sense).
7. A subject is not an immaterial Cartesian being. Events in the brain importantly affect mental ascriptions (and self-ascriptions).
8. First- and third-person content ascriptions can fail to meet their normal criteria in disconnection syndromes.
9. A broken brain affects both first-person and third-person knowledge of mental activity.
10. We try to make sense of a person's behavior as a coherent stream of intentional activity, so that the unity of the self is a socially enforced norm (based on normal embodiment), which may not be easily applied if the brain is broken.
11. The subject always tries to give his or her activity narrative coherence. Even the fragmented brain constructs a tract of emergent and more or less coherent activity.
12. The resources for reintegration are available to an embodied neurocognitive organism through social forces and interaction with a natural environment.
13. The subject is best thought of nonreductively, i.e., not just as a set of states and events produced by a brain but as a unified discursive subject inhabiting a shared world with others. On this basis we can understand the processes that overcome the defects caused by a broken brain.

A human being seems to operate as a unitary conscious self drawing on conceptual techniques that are learnt discursively. The idea that one configures oneself by the use of such techniques explains most of the findings about the fragmented self that are often held to be damaging to the folk conception of personal identity – or what makes a person the same person at different times and places. On this view, a person is not reducible to a set of states and events and the relations between them (as implied by the reductive view), and can, as Luria (1973) colorfully puts it, 'fight with the tenacity of the damned to recover the use of his damaged brain'.

Symbol Systems

Intermediate article

Michael L Anderson, University of Maryland, College Park, Maryland, USA
Donald R Perlis, University of Maryland, College Park, Maryland, USA

CONTENTS

A symbol is a pattern (for example, of physical marks, or electromagnetic energy) that denotes, designates, or otherwise has meaning. The notion that intelligence requires the use and manipulation of symbols, and that humans are therefore symbol systems, has been very influential in artificial intelligence.

INTRODUCTION

We begin this article with a presentation and discussion of the idea of a physical symbol system (PSS), as formulated by Newell and Simon. This notion – and the associated physical symbol system hypothesis (PSSH) – was first presented, under a somewhat different name, in Newell and Simon (1972), with later fuller formulations in Newell and Simon (1976) and Newell (1980), and still later elaborations in Newell (1990).

We then discuss various objections to PSSH, and replies to those objections, especially with reference to the themes of symbol grounding, situated cognition, embodiment, and situated robotics.

PHYSICAL SYMBOL SYSTEMS

In 1972 Allen Newell and Herbert Simon published their seminal book *Human Problem Solving*, in which, among many other things, they described 'information processing systems'. In 1975, Newell and Simon were jointly awarded the ACM Turing Award, and on that occasion they presented a paper in which they offered a more succinct description of these systems, under the now-standard name of 'physical symbol systems' (Newell and Simon, 1976, pp. 114–116):

> One of the fundamental contributions of computer science has been to explain, at a rather basic level, what symbols are … Symbols lie at the root of intelligent action … One [structural] requirement [for intelligence] is the ability to store and manipulate symbols. …
>
> A physical symbol system consists of a set of entities, called symbols, which are physical patterns that can occur as components of another type of entity called an expression (or symbol structure). Thus, a symbol structure is composed of a number of instances (or tokens) of symbols related in some physical way (such as one token being next to another) … A physical symbol system is a machine that produces through time an evolving collection of symbol structures.

So defined, PSSs are very broadly conceived, largely because symbols themselves are conceived in very broad terms. Indeed, it would be difficult to specify any physical entity that would not count as a 'symbol' by this definition.

Associated with the notion of a PSS are various further notions. Thus, an expression in a PSS 'designates' an object if the PSS's behavior depends on the object (for instance by affecting the object); and a PSS can 'interpret' one of its expressions E if E designates a process that the system can carry out.

Designation and interpretation are intended to connect the PSS to the world. That is, the PSS must be able, somehow, to ground its symbols in real referents, and to act upon them. Moreover, in allowing for the double role of object (designatee) and process in a single expression (so that 'pull the chain' is both a sentence and a process), a PSS appears able to play the role of a self-modeling agent. This is crucial to the development of Newell and Simon's criteria for general intelligence. (*See* **Symbol-grounding Problem**)

Newell and Simon (p. 116) then assert the PSSH:

> A physical symbol system has the necessary and sufficient means for general intelligent action … This is an empirical hypothesis.

Given how broadly a PSS is defined, human brains would seem to count as PSSs. Our brains appear to manipulate symbol structures and carry out processes on the basis of (some of) those structures,

which in turn affect objects in the world (as well as other symbol structures). Thus the PSSH might seem obviously true, but Newell and Simon do not see it as obvious. Their hope is that ongoing research in artificial intelligence will succeed in 'bringing forth empirical evidence' in favor of PSSH. In the remainder of their 1976 paper they discuss evidence for PSSH, especially in terms of heuristic search via the 'heuristic search hypothesis' (p. 120):

> The solutions to problems are represented as symbol structures. A physical symbol system exercises its intelligence in problem solving by search – that is, by generating and progressively modifying symbol structures until it produces a solution structure. …
>
> Physical symbol systems must use heuristic search to solve problems because such systems have limited processing resources. (*See* **Search**)

Later, Newell (1980) explored the nature of PSSs in more detail, relating them to standard theoretical machinery. For instance, he defined PSSs simply as universal Turing machines: machines that can be programmed so as to simulate any computationally possible procedure whatsoever. Such a machine must be encodable as an expression that can serve as data, so universality entails symbolic expressions.

Although universal machines seem a far cry from the 1976 definition of PSSs, Newell argues convincingly that they are equivalent. He further argues that universal machines provide the first satisfactory definition of what constitutes a symbol: namely, something that can designate something, via a given machine (or symbol system). Thus Newell turns the definitional process backwards, defining symbol in terms of symbol system. A symbol, then, is directly tied to its use in a physical context, rather than having a prior existence. As a corollary, almost anything whatsoever can be a symbol. This has provoked objections to the PSSH, which we discuss below.

Given the equivalence between a PSS and a universal machine, the PSSH implies that universality is essential for intelligent behavior. Implicit in this, and made clearer in other work (on production systems and especially Soar) is the idea that it is the ability to represent, with symbolic expressions, one's own behavior that allows for behavioral changes and hence learning.

There are many other capacities of PSSs besides designation and interpretation, some of which are discussed by Newell in some detail. They have to do with internal manipulation of expressions, as well as input and output, to make the two basic capacities of designation and interpretation as powerful as possible.

Newell also outlines a series of levels of description of a physical computer: the device level (the electronics); the circuit level (electrical processes); the logic level (memory values and operations on them); the program level (the PSS level for a computer); and the processor-memory-switch level (the level of description of the various large-scale computer units, such as memory devices, processors, and input–output devices). He argues that there must exist a neural (biological) level of organization that supports a symbol structure: an organization he calls an 'architecture'. He regards this as an empirical hypothesis on a par with the PSSH.

This hypothesis is a forerunner to his definition of the 'knowledge level' (Newell, 1982), which is an addition to the above standard hierarchy for computers. Suppose, at the program (PSS) level, one were to implement an additional level of description via a special 'intelligent' program. This program would have stored knowledge (at the symbol level) and would bring that knowledge to bear on whatever problem it encountered. It would thus be a kind of reasoning engine. Newell calls this new level of behavior the knowledge level, and he formulates a principle of rationality for it: if an agent knows that one of its possible actions will achieve one of its goals, then the agent will perform that action. This is clearly an idealization, since it typically is not possible to bring all available knowledge to bear (because of resource limitations). Newell suggests that human cognition is at best an approximation to a knowledge-level system.

DEBATES CONCERNING THE PHYSICAL SYMBOL SYSTEM HYPOTHESIS

The computational model of human intelligence, as expressed for example in PSSH, has been extremely influential in the development of artificial intelligence, resulting in many techniques for simulating – and many systems that display – intelligent, if limited, behavior. These include techniques for problem solving and planning, especially various search techniques (Russell and Norvig, 1995), architectures like SNePS (Shapiro, 1979), and systems like Soar (Newell, 1990; Laird *et al*., 1987) and Hilare II (Giralt *et al*., 1991), as well as logic-based production systems that are time-situated and able to handle uncertainty and contradictory information (Bhatia *et al*., 2001). (*See* **Soar**)

However, this approach to understanding and reproducing intelligent behavior has been increasingly criticized by those who stress the importance of interaction with and utilization of the external environment, and the practical orientation of real-world agents, not just in shaping and guiding particular instances of cognition but in determining the nature of cognition in general (Anderson, forthcoming). We will provide only a brief account of the debate, primarily with an eye to better understanding PSSH. (*See* **Situated Cognition**; **Symbol-grounding Problem**; **Situated Robotics**; **Embodiment**)

To proponents of the situated or embodied approach to understanding intelligence, PSSH suggests a picture of cognition along the following lines. Firstly, a symbol system is characterized by a distinctive kind of decomposition of cognitive functions, such that the sensorimotor system is independent of, and functions primarily as the source of inputs to and the target of outputs from, the reasoning system. Problem solving proceeds in temporally and conceptually distinct steps: the world is sensed (input is received from the sensory system); a model of the world is built; a plan of action is formulated via computation on the model; and an action is taken (output is sent to the motor system). Secondly, the symbols, in terms of which the world is modeled, and by the transformations of which cognition proceeds, are meaningful primarily in terms of their internal relations to other symbols, and not in virtue of their physical relations to external objects, the behavioral dispositions of the cognitive system, or the particularities of their physical instantiation. Symbols 'denote' objects or aspects of the environment, and their representative function rests on this relation of denotation.

Proponents of embodied or situated cognition (SC) question whether intelligent organisms, humans included, fit the above descriptions. They do not deny that cognition involves abstract reasoning and planning, nor that humans employ symbols when engaging in this sort of reasoning. Rather, they suggest that abstract reasoning is only the tip of the cognitive iceberg; that it rests on and requires many other substantive cognitive capacities; and that these other capacities are not symbolic in nature, but rather involve states and processes that are tightly coupled to, and proceed via interaction with, the environment of the agent in question.

For example, whereas symbolic representation suggests an abstract relation of denotation, many internal representational states are in fact directly causally coupled to objects in, or aspects of, the environment. Thus a visual representation may cause a very particular pattern in the sight centers of the brain, which changes with changes in environment or in the relationship between the environment and the perceiver. This inner state is representational only in virtue of this continuing causal coupling, which suggests that the information about the world it contains should be understood not on a grammatical model, which involves abstract denotation of objects and their relations, but rather in terms analogous to the Watt governor, which carries information about the speed of an engine (in the angle of its arms) only in virtue of its direct coupling with that engine.

Whereas PSSH suggests that the functioning of the sensorimotor and reasoning components of an intelligent system can be understood largely in isolation from one another, SC maintains that the process of sensing and representing in fact involves the continual cooperation of these components, which should perhaps not therefore be presented as functionally decoupled. In general, what is worth paying perceptual attention to, and what concepts and categories are appropriate to bring to bear in representing the world, depend upon what one is doing (Clancey, 1993). Further (and partly for this reason), representations, tend to be cast in functional terms – 'the-bee-that-is-chasing-me' rather than 'bee12' (Agre and Chapman, 1987; Bickhard, 1993) – and the world is understood, in part, in terms of the actions it invites or 'affords': a chair is perceived not in terms of abstract qualitative descriptions, but as affording sitting (Gibson, 1979). This suggests that the content and meaning of inner mental states, and the processing they undergo, cannot be understood in isolation from the ongoing activity of the representing agent. Likewise, whereas PSSH suggests that cognition should be understood in terms of the four-step sense–model–plan–act cycle, and that the calculation on symbols that occurs after sensing and before acting is the meat of thinking, SC claims that cognition can (and often does) involve interaction with the environment at any stage – for instance, rotating a puzzle piece to make it easier to visualize, or writing down the intermediate results in a complex mathematical calculation. Thus, rather than being just the result of cognition, a given action can be part of the cognitive process.

Whereas PSSH suggests that cognition should be understood in terms of abstract rules for manipulating abstract symbols, SC maintains that cognition is in fact rooted in basic coping strategies and the embodied experience of thinking agents. Thus, even the apparently abstract rules of logic are best

understood in terms of more basic experience. Lakoff (1987), for instance, suggests that the 'exclusive or' operator is rooted in and derived from our basic experience with physical objects and containers: an item can be in one box or the other, but not both.

One important response to this challenge can be found in Vera and Simon (1993). There the authors argue that proponents of SC have interpreted the notion of a 'symbol' in a restricted sense, much more narrow than originally intended, and that when a symbol system is understood more broadly, there is no necessary antithesis or tension between SC and PSSH. We quote their characterization of symbol systems at length (Vera and Simon, 1993, pp. 8–9):

> A physical symbol system is built from a set of elements, called symbols, which may be formed into symbol structures by means of a set of relations. A symbol system has a memory capable of storing and retaining symbols and symbol structures, and has a set of information processes that form symbol structures as a function of sensory stimuli, which produce symbol structures that cause motor actions and modify symbol structures in memory in a variety of ways.
>
> A physical symbol system interacts with its external environment in two ways: (1) it receives sensory stimuli from the environment that it converts into symbol structures in memory; and (2) it acts upon the environment in ways determined by symbol structures (motor symbols) that it produces. Its behavior can be influenced both by its current environment through its sensory inputs, and by previous environments through the information it has stored in memory from its experiences.
>
> Henceforth, we will usually refer to both symbols and symbol structures simply as 'symbols'. Symbols are patterns. In a computer, they are typically patterns of electromagnetism, but their physical nature is radically different in different computers (compare the vacuum tubes of the 1940s with integrated circuits of today). And, in any event, their physical nature is irrelevant to their role in behavior. The way in which symbols are represented in the brain is not known; presumably, they are patterns of neuronal arrangement of some kind.
>
> When we say that symbols are patterns, we mean that pairs of them can be compared (by one of the system's processes) and pronounced alike or different, and that the system can behave differently, depending on the same/different decision.
>
> We call patterns symbols when they can designate or denote. An information system can take a symbol token as input and use it to gain access to a referenced object in order to affect it or be affected by it in some way. Symbols may designate other symbols, but they may also designate patterns of sensory stimuli, and they may designate motor actions. Thus, the receipt of certain patterns of sensory stimulation may cause the creation in memory of the symbol (say, CAT) that designates a cat (not the word 'cat', but the animal). Of course, this does not guarantee that there is really a cat out there: that depends on the veridicality of the processes that encode the stimulus into the symbol designating a cat. Similarly, a motor symbol may designate the act of 'petting' (with some parameters to assure that the cat will be the object of the petting).

It is not clear that this characterization of PSSs is very different from that offered in the name of SC, above. In particular, Vera and Simon explicitly maintain that symbols are 'patterns that designate or denote', and define such symbols separately from the patterns of sensory stimuli, in response to which symbols may be generated. It also appears to have the same general 'flavor', suggesting as it does the sense–model–plan–act cycle to which SC objects. A physical symbol system operates as follows: stimuli are received; symbols that denote the environment are generated; these symbols are processed to produce more symbols, some of which designate actions, which are then sent to the motor system to cause a motor response.

However, Vera and Simon's discussion of SC suggests that they may have in mind a somewhat broader definition of symbol (pp. 38–39):

> In some situations, an actor's internal representations can be extremely simple, but no one has described a system capable of intelligent action that does not employ at least rudimentary representations. Perhaps the barest representation encompasses only goals and some symbolization of a relation between goal and situation, on the one hand, and action in the other. But some representation of these is unavoidable if action is to be purposive. … In systems like Pengi [Agre and Chapman, 1987] and the creatures of Brooks [Brooks, 1999], often taken as paradigmatic examples of applied [SC], there are substantial internal representations, some of them used to symbolize the current focus of attention and the locations of relevant nearby objects, others used to characterize the objects themselves in terms of their current functions.

Or (p. 37):

> That the symbols in question are both goal-dependent and situation-dependent does not change their status. They are genuine symbols in the traditional information-processing sense. …'The-bee-that-is-chasing-me' is a perfectly good symbol; it denotes a distinct class of object in the world (i.e. any bee that is engaging in the activity of chasing me).

This claim seems convincing in reference to Pengi. Pengi's inner states are symbolic because they do in fact denote, albeit in terms of a functional characterization. It is much less clear that the inner states in Brooks' creatures, are of this sort, or that we should accept this apparent broadening of the term 'symbol' to include any internal state. Brooks's six-legged robot Genghis achieves walking behavior with a very simple set of controllers (Brooks, 1999). The position of each leg is represented in terms of two numbers, α and β, which give, respectively, its horizontal and vertical position. An α-balance machine continually sums the six α values and sends the sum to each leg, so that if one leg is forward, all legs will be sent a signal casuing them to move back slightly to compensate. There is also a simple controller attached to each leg, such that if the β is positive (the leg is up), it increases α by suppressing the signal from the α-balance machine. In addition there is a controller which decreases β (puts the leg down) whenever β is positive, and an up-leg trigger which can cause the leg to go up by suppressing the leg-down command. Finally, there is a walk trigger, which sends a timed signal to the up-leg triggers (e.g. to cause three of the legs to go up every 2.4 seconds). When the legs go up, they move forward and down (because of the leg-forward and leg-down controllers), while the three legs on the ground move backwards (because of the α-balance machine). Then the other three legs go up, and so on. This walk trigger can, in turn, be connected to sensors to cause it to run only under certain conditions (e.g. when the infrared sensors register heat). Although there is certainly representation here, it is difficult to see this activity in terms of denotation and symbol processing; it seems much more natural to understand the representations of leg position as instances of causal coupling, and Genghis' walking behavior, in reactive terms. Although one can stretch the definitions of 'symbol' and 'denotation' to cover this case, doing so would not thereby erase the difference between the 'symbols' in Genghis and their relation to the things they 'denote', and those employed in Pengi. Every environmentally reactive system has internal states: surely some of these states are not symbolic – they do not denote, nor can they be systematically combined with other inner states to form symbol structures.

Vera and Simon approach the issue of affordance – the perceived invitation by an environment to take certain actions – in a similar fashion, accepting the importance of affordances to guiding agency, but insisting that these affordances be understood symbolically, i.e. in terms of internally encoded states (p. 41):

> We have already seen that when people are dealing with familiar situations, using habitual actions, their internal representations, at the conscious level, may be almost wholly functional, without any details of the mechanisms that carry out these functions. The 'affordances' of the environment, represented internally, trigger actions.
>
> Of course, the absence of consciousness of mechanisms implies neither that mechanisms are absent nor that they are non-symbolic. To acquire an internal representation of an affordance, a person must carry out a complex encoding of sensory stimuli that impinge upon eye and ear. And to take the corresponding action, he or she must decode the encoded symbol representing the action into signals to the muscles.

Vera and Simon may be on more solid ground here, for affordances are not the same as causes: they represent the behavioral options offered by an environment, and only act to trigger a given action under particular cognitive circumstances. A chair affords sitting, but triggers sitting only if I want to sit down. Thus, it seems that it must be possible for these representations to be related to other complex cognitive states like desires, which may in turn play roles in longer-term plans and activities. Still, it is worth pointing out that there are important distinctions to be drawn between affordances, which are often unconscious, action-oriented inner states that are perceptually active (in that they directly inform the content of perception) and serve primarily to allow substantial and inexpensive coordination between sensory input and motor responses, and abstract concepts like `CAT`, which, although certainly grounded in sensory experience, also have substantial logical, hierarchical and lexical relations, important to their meaning, the full extent of which is not perceptually active or involved in sensorimotor coordination. Thus, while it may be plausible in some circumstances to understand the role of the latter symbol in the linear terms suggested by PSSH – whereby one senses something, which triggers the symbol `CAT`, which symbol is processed within a network of beliefs and desires (I like cats and like to pet them), thereby producing the symbol structure `Pet(CAT)`, which, when sent to the motor system, causes my petting of the cat – it is not immediately obvious that these simple coordinations between the sensory, motor, and conceptual systems are sufficient, or of the right form, to support the deployment of affordances.

This is relevant to the larger question of how best to understand human problem-solving behavior,

which, as Vera and Simon accept, often involves interactions with the environment whose role is epistemic (Kirsh and Maglio, 1995), i.e. part of the problem solving itself (aimed, for instance, at simplifying the problem at hand, as when one rotates a puzzle piece to better 'see' where it might fit) rather than an implementation of a solution reached by cognition alone. They are certainly right to insist that continual interaction with the environment is fully compatible with PSSH (p. 10).

> [S]equences of actions can be executed with constant interchange among (a) receipt of information about the current state of the environment (perception), (b) internal processing of information (thinking), and (c) response to the environment (motor activity). These sequences may or may not be guided by long-term plans (or strategies that adapt to feedback of perceptual information).

This way of modeling environmental interaction in problem solving treats our interaction with the puzzle piece (sense model, look for fit, rotate model, look for fit, rotate model, see fit, place) as just a variation of the sense–symbolize–plan–act cycle with more frequent attention to incoming sensory information and its changes. At a certain level of abstraction, this is no doubt the case, for surely epistemic actions involve internal processing just as do pragmatic actions. Yet it seems that, when the object of an action is to simplify a calculation or a search, or otherwise change the epistemic parameters of a task, the coordinations required between the sensory, symbolic, and motor systems are somewhat different from those required in the case of pragmatic action.

This is not to say that the execution of epistemic actions does not require symbols and symbol processing. Indeed, it may be that epistemic actions are even more symbol-based than pragmatic ones, for they may involve modeling not just the environment but also the self and its cognitive capacities. Alternately it could be that a different decomposition of cognitive functions would diminish the need for symbolic coordination between the parts, even in the case of epistemic actions. Proponents of SC hope for the latter, while PSSH expects the former.

When the debate between SC and PSSH is cast in terms of whether cognition depends on symbols, or whether it is primarily reactive and interactive, it has a tendency to devolve into semantic questions: what is the meaning of 'symbol'; and is a sense–symbolize–plan–act system really interactive? This is not the most productive impasse; for both positions have room for both symbols and interaction.

There are nevertheless substantive differences between the two positions, which we suggest come down to three main issues:

- *The nature and role of concepts*. We define a concept as a structured, contentful inner object (constituent of thought) that is semantically evaluable, redeployable and largely stable, and that has hierarchical and logical connections to other concepts. Given this definition, there is a disagreement about when such inner structures are needed to explain intelligent behavior. This definition of a concept is similar to, although somewhat narrower than, the PSS definition of a symbol, suggesting that PSSH expects to discover a very central role for concepts at nearly all stages of cognition. In contrast, SC expects a larger role for nonconceptual content, which is best specified in terms of the abilities, skills and dispositions of the agent, or in terms of significant, nonverbalizable bodily or perceptual experience (Chrisley, 1995).
- *The details of cognitive decomposition, and of the relations and coordinations between the parts*. Although PSSH is not committed to any particular implementation of intelligent agency, it has tended in practice to isolate perception and action from reasoning components, and to handle coordination between subsystems or agents in terms of the distribution and interpretation of symbolically encoded information. In contrast, SC is committed to systems that have much more interpenetration between perception, action and reasoning systems (as in the case of affordances), and in which coordinations between subsystems are indirect (as when all systems have access to the same sensor stream, but do not directly exchange information), mediated by the environment (as when Genghis, in lifting one leg, naturally increases the weight on the other five legs, allowing the 'information' that a leg has gone up to be transmitted to the other leg controllers with no direct information exchange), or subsymbolic (Braitenberg, 1984; Edelman, 1992).
- *The nature and origin of higher-order cognition*. Although Vera and Simon do not directly address the SC claim that the contents and rules of higher-order cognition are rooted in more basic experience (for example, the claim that 'exclusive or' is derived from experience with objects and containers), it seems that such claims, insofar as they primarily pertain to the question of how such laws can be understood or learned by humans, are fully compatible with PSSH. Still, the overall project of naturalism, of which SC is one instance, faces difficulties in accounting for certain formal properties of systems like logic and arithmetic (e.g. completeness), and the apparent necessity of the truths they express (one would expect a system based on contingent experience to be likewise contingent, yet the fact that $2 + 2 = 4$ does not appear to be a contingent truth). And questions remain about the nature of abstraction (and how to implement an abstracting agent), and self-modeling, which seem necessary to high-level cognition no matter how one accounts for its origin.

Synaesthesia

Intermediate article

Simon Baron-Cohen, University of Cambridge, Cambridge, UK
John Harrison, Cambridge Psychometric Consultants, Cambridge, UK

CONTENTS

Synaesthesia is experienced when stimulation of one sensory modality gives rise to a perception in a second modality, without that second modality having received any direct stimulation.

WHAT IS SYNAESTHESIA?

Synaesthesia occurs when stimulation of one sensory modality automatically triggers a perception in a second modality, in the absence of any direct stimulation to this second modality (Vernon, 1930; Marks, 1975; Cytowic, 1989, 1993; Motluk, 1994). So, for example, a sound might automatically and instantly trigger the perception of vivid color, or vice versa. The woman EP, the subject of Baron-Cohen *et al.*'s (1987) study, provided a number of descriptions of color–word correspondences, describing the sound of the word MOSCOW as 'Darkish grey, with spinach green and pale blue'. Those with the condition describe the percept not as part of their external visual experience, nor in their 'mind's eye', but somewhere else, phenomenologically.

Many combinations of synaesthesia are reported to occur naturally, including sound giving rise to visual percepts ('colored-hearing') and smell giving rise to tactile sensation, as in Cytowic's (1993) subject MW. Colored-hearing synaesthesia appears to be the most common form. Certain combinations of synaesthesia almost never occur (e.g. touch to hearing). Synaesthesia is also sometimes reported by those who have used hallucinogenic drugs, such as Lysergic Acid Diethylamide (LSD) or mescaline. This article will focus on the naturally occurring form of synaesthesia, whilst acknowledging that there may be a connection to be found with the drug-induced form.

Terminology

'Developmental' synaesthesia

'Developmental synaesthesia' is distinct from acquired synaesthesia (of which there are at least two forms) and pseudosynaesthesia. Developmental synaesthesia in most cases has several characteristics: (1) it has a childhood onset, in all cases before four years of age; (2) it is different from hallucination, delusion, or other psychotic phenomena; (3) it is different from imagery arising from imagination; (4) it is not induced by drug use; it is (5) vivid; (6) automatic/involuntary; and (7) unlearnt.

Synaesthesia caused by neurological dysfunction

A variety of neuropathological conditions can give rise to acquired synaesthesia. A full account of the varieties of acquired synaesthesia is given in Critchley (1994). Note that the resultant synaesthesic percepts are often much simpler than the complex forms seen in developmental synaesthesia.

Synaesthesia as a consequence of psychoactive drug use

Synaesthesia can result from the use of psychoactive drugs (Cytowic, 1989). The mechanisms by which drug-induced synaesthesia occur are not well understood, though the use of LSD, mescaline, and psilocin are all reported to cause confusion between the sensory modalities, so that sounds are perceived as visual (Rang and Dale, 1987). Neurophysiological studies reported by Aghajanian (1981) suggest different sites of action for LSD and mescaline, with LSD seeming to work by

inhibiting the serotonin-containing neurons of the raphe nuclei, and mescaline by acting upon the noradrenergic system. Drug-induced synaesthesia differs from developmental synaesthesia in several ways: (1) it is often accompanied by hallucinations and loss of reality-monitoring; (2) it is transient; (3) it usually has an onset only in adult life (or whenever the drug was used); and (4) it can produce sensory combinations which do not otherwise occur naturally.

What Synaesthesia Is Not

Metaphor

Almost all writers on the topic of synaesthesia have been drawn into discussion of the possibility that a number of authors, poets, artists, and musicians may have had synaesthesia. A typical list of these individuals would include the composers Liszt, Rimsky-Korsakov, Messiäen, and Scriabin; the poets Basho, Rimbaud, and Baudelaire; the artists Kandinsky and Hockney; and, finally, the novelist Nabokov. There is no evidence of these individuals having been tested formally for synaesthesia. Much of the literature may instead reflect a form of metaphor or analogy. Thus, Charles Baudelaire appears to have believed in the unity of sensation (as implied by his poem 'Correspondances'). Metaphor is widespread in language and provides ripe conditions for confusion with developmental synaesthesia. Distinguishing the 'metaphor as pseudosynaesthesia' from developmental synaesthesia relies on objective tests. However, the key differences are that in metaphor: (1) no percept is *necessarily* triggered; (2) the subject will often acknowledge that the description is only an analogy; and (3) it is voluntary.

Association

A second form of pseudosynaesthesia includes individuals who have simply learnt to pair words/letters with colors (e.g. alphabet books in which letters are depicted in a variety of colors). Detailed examination of the color-letter alphabets of individuals with developmental synaesthesia often yields the finding that successive letters have very similar colors. This is in marked to contrast to colored alphabet books in which successive letters have markedly different color representations.

HISTORY

The closing decades of the nineteenth century saw a considerable number of accounts of synaesthesia, most notable amongst which was Galton's (1883) *Inquiries into Human Faculty and Its Development*. Scientific interest in the condition declined with the rise of behaviorism and very little on the topic appears in the literature from the late 1920s onward. This was probably because behaviorism banished reference to mental states from scientific language. As synaesthesia could only be defined by self-report and reference to mental states, it was not considered 'scientific'.

Since the 1990s synaesthesia research has enjoyed something of a renaissance. Various disciplines within cognitive neuroscience have contributed both new data and theory. Such developments have led to the condition being widely recognized as having a neurological reality. This new acceptance of the condition is in part due to objective approaches to studying it now being available.

EXPERIMENTAL WORK ON SYNAESTHESIA IN PSYCHOLOGY AND NEUROSCIENCE

The conventional test for the colored-hearing synaesthesia involves assessing a subject's *consistency* in reporting color descriptions for words across two or more occasions, when the subject has no prior warning of the retest. This consistency should be irrespective of the length of interval between testing sessions (Baron-Cohen *et al*, 1987; Baron-Cohen *et al*., 1993). Using this method, consistency is typically as high as 90 per cent, even when retested over years and even when stringent criteria are set for retest descriptions.

The advent of neuroimaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) has also provided an opportunity to image the brains of individuals with synaesthesia *in vivo*. Cytowic used the xenon inhalation technique to image the brain of a single subject (Cytowic and Wood, 1982) and others have used PET (Paulesu *et al*., 1995) and more recently fMRI (Gray *et al*., 1997). Given the marked consistency of patterns of activation in synaesthetes studied in the Paulesu *et al*. study, it might ultimately prove possible to determine the presence of synaesthesia objectively using functional brain imaging techniques. The neuroimaging data is discussed later in relation to theories of synaesthesia.

THEORIES OF SYNAESTHESIA

Over the past 200 years a number of hypotheses have been put forward to explain the cause of synaesthesia.

Preserved Neural Connectivity

The normal adult human brain does not contain direct neural connections between auditory and visual areas. However, the early developing brain in many species does. This first theory holds that, probably for genetic reasons, in individuals with synaesthesia, pathways between auditory and visual areas in the brain continue to exist beyond neoteny, such that when words, or sounds, give rise to activation in auditory areas, visual cortex is also stimulated.

There is evidence for the presence of such connective pathways in other species (see Kennedy *et al*., 1996). Kennedy and others in a number of studies (Dehay *et al*., 1984; Kennedy *et al*., 1989), have found that connections between auditory and visual areas exist in the brain structure of species such as the macaque monkey (*Macaca irus*) and the domestic cat (*Felis domesticus*). These projections appear to be transient, typically disappearing approximately three months *post partum*.

There is also some evidence that these transitory pathways exist in human neonates, and may, as in cats and macaques, get 'pruned' as part of the biological maturation of the brain. Much of this evidence is reviewed by Maurer (1993). Maurer's hypothesis is that human babies mix the input from different senses and that this gives rise to normal 'synaesthesia'. We know from the work by Meltzoff and Borton (1979) that babies who suck on either a 'nubby' or a 'smooth' pacifier (dummy) will prefer to look at a picture of the pacifier they sucked on, thereby showing a match between touch and vision. The Meltzoff and Borton study is usually taken as evidence for cross-modal transfer. Maurer goes one step further in suggesting that synaesthesia might be a normal stage of perceptual experience in addition to cross-modal transfer.

Maurer's evidence in support of this view comes from other studies of neonates. One such study is that reported by Lewkowicz and Turkewicz (1980). In this experiment one-month-old children, who had seen a patch of white light for 20 trials, were presented with bursts of 'white noise' presented at different intensities. During the noise presentation, the patch of light that they had been trained on was interspersed repeatedly and the children's heart rate was measured. Normally heart rate increases as a function of noise intensity, but Lewkowicz and Turkewicz found that the heart rate recorded at a noise intensity of 74 dB showed the lowest heart rate change and that for values greater or less than this value heart rate increased. Lewkowicz and Turkewicz's interpretation of this finding was that 'infants were responding to the auditory stimuli in terms of their similarity to the previously presented visual stimulus' (1980, p. 597), or, as Maurer put it, 'the children responded least to the "familiar" intensity' (p. 110). Maurer also cites evidence from electrophysiological studies of neonates showing that the amplitude of somatosensory evoked potentials increases when they are played white noise. Normally, these potentials only increase as a consequence of tactile stimulation. Finally, she cites the work of Neville (1993) that in early infancy auditorily evoked potentials to language evoke a potential in the occipital cortex, whereas in older individuals these stimuli yield potentials only in auditory areas such as the temporal lobes.

The evidence in this section is consistent with the notion that synaesthesia might be due to the persistence of neural information passing from auditory to visual brain areas, beyond the neonatal stage. Taken in the context of development, it also suggests the intriguing possibility that we might *all* be colored-hearing synaesthetes until we lose connections between these two areas somewhere about three months of age, at which point cortical maturation gives rise to sensory differentiation. This is consistent with Cytowic's (1989) view of synaesthetes being 'cognitive fossils'.

Sensory Leakage Theory

Jacobs *et al*. (1981) proposed what can be called the 'Sensory Leakage Theory'. This is an account of how simple photisms arise in cases of acquired synaesthesia, though it could in principle be extended to account for developmental synaesthesia. As mentioned earlier, most cases of *acquired* synaesthesia arise in individuals who suffer brain damage to anterior portions of the brain, often the optic nerve. Close examination of the nine patients reported in Jacobs *et al*. reveals that four of these patients (cases 1, 2, 4, 7) also experienced photisms in the *absence* of auditory stimulation, casting doubt on whether these instances should be described as cases of auditory-visual synaesthesia at all. It is also worth observing that seven patients always experienced their photisms when they were 'relaxed, drowsy or dozing' (p. 214), circumstances in which hypnagogic hallucinations are possible.

The essence of Jacobs *et al*.'s theory is that auditory information 'leaks' into pathways and areas in the brain that ordinarily deal with visual information. Jacobs *et al*. expand this 'leakage' theory by suggesting that there are 'numerous regions of the brain where visual and auditory pathways lie in

close anatomic proximity' (p. 216) and that at these points post-synaptic fibres might converge to cause the synaesthesia seen in a range of pathological states such as congenital blindness and drug intoxication.

Evidence to support leakage between areas subserving different forms of sensory information is sparse, causing some difficulties for Jacobs *et al.*'s theory. However, recent work has suggested that rather than posit the need for leakage, it is possible to find at certain locations in the brain classes of neurons that are responsive to stimulation from more than one sensory modality. For example, in a study of nonhuman primates carried out by Graziano *et al*. (1994), recordings were made from neurons (N = 141) in the ventral portion of the premotor cortex. Of these neurons, 27 to 31 per cent were found to be bimodally responsive, firing as a result of either, or both, visual and somasthetic stimulation.

Sadato *et al*. (1996) showed that congenitally blind subjects show increased bloodflow to primary visual areas when reading Braille, a finding the authors account for by suggesting that in these subjects 'cortical areas normally reserved for vision may be activated by other sensory modalities' (p. 526). Such an account might also explain the case of acquired synaesthesia reported by Rizzo and Eslinger (1989). Their subject, a 17-year-old who had developed retrolental fibroplasia as the consequence of perinatal difficulties, exhibited a florid form of colored hearing for musical tones. Rizzo and Eslinger failed to find evidence to suggest visual area activation as a consequence of auditory stimulation, but limited themselves to the use of electroencephalography as a means of detecting such activity. The Sadato *et al*. finding suggests that functional neuroimaging might prove to be a useful technique for investigating cases of acquired synaesthesia.

Cytowic's Theory of Synaesthesia

The most controversial theoretical account of the cause of synaesthesia is that most recently advanced by Cytowic (1993) in his book *The Man Who Tasted Shapes*. Cytowic proposes that synaesthesia occurs because 'parts of the brain get disconnected from one another … causing the normal processes of the limbic system to be released, bared to consciousness, and experienced as synaesthesia' (p. 163). His assertion that the limbic system is the critical brain locus can and has been tested. In the final chapter, Cytowic concedes that whilst he has no direct evidence to implicate a particular neural structure, given the 'stunning shut-down of the cortex' (p. 152) observed in the ^{133}Xenon studies of blood flow in the subject MW's brain, he points to the limbic areas as being 'the seat of synaesthesia'. Direct evidence of the involvement of the limbic system would have been provided by evidence of blood flow changes in this brain region, though unfortunately neuroimaging using ^{133}Xenon inhalation does not permit such deep structures to be imaged.

This is not a limitation shared by PET and so the importance of the limbic system in synaesthesia can be evaluated using this technique. This was one of the questions addressed in the study of colored-hearing synaesthesia reported by Paulesu *et al*. (1995). This study compared brain activity in synaesthetes and control subjects whilst listening to either words or pure tones. The synaesthetes reported color percepts for words but not for nonword sounds, and so a comparison of brain activation on synaesthetes listening to words as compared with tones, and with control subjects, should yield clues to the neural basis of colored-hearing synaesthesia. From this analysis two areas of particular interest emerged, posterior infertemporal cortex and the parietal-occipital junction, both of which have known involvement in color perception. However, in neither the between-groups nor the within-groups comparisons was there any suggestion of limbic system involvement. Of course it might be that Cytowic's subject MW is different in *kind* from the subjects scanned by Paulesu *et al*. Given MW's grossly abnormal resting blood flow levels, together with his polymodal synaesthesia, this remains a strong possibility.

The Learned Association Theory

This theoretical proposition was originally suggested as an explanation of synaesthesia by Calkins (1893) and holds that in colored-hearing synaesthesia, the color–word and/or sound correspondences reported are due entirely to learned association. The idea is that the color–letter associations are derived from colored alphabet books, or colored letters, that the individual saw as a child. Whilst this is a plausible account of the acquisition of pseudosynaesthesia, we suspect, for a number of reasons, that it is an unsatisfactory account of developmental synaesthesia. Reasons include the following:

1. The sex ratio. The sex ratio in synaesthesia is 6:1 (f:m). Why should so many more women, as compared to men, form such associations? A socialization account

which would lead to this sex ratio is not immediately obvious, though transmission from mothers to daughters via modeling may be a possibility (though a tenuous one).

2. Consecutive letters. Careful scrutiny of the 'colored alphabets' of many synaesthetes, yields the finding that often consecutive letters are closely described in color terms (e.g. 'M' = olive green, 'N' = emerald green, 'O' = washed-out pale green). When compared to colored alphabet books, it is found that publishers logically go to great lengths to ensure that consecutive letters are printed in very different colors. Learned association therefore cannot account for the specific colors of particular letters or phonemes.
3. Synaesthesic twins. A comparison of the colored alphabets of twins so far has yielded substantial variation in the color–letter correspondences made by each of the pair. The same variation is also seen among siblings and by mothers and daughters in the same family. It is surprising that there is not greater similarity in the color–letter correspondences of family members if colored alphabets are acquired as learned associations.
4. Lack of recollection. Most people with synaesthesia are unable to report *knowing* that their letter–color associations were learnt either purposefully or incidentally via exposure to colored alphabet letters or books.

The learned association theory of synaesthesia has not yet provided satisfactory explanations of these anomalies.

The Genetic Theory of Synaesthesia

The possibility that synaesthesia might be an inherited trait seems to have first been put forward by Galton (1883). Genetic mechanisms might cause the preserved neural connectivity described above. Earlier we reviewed the evidence for transitory connections between auditory and visual brain areas in other mammalian species. Assuming that such connections are also to be found in our species, one explanation for synaesthesia is that in individuals with the condition these neonatal pathways persist due to inherited mechanisms. A recent study (Baron-Cohen *et al*., 1996) has provided evidence to support the notion that synaesthesia might be an inherited trait. In that study, the pedigrees of seven families of probands suggested that the condition is inherited.

If the genetic theory is supported, this begs the question of by what mechanism such a biological inheritance has its effect. A candidate mechanism would be the expression of genes that regulate the migration and maturation of neurons within the developing brain. A second candidate mechanism is 'neuronal pruning' (apoptosis). On this account synaesthesia can be best explained not by positive forces creating neural pathways that in non-synaesthetes do not exist, but by maturational effects that lead to neonatal pathways being left active. This would be consistent with Maurer's observations regarding the emergence of modality-specific responses in three-month-old human neonates.

The Cross-modal Matching Theory

This is based on evidence of cross-modal matching in normal subjects, in addition to those found by Lewkowicz and Turkewicz described earlier. Much of the work looking at cross-modal analogs of characteristics such as brightness/loudness, etc. has been carried out by Marks (Marks, 1982a, b, 1987).

Marks (1982a) showed that normal subjects exhibited remarkable consistency when asked to rate a selection of auditory-visual synaesthetic metaphors using scaled ratings of loudness, pitch, and brightness. For example, 'sunlight' was rated as louder than 'glow', which was in turn rated as louder than 'moonlight'. A second study reported by Marks (1982b) required subjects to set the loudness of a 1000-Hz tone and the brightness of white light for 15 cases of visual-auditory metaphor taken from works of poetry. Again, marked consistency characterized the performance of these subjects, leading Marks to propose that intensity might be a common sensory dimension.

The Modularity Theory

In order for us to 'know' that a percept is visual, auditory, olfactory, etc. we must have a method of identifying information as being of one sensory kind or another. We may achieve this via a *modular* structure to sensation (Fodor, 1983). The modularity theory holds that whereas in non-synaesthetes, audition and vision are functionally discrete, in individuals with synaesthesia a breakdown in modularity has occurred (Baron-Cohen *et al*., 1993). The consequence of this, in the case of colored-hearing synaesthesia, is that sounds have visual attributes. Testing the modularity theory is a challenge for future research.

RELEVANCE OF SYNAESTHESIA FOR COGNITIVE SCIENCE

Investigations of colored-hearing synaesthesia suggest that individuals with the condition are

consistent in their descriptions of word–color correspondence and report similar phenomenological accounts of the condition. Further, synaesthetes appear to show different patterns of brain activation when listening to color-evoking sound stimuli. The existence of unusual neural connections between auditory and visual areas has been postulated to explain synaesthetic experience, perhaps as the result of a failure of apoptosis. Recent accounts of familiality of the condition suggest that genetic factors may sustain neonatal auditory-visual pathways. If this proves to be the case, synaesthesia may teach us how unusual wiring in the brain can lead to altered perception, and how genes may affect subjective experience.

Thought Experiments

Intermediate article

Tamar Szabó Gendler, Syracuse University, Syracuse, New York, USA

CONTENTS

Thought experiment: to perform a thought experiment is to reason about an imaginary scenario with the aim of confirming or disconfirming some hypothesis or theory.

WHAT ARE THOUGHT EXPERIMENTS?

To perform a thought experiment is to reason about an imaginary scenario with the aim of confirming or disconfirming some hypothesis or theory. In its original usage, the expression was reserved for cases intended to evoke intuitions about the physical world; more recently, it has also been used to refer to cases intended to evoke intuitions concerning the proper application of nearly any descriptive or evaluative concept.

So, for instance, Galileo's famous refutation of the Aristotelian view that heavy bodies fall faster than light ones is a paradigmatic example of a scientific thought experiment concerning the physical world. Galileo asks his reader to imagine a heavier body strapped to a lighter one, and shows that the Aristotelian is committed to saying that the joined object will fall both faster and more slowly than the heavier body alone. By contrast, John Searle's (1980, 1984) case of the Chinese Room is a classic example of a philosophical thought experiment concerning the application of our concepts. In an effort to undermine the thesis that a suitably programmed computer might manifest understanding, Searle asks his reader to consider whether a person locked in a room with a sheaf of Chinese characters and a set of instructions enabling her to select certain batches of characters ('answers') when prompted by certain other batches of characters ('questions') would be properly credited with understanding Chinese. (Searle expects his reader to give a negative answer.) Other examples are presented and discussed below.

Although Ernst Mach is generally credited with having coined the expression *Gedankenexperiment* in his 1897 essay of the same name, and although contemporary German, English, and French usage can be traced to Mach's writings, the expression *Gedankenexperiment* appears in the Danish Kantian Hans Christian Örsted's 1811 'Prolegomenon to the General Theory of Nature', and a term for experiment with thoughts – *mit Gedanken experimentieren* – can be found in a 1793 entry to German polymath Georg Christoph Lichtenberg's 'Common Place Book' (cf. Lichtenberg, 1793/1983; Mach, 1897; Mach, 1905/1976; Schildknecht, 1990, pp. 147ff; Witt-Hansen, 1976).

In any case, use of the method antedated its labeling by several thousand years, having been employed by ancient and medieval philosophers and natural philosophers, and by scientists and philosophers in the early modern and contemporary periods (for representative discussions, see Rescher, 1991; King, 1991; and other papers collected in Horowitz and Massey, 1991). After the publication of Mach's 1897 essay, the term itself seems to have taken roughly four decades to become widespread in scientific circles. (Despite his extensive reading of Mach, for instance, Einstein appears not to have used the expression in his own writings. In general, however, it is difficult to trace reliably the term's history, as later editions of works often interpolate it where it was not originally used.) Employment of the expression 'thought experiment' in its philosophical sense seems to have begun sometime in the 1970s, and it was only in the last decade of the twentieth century that philosophical reference works began to include entries for the term. (For an extensive

bibliography of the philosophical literature on thought experiment, see Gendler, 2000, pp. 229–250.)

Given how broadly the term is used, it seems that nearly any imaginary example might reasonably be termed a 'thought experiment'. As a matter of sociological fact, however, the expression tends to be reserved for cases involving a certain degree of visualization, complexity, or novelty. So, for instance, although they describe imaginary scenarios whose consideration may play some role in confirming or disconfirming some hypothesis or theory, simple examples in physics books ('a car travelling at 65 miles per hour strikes a concrete wall …') are rarely considered material for thought experiments, nor are their equally austere analogs in philosophy, psychology, linguistics, law, and so on.

KINDS OF THOUGHT EXPERIMENTS

Although a number of taxonomies for thought experiments have been proposed, none has become canonical. Perhaps the most widely accepted distinction is between scientific and philosophical thought experiments, though these categories are rarely made precise: scientific thought experiments are simply those concerning scientific subject matter, philosophical thought experiments those concerning nonscientific subject matter (cf., for instance, Horowitz and Massey, 1991; Sorensen, 1992).

A more sharply focused version of the scientific/nonscientific distinction is made by George Bealer (1998, pp. 207–208), who distinguishes imaginary cases that are used to evoke physical intuitions from those used to evoke intuitions about the application of nonphysical concepts. The former involve asking the reader to determine what would happen in a given imaginary scenario assuming that natural laws are held constant; the latter involve asking the reader to decide whether a particular scenario is logically or metaphysically possible, or whether a given concept applies to such a scenario. Bealer maintains that the term 'thought experiment' should be reserved for cases of the former sort, roughly the class generally referred to as 'scientific thought experiments'. Tamar Szabó Gendler (2000, pp. 25–27) suggests a slightly different taxonomy, distinguishing between factive and conceptual/valuational thought experiments. Factive thought experiments are those where the question asked is naturally described as 'what would happen?'; conceptual/valuational thought experiments are those where the question asked is naturally described as 'how should we describe or evaluate this outcome?' Thought experiments that are factive tend to be those involving scientific subject matter; thought experiments that are conceptual/valuational tend to be those involving philosophical subject matter.

James Robert Brown (1991) provides a taxonomy of scientific thought experiments that has gained some currency in certain philosophy of science circles. Brown distinguishes between destructive and constructive thought experiments, subdividing the latter category into mediative, conjectural, and direct. Destructive thought experiments are those involving imaginary examples designed to raise difficulties for a particular theory; constructive thought experiments are those aimed at establishing a positive result. Within the class of constructive thought experiments, mediative thought experiments are those which facilitate the drawing of a conclusion from a specific, well-articulated theory; conjectural thought experiments are those where thinking about an imaginary scenario causes us to consider a phenomenon for which we then provide some sort of theoretical explanation; direct thought experiments are those that directly yield a well-established theory. Thought experiments that are simultaneously destructive and direct-constructive Brown calls platonic, since, he claims, they give us *a priori* knowledge of nature.

Other taxonomies have also been proposed, though like those described above, none has gained canonical status. Nicholas Rescher (1991), for instance, distinguishes between thought experiments that are explanatory and those that are refutatory, offering further subdivisions into six more precisely articulated methods. Sarah Thomason (1991) divides thought experiments in linguistics into two categories: those that identify what sort of evidence might be conclusive in testing a particular theory, and those that test linguistic hypotheses by providing introspective data (these might be called 'experiments-in-thought'). D. A. Anapolitanos (1991) offers a six-celled taxonomy of thought experiments in mathematics; Richard Gale (1991) distinguishes thought experiments that yield clear-cut counterexamples from those that result in undecideable cases; Allen Janis (1991) distinguishes three ways in which thought experiments in physics might fail; Roy Sorensen (1992, pp. 197–202) classifies thought experiments on the basis of whether the corresponding actual experiment is gratuitous, unaffordable, or impossible; Pierre Duhem (1914/1954, p. 202) similarly distinguishes merely unperformed experiments, experiments which could not be performed

with precision, physically unperformable experiments, and absurd experiments; and Sören Häggqvist (1996, pp. 136–159) and Kathleen Wilkes (1988, chap. 1) each present principles for distinguishing successful from unsuccessful thought experiments.

USES OF THOUGHT EXPERIMENTS IN PHILOSOPHICAL COGNITIVE SCIENCE

In the cognitive science literature, the term 'thought experiment' is generally used to refer to some widely discussed imaginary case designed to evoke intuitions about the proper application of a concept such as 'meaning' or 'consciousness'. So, for instance, among the cases generally referred to as 'thought experiments' are Frank Jackson's case of Mary the Color Scientist, Derek Parfit's case of fission, Hilary Putnam's case of Twin Earth, and John Searle's case of the Chinese Room. For whatever reason, discussions of zombies and inverted spectra are less commonly referred to as 'thought experiments', though slight variations on them, such as Ned Block's case of inverted Earth, generally are. Each of these cases is described briefly below, followed by a discussion of some of their common features.

Jackson's Mary

In an effort to undermine the view that all facts are physical facts, Frank Jackson (1982) presents the example of Mary, a person who has never had color experiences, having been confined all her life to a black and white room and denied all access to color-involving visual stimuli. Mary is also a brilliant scientist who specializes in the neurophysiology of vision, and who knows all physical facts (including all neurological facts) about color vision. Jackson asks what would happen if Mary were released from her confinement and shown a red object: would Mary learn anything new? Jackson (1982) expects his reader to agree that the answer is 'yes', and concludes that what Mary has learned when she has learned what it is like to see red is a nonphysical fact.

Parfit's Fission Case

In an effort to undermine the view that personal identity is what properly underlies our concern for our future continuants, Derek Parfit (1984/1987) discusses a pair of cases involving brain transplants from an individual in whom all cognitively relevant features are realized in duplicate – once in the left half of the brain, and once in the right. In the first scenario, the left half of the original person's brain is transplanted into the body of his decerebrated identical triplet, resulting in an individual qualitatively identical to the original in all bodily and psychological characteristics, while the right half of the original brain is destroyed. In the second scenario, both the left and right halves of the brain of the original individual are transplanted, each into the decerebrated body of one of his identical triplets, resulting in two individuals each qualitatively identical to the original in all bodily and psychological characteristics. Parfit suggests that the relation between the original individual and his successor in the first case is a relation of personal identity, and *a fortiori* is sufficient to render his prudential concern for that continuer rational. In the second case, the relation between the original individual and each of his two continuers is intrinsically identical to that in the first case; hence, contends Parfit, it is sufficient to render prudential concern for each of them rational. But a relation of identity does not hold between the original individual and both of his two continuers (since identity is a one–one relation). So, concludes Parfit, identity is not what matters in making prudential concern rational.

Putnam's Twin Earth

In an effort to show that an individual's social or physical environment is partly determinative or constitutive of that individual's mental states, Hilary Putnam (1975) presents the example of Twin Earth, a planet identical to Earth in all respects but one: the substance that plays the macro-role of Earthly water is not H_2O, but a substance with a different chemical structure that Putnam calls XYZ. Putnam imagines two individuals: one on Earth named Oscar, and his molecule-for-molecule Twin-Earth duplicate Twin-Oscar. Putnam holds that when Oscar says *water* he refers to water (that is, H_2O), but that when Twin-Oscar says *water* he refers to twin-water (that is, XYZ). So, concludes Putnam, reference is at least partly determined by physical environment. (See also Burge, 1979 for a number of parallel cases). (*See* **Externalism**)

Searle's Chinese Room

See the description in opening section.

Zombies

In an effort to bring out certain issues related to the nature of conscious experience and the plausibility

of physicalism, numerous philosophers have discussed the case of zombies, beings molecule-for-molecule identical to human beings but who lack all conscious experience (cf. Kirk, 1974; Dennett, 1991; Chalmers, 1996). On the basis of such cases, some have concluded that consciousness cannot be fully explained in physical terms.

Inverted Spectrum and Inverted Earth

In an effort to illuminate various issues relating to the status of qualia, materialism, behaviorism and consciousness, numerous philosophers have employed a case first introduced by John Locke (1689/1975 at II:XXXII:15). In its simplest form, the Inverted Spectrum example hypothesizes an individual whose visual experience on seeing, say, yellow is qualitatively identical to the visual experience of a normal person seeing, say, blue. Variations on the case abound. For instance, in arguing against certain representationalist and functionalist accounts of qualia, Ned Block (1990) introduces the example of Inverted Earth, a planet whose colors are inverted, so that grass on Inverted Earth is red and the sky on Inverted Earth is yellow. A person is transported to Inverted Earth, and given color-inverting contact lenses that cause everything on Inverted Earth to appear to her to be normally colored (cf. also Shoemaker, 1982; Chalmers, 1996). (*See* **Functionalism**; **Materialism**; **Qualia**)

Discussion of Common Features of the Above

Appellation notwithstanding, such cases tend to share the following features: (a) a scenario is described; (b) an intuition concerning the scenario is presented with the assumption that it will be endorsed, or some argument is presented for why a particular evaluation of the scenario is correct; and (c) this intuition or evaluation is then taken as a datum in understanding something about cases beyond the scenario. So, for instance, in the case of Twin Earth, the imaginary scenario described posits the existence of the planet on which something qualitatively identical to water has the chemical structure *XYZ*; the intuition Putnam expects the scenario to evoke is that speakers of English and speakers of Twin-English refer to something different by their use of the word *water*; and the larger lesson is that 'meanings [or at least reference] ain't just in the head' (Putnam, 1975, p. 227, italics omitted). In the case of fission, the imaginary scenario posits a pair of cases where the relations between the earlier and later individual(s) are qualitatively indistinguishable, but differ in their identity properties; Parfit's arguments aim to show that this gives us a case where prudential concern for a nonidentical continuer is rational; the larger lesson is that 'personal identity is not what matters' (Parfit 1984/1987, p. 255, italics omitted).

Challenges to particular thought experiments may come at any of these three levels: (a′) incoherence criticisms: the scenario described is in some sense incoherent; (b′) misleading intuition/unsound argument criticisms: although the scenario described is coherent, the intuition it generates is unreliable or the argument establishing the correct evaluation of the scenario is unsound; or (c′) inapplicability criticisms: although the scenario described is coherent and the evaluation of the scenario correct, the conclusion drawn on its basis is mistaken. So, for example, some have argued (a′) that fission is biologically or physically or conceptually impossible; others (b′) that though the scenario described is coherent, it does not present us with a case where someone would bear a relation of rational prudential concern to a nonidentical continuer; and others (c′) that though the scenario presents a case where someone would bear a relation of rational prudential concern to a nonidentical continuer, this does not show that identity is not what matters for rational prudential concern in ordinary cases.

PHILOSOPHICAL AND EMPIRICAL THEORIES OF THOUGHT EXPERIMENTAL COGNITION

Perhaps the most perplexing question raised by the technique of thought experiment is the epistemic puzzle articulated sharply by Thomas Kuhn: 'How, relying exclusively on familiar data, can a thought experiment lead to new knowledge?' (Kuhn, 1964/1977, p. 241). The question can be broken in two: (a) how can thought experiments lead to beliefs that are properly classified as *new*? (b) how can thought experiments lead to beliefs that are properly classified as *knowledge*?

Classic rationalist discussions answer both questions simultaneously by suggesting that in certain cases, thought experimental reasoning can lead to rational insight and thereby give access to *a priori* truths (for a modern defence see Brown, 1991). Classic empiricist answers, such as Mach's, suggest that thought experiments provide access to unsystematized empirical knowledge itself acquired through experience or evolution. The justification for beliefs formed thereby is thus

parasitic on the basic knowledge; their novelty is a consequence of its having been previously unavailable in propositional form. Kuhn's own answer is that thought experiments work by forcing a simultaneous rethinking of conceptual structures and the information they contain, and in this way are able to yield beliefs that are both novel and justified.

Recent discussions of thought experimental cognition have tended to focus on whether the structured contemplation of imaginary examples produces distinctive sorts of cognitive access, rendering thought experiment epistemically indispensable. In a series of articles, John Norton (1991, 1996) has argued against this position, defending instead the view that thought experiments are arguments of a certain sort. Norton's view has been widely discussed and criticized by those who, following Mach (1905/1976, 1933/1960), hold that at least some knowledge accessed by thought experiment is nonpropositional or nonconceptual, and that contemplation of imaginary cases gives us access to that knowledge in a way that argument alone cannot (cf. Arthur, 1999; Brown, 1991; Gendler, 2000, chap. 2). Some, such as Nancy Nersessian (1993) and Nenad Miscevic (1992), have tried to make Mach's notion more precise by assimilating the technique of thought experiment to recent psychological work on mental modeling. Others, such as Daniel Dennett (1984), have suggested that many philosophical thought experiments are best understood as 'intuition pumps'. Yet others stress the parallels between thought experiments and actual experiments, contending that similar explanations can be offered for the utility of each (cf. Sorensen, 1992; Gooding, 1992).

CONTROVERSIES AND ISSUES REGARDING THE USE OF THOUGHT EXPERIMENTS

Controversies concerning thought experiments can be divided into two main categories: controversies about the standard interpretations of particular thought experiments, and controversies about the utility of the methodology itself. Even those whose concern is with the methodology itself, however, tend to be opposed to the use of far-fetched examples, rather than to the technique of reasoning about imaginary cases as such.

Controversies about particular thought experiments are generally expressions of substantive philosophical disagreements. For instance, debates about what, if anything, Mary learns when she leaves the black-and-white room; about whether the person locked in the Chinese Room understands Chinese and if not, what that shows; about whether zombies are negatively conceivable (not *a priori* incoherent) or positively conceivable (verified by a clearly and distinctly conceivable scenario), and if so what that implies about the status of physicalism or the nature of consciousness – each involves conducting a significant philosophical debate primarily through discussion of a particular imaginary case. Similarly, debates about the proper understanding of particular scientific thought experiments – for instance, Einstein and Bohr's 1930 debate concerning the clock-in-the-box – can also be understood along these lines (cf. Bohr, 1949). Occasionally, however, disagreements about a particular case are better understood as disputes about the methodology of thought experiment; this is particularly striking in debates about whether the concept of personal identity is sufficiently far-reaching to deliver reliable intuitions about fission cases.

In general, uneasiness with the methodology of thought experiment tends to be focused on thought experiments involving far-fetched cases, though there are certain strands of Marxist thought that stress the importance of focusing on the actual rather than the hypothetical, and strains of moral particularism that suggest that no situation may stand in as surrogate for another (cf. Dancy, 1985). Far more typical, however, are discussions such as those of Kathleen Wilkes (1988), who expresses misgivings about the use of wildly fantastic imaginary cases in discussions of personal identity on the grounds that the intuitions they evoke are unreliable as guides to our actual conceptual commitments. W. V. O. Quine (1972) expresses similar reservations, claiming that our concepts are indeterminate in their application when we consider such bizarre cases. Others have offered parallel arguments from a Wittgensteinian perspective (e.g. Gale, 1991).

In recent years, two other areas of related interest have begun to be explored, both of which raise concerns for the reliability of thought experiment as a methodology. As before, the implications of these investigations will need to be considered on a case-by-case basis. Following the work of psychologists such as Daniel Kahneman and Amos Tverksy, demonstrating that human reasoning is, in a wide range of cases, subject to apparently intractable cognitive illusions, a number of philosophers and psychologists have begun to consider whether intuition itself is reliable in the ways that thought experimental reasoning seems to presuppose (see,

for instance, the papers collected in DePaul and Ramsey, 1998). In a related vein, though for reasons arising from a concern with the nature of modality and the relation between epistemology and metaphysics, a number of philosophers have begun to rethink the relation between conceivability and possibility (see, for instance, papers collected in Gendler and Hawthorne, forthcoming). If, as some suggest, what we can conceive (or fail to conceive) is unreliable as a guide to what is genuinely possible, or if we lack a reliable sense of what we are capable of conceiving, then reasoning about imaginary scenarios may be an ineffective means of confirming or disconfirming certain hypotheses or theories.

Turing Test

Introductory article

David J Cole, University of Minnesota, Duluth, Minnesota, USA

CONTENTS

Alan Turing proposed a test for deciding whether a computer can think: if a computer could converse well enough to pass for human, it should be recognized as intelligent. This behavioral test is a natural extension to machines of one way we assess each other's intelligence; but it has been subjected to many criticisms, including the Chinese room argument, the frame problem, and claims that Gödel's results show that computers are limited in ways that human intelligence is not.

TURING'S PROPOSED TEST FOR MACHINE INTELLIGENCE

Can computers think? This is a question about what is possible, a metaphysical question concerning the nature of reality. Answering it requires exploring the nature of digital computation and of thought.

How could one tell if a computer was thinking? This is a very different question, an epistemic question about how one could know. The Turing test is a method for answering this second question. It was proposed in 1950 by the English mathematician Alan Turing (1912–1954) in a journal article entitled 'Computing machinery and intelligence'. Turing argued that the epistemic question was easier to address than the metaphysical question.

Turing's basic idea is this: if a person communicating online with a machine cannot tell by asking questions whether they are communicating with a human or a machine, then the machine is intelligent. It can do as well as a human in a very demanding task, conversation.

Turing was the leading twentieth-century theoretician of computers until his suicide at the age of 42 after he had been arrested for homosexual conduct and sentenced by the British authorities to receive estrogen injections. When he was just 24, Turing had created the idea of a simple abstract universal computer, now known as a Turing machine. This conceptual device helped provide a theoretical basis for understanding digital computers and their capabilities and limits.

Turing believed that suitably programmed computers could think intelligently, and would do so by the end of the twentieth century. He also believed that humans were prejudiced against the possibility of an intelligent machine. Furthermore, he thought that the question whether machines could think would embroil us in endless difficulties about the definition of 'thinking'.

Turing first describes a game he calls the 'imitation game'. The game is played by three people: a man, a woman, and an interrogator. The man and woman (A and B) cannot be seen or heard by the interrogator, who asks each of them written questions, either on slips of paper or via a remote keyboard. The object of the game is for the interrogator to determine which is the man, and which is the woman, while A and B both present themselves as women. Turing then asks what would happen if we replaced the man with a computer, and changed the game to one in which the interrogator must determine which is the human and which is the machine? Turing held that this imitation game test should replace the original question about whether machines can think. If human interrogators cannot tell the difference between machine and human in conversation, then it is reasonable to say that the machine can think: the machine passes the Turing test.

HISTORY OF THE TURING TEST

Two years before his 1950 article, Turing reported that he ran a similar test using a 'paper machine' for playing chess. A paper machine is a set of program instructions that are executed by a human using pen and paper. The human operator of the machine need not know how to play chess: the program determines the moves. Turing reports that a mediocre chess player found it 'quite difficult' to tell

whether a remote opponent was another human or a paper machine. Since Turing knew that an electronic computer could in principle execute the program of the paper machine, he had experimental evidence by 1948 that a computer might pass for a mediocre human chess player.

Turing was optimistic about the future success of computers passing the full version of his test (and he would no doubt have been pleased that a computer, Deep Blue, beat the world chess champion in 1997). The machines Turing knew and helped design were huge, rare, and very expensive. These were the size of a room, based on vacuum tubes, hand-wired with acoustic mercury delay lines for memory. Even with such machines in mind, Turing predicted that advances in programming would be rapid and that by the year 2000 a computer would be able to pass for a human 30 percent of the time after 5 minutes of questioning.

In the second half of the twentieth century, computer hardware advanced more rapidly than anyone, including Turing, could have foreseen. But progress towards passing the Turing test was much slower. By the 1960s, Joseph Weizenbaum had created a program, Eliza, that simulated a Rogerian psychotherapist. In conversation, the program took the initiative, asking questions that elicited responses in the subject, then using keywords in the subject's response to generate new questions (or, failing that, moving on to a new topic). Some subjects preferred Eliza to human therapists. Given the relative simplicity of the Eliza program (one version in BASIC is only 256 lines of code), Weizenbaum drew pessimistic conclusions about our ability to use computers wisely.

By the 1970s, more complicated programs had been developed, using stored background information and more sophisticated language parsers to generate answers to questions posed in natural language. Some researchers in artificial intelligence (AI) claimed that these programs could understand the questions posed in English.

In 1988, the New Jersey industrialist Hugh Loebner and the Cambridge Center for Behavioral Studies set up an annual contest to implement the Turing test. Loebner funds prizes for the best entrants. Since 1990, a Loebner Prize of $2000 has been awarded each year for the best entry, and a grand prize of $100 000 will be awarded to a program that produces responses indistinguishable from a human.

Many of the Loebner entrants have been related in design to the simple ELIZA program. In response both to the tricks that can be used to pass restricted Turing tests and to the charge that computers merely simulate understanding, various proposals have been made for more comprehensive tests. For example, one could require that the machine have sensors and actuators and so be able to identify objects that are sent to it by the interrogator. Such a machine would not only generate the verbal report that it had seen a hamburger, it would have been connected by sensors to the real world that it talks about during the Turing test.

ARGUMENTS FOR THE TURING TEST

The main justification for the Turing test is that it naturally extends ordinary ways of detecting intelligence. Turing does not propose a definition of intelligence. Instead, the test makes use of conversation: a familiar means by which people ordinarily appreciate and assess the intelligence of others. To determine how intelligent someone is, we typically ask questions. The questions may be very deliberate and systematic, as in an IQ test, or they may be more informal, as when one meets someone at a party, or interviews a candidate for a scholarship. Knowledge, understanding, and the ability to make inferences is quickly revealed in linguistic production.

An additional consideration concerns the concept of intelligence itself. One influential approach to understanding intelligence and other mental properties was forcefully described by the British philosopher Gilbert Ryle in his book *The Concept of Mind*, published the year before Turing published his paper. In Ryle's analysis, to be intelligent is just to do things intelligently. Intelligence is not a thing, a hidden faculty or force; intelligence is a way of handling problems (including the problem of how to respond to questions). Like the property of fragility, intelligence is a dispositional property: it is manifest under certain conditions. One sees that someone is intelligent by observing how he or she behaves. If this analysis is correct and intelligence is manifest in behavior, then an appropriately designed behavioral test such as the Turing test should be adequate for detecting intelligence.

Furthermore, Turing and others have remarked on the analogies between human brains and computing machinery. Brains are composed of billions of very similar elements whose primary operation appears to be activating or inhibiting other similar elements. Cognitive psychologists have noted that complex behavior is generated by the interaction of many simple subsystems in the brain. Many cognitive scientists believe that the sub-processes that ultimately produce intelligent behavior can be described as computations on information from

memory and the senses. If we ourselves are machines running computational processes, then wouldn't machines employing electronic technology running computationally equivalent processes also be intelligent? And if these same processes are in practice necessary to produce intelligent behavior, then wouldn't a behavioral test such as that envisioned by Turing reveal intelligence?

Turing believed that humans were prejudiced against the possibility of an intelligent machine. He thought that many had theological reasons for believing that thinking required a soul, or would be threatened by the implication that thought was not exclusively human. Turing therefore designed the test conditions to conceal the identity of the test subject.

Daniel Dennett has defended the Turing test. He participated in early administering of the Loebner version of the Turing test, although he later distanced himself from the project. Dennett points out how very difficult it would be for a machine to pass the Turing test with unrestricted subject domains under reasonably astute questioning. Vast amounts of knowledge would be required, including much background knowledge that is not explicit in books: for example, that lawyers usually know how to tie their shoes, that lawyers are unlikely to be found in the company of lumberjacks, that peanut butter is a poor ingredient for cocktails, or that people look silly with their shirt label sticking up on the back of their neck. Dennett also reminds us that the Turing test is not meant to define intelligence, just to test for it. Nor is the test meant to be so absolute that it might not be made to give an incorrect response with luck and clever programming. Rather, it is like other tests – of gasoline octane, of human competence, of water purity – that draw general conclusions from a sample. Dennett concludes that with able questioners asking subtle questions that draw on life's many experiences, the Turing test is adequate for what Turing intended, namely to reveal an intelligent computer.

PROBLEMS WITH THE TURING TEST

The main problem with the Turing Test is that it is behavioristic. The test examines only observable behavior, not how it is produced. This raises the possibility that something unintelligent might appear to be an intelligent being, by merely simulating intelligence. In principle, programmers might merely produce a huge list of likely test questions, paired with reasonable answers. Then the machine need have no intelligence; it could just be an automated look-up machine. In practice it is impossible to cover every possible question in such a list. However, there could be simple routines for handling unknown subject matter, such as responding 'I don't know' or 'I don't like to talk about …'. Indeed, just such methods have enabled the simple Eliza-type programs to pass the Turing test and to pose as human beings on the internet. But these programs are not intelligent. They do not understand the language they use, and whatever intelligence they may seem to display is entirely that of their programmers. If such a program produces a clever response to a question, we should admire the programmer, not the machine that looked up the response in a table. Computers running such programs have won the Loebner contest, but they do not think.

A quite different criticism of the Turing test is based on Gödel's incompleteness theorem. In 1931 Kurt Gödel proved that certain truths of arithmetic were not provable in a formal logic system. Some thinkers, notably J. R. Lucas in the 1960s and Roger Penrose in the 1990s, have taken this to show that human intelligence exceeds that of any possible formal symbol manipulator. If the Gödelian objection is sound, a computer could be unmasked as a result of limitations to which humans are not subject.

It is highly controversial whether Gödel's theorem implies that there is a difference between human and machine capabilities. Turing himself was very familiar with Gödel's theorem, and proved related results of his own. But he (along with many others) did not believe that these results showed that there was an important difference between human and machine potential for intelligence. Turing argued that intelligence is compatible with making mistakes, and in fact that under certain circumstances intelligent people will make mistakes where a less intelligent person would not. Therefore results about what is provable without mistake do not show that machines cannot be intelligent. Indeed, Gödel's theorem establishes a limitation on what anyone could prove using certain techniques; it does not establish specific limitations on computers, or that humans have access to proof techniques that machines cannot have.

Another criticism of the Turing test, and probably the best known, is John Searle's Chinese room argument. Searle argues that computers, no matter how they behave, cannot really understand language: they can merely simulate understanding. This problem is not confined to the look-up programs described above: Searle argues that it is a problem with any kind of program. Searle argues

that the Turing test cannot show that computers think or understand the questions that are put to them. His argument is simple: a person could do exactly what a computer does in producing answers to questions, yet not understand the language in which the questions are posed. An example is Turing's own paper machine mentioned above. The human operator of a paper chess machine need not know anything about chess. The operator just manipulates some symbols on paper, such as 'KP2–KP4', in accordance with thousands of instructions, yet the result may appear to be a proficient chess player. Similarly, the human operator of a paper program that passes the Turing test need not know the language in which the test was conducted.

Searle imagines a human who only speaks English, working in a room operating a paper machine. Questions posed in Chinese are slipped under the door of the room. The operator inside the room might match the Chinese symbols with those on numbered cards and thereby convert the Chinese input to strings of numbers. Using this numerical input the operator of the paper machine runs the program, and finally, after another conversion, produces strings of Chinese symbols and passes them back out under the door. If the program of the paper machine is a good one, it will appear to those outside the room submitting the questions and reading the answers that the occupant of the room understands Chinese. However, the occupant of the room merely runs a cleverly designed program. And so, computers running similar programs may appear to understand language, but they don't. Passing the Turing test can never show that a computer has intelligent understanding.

Many accept Searle's conclusion, but many do not. One reply to Searle is that whether or not the person running the paper machine understands the language of the inputs and outputs is irrelevant to whether the inputs and outputs are understood – the mind doing the understanding is not the paper machine operator's. The personality, knowledge, and intelligence displayed in answering the questions will not be those of the paper machine operator. Another mind is created by running the program. The understander exists as a result of the processes in the machine, but this mind is not identical with the machine, any more than a person is identical with his or her body (which may still exist even if the person is dead).

Searle draws a larger conclusion from his argument, namely that computers are confined to syntactic manipulation of symbols, and that one cannot get semantics or meaning from syntactic transformations. A computer can manipulate symbols, but it does not understand what the strings of symbols mean. Searle does not deny that a physical system can understand – he holds that we are physical systems that understand meaning and are intelligent. His negative conclusion applies just to digital computers. Just as it is intrinsic to the nature of 'talking' clocks and dolls to not understand, no matter how appropriate their responses, so it is intrinsic to the nature of digital computers that they do not actually understand language, no matter how appropriate their responses on some occasions. Though a computer may simulate intelligent conversation by syntactic manipulations of strings of symbols, the computer will never understand what any of the symbols mean. Computers are inherently simulators: their realities are always virtual.

Against this claim it can be maintained that computers are not inherently either simulators or syntax manipulators. Computers are complex causal systems. Humans attribute syntactic significance to the voltages in these electronic systems because that suits human purposes and aptitudes. A computer that alters the spark advance in an automobile engine in response to engine load does not simulate a mechanical spark advance system; it replaces the mechanical analog system with a more flexible digital one.

Another way of responding to Searle's argument against computer intelligence is to claim that it involves a confusion of levels. Thus, while the digital spark advance system uses digital techniques at the level of implementation, its output varies continuously as a function of the input: its overall behavior is analog. Similarly, a microchip that replaced a neuron in someone's brain might use digital techniques to calculate when to fire, while at the level of its overall function it might behave exactly as the neuron it replaced. From the standpoint of other neurons, it is simply another causal element. That it achieves its high-level causal role by low-level digital processes is irrelevant to the character of the larger system. On this view, a digital computer can realize a system of another type – even a system with the causal architecture of a mind. The digital realization may be at a low level, as it is with a neural network, or it may be at a higher functional level.

Other defenders of the possibility of computer intelligence appeal to particular theories of meaning to respond to the claim that computers only simulate and only perform meaningless syntactic manipulations. Many philosophers believe that meaning is not inside the head (or the machine),

but that meaning exists because of connections between symbols and the world. Since those connections exist whether the symbols themselves are located inside a human head or a computer, a computer can operate on symbols that are intrinsically meaningful. On this view, meaning is not dependent on any operation of interpretation, whether by users of the computer or by the computer itself.

Besides the Chinese room argument, there are other arguments against the possibility of intelligence in computers. For example, Hubert Dreyfus has argued that computers lack other essential characteristics of human intelligence. Human intelligence involves unconscious abilities, and appreciation of context, which cannot be captured in the explicit rule-following to which computers are confined. Related to this argument is the 'frame problem'. The frame problem is defined differently by different researchers. Generally, to behave intelligently, a system must have a current representation of many features of the world – in particular, the relevant features. What should be the form and extent of its representational system? Information used by the system must be readily available and must be updatable. One cannot know everything, so one must be selective, and this appears to entail that one must know what information is relevant to solving the problem at hand. Humans do this intuitively. But computers must be given explicit rules for dealing with every aspect of a situation. A mouse, for example, can scurry across the floor and dodge a cat. But a program that could analyze the rapidly changing visual field of a robot mouse, as well as the position and pressure information from joints and touch sensors, and then go on to calculate the torques and movements needed at all the mouse joints to produce such behavior, would be enormously complicated, and perhaps impossible. And so even our best robots still move slowly and crash into things.

Defenders of traditional AI approaches argue that the problem could be solved using huge databases of information, parallel processing, and faster hardware. Others have held that while traditional programming approaches are open to the objection that computers only follow rules, or cannot handle the frame problem, connectionist approaches avoid these objections. In connectionist approaches, there are no rules or explicit representations in databases; these are replaced by networks, an idealization of the networks of neurons found in biological brains. These networks have shown success in pattern recognition and other areas where traditional programming has produced disappointing results.

Still others have held that the solution lies in decentralized systems that are highly adapted to their environments, and that such 'situated intelligence' does not need to model the world centrally or update the model constantly.

Other new approaches to AI are being developed, which may, according to their proponents, provide the means for producing truly intelligent machines.

Although Dennett has been a defender of the Turing test, he and others have been critical of the conduct of actual tests, including the Loebner Prize tests. In addition, he and others have argued that aiming to pass the Turing test has not been good for AI. Passing the test requires the ability to produce an illusion of humanness. Winning programs use special effects, not the reality of good artificial intelligence and a massive database of information reflecting experience in the world. To build such a database of common-sense 'world knowledge' has for many years been the aim of the CYC project in Texas. Critics of this project argue that it is still book learning, not real experience, and also that it is impossible to codify human experience with the world. Dennett has argued that in order to pass a reasonable Turing test, a computer would need to interact with the real world, with sensors and manipulators. Turing himself thought that to be intelligent, a computer would need to learn from experience.

Unfortunately, at this time we do not understand the nature of concepts, how learning takes place in humans, how humans solve the frame problem, how hypotheses are formed or stored, or the nature of mental representations. So our lack of understanding of thought and intelligence returns to haunt us: in order to build a machine that can pass the Turing test, we may have to confront those metaphysical questions that Turing sought to avoid.

SIGNIFICANCE OF THE TURING TEST FOR COGNITIVE SCIENCE

Turing believed that by the beginning of the twenty-first century, the use of the word 'intelligence' and educated opinion would have changed to the extent that it would be acceptable to speak of machines that think. Perhaps this change has come about. If so, it may be more a product of popular culture than of actual results in AI. A thinking clockwork machine appeared in L. Frank Baum's science fiction story *TikTok of Oz* in 1904. In the mid-1920s, robots were on stage and screen, in the

Czech playwright Karel Čapek's play *R.U.R.* (where the word 'robot' first appeared), and in Fritz Lang's film *Metropolis*, in which a (female) robot was so human that it could lead a human workers' rebellion. Since 1950, the year of Turing's article, robots have appeared frequently in film. In Stanley Kubrick's 1968 adaptation of Arthur C. Clarke's story *2001: A Space Odyssey*, a thinking computer, HAL, played a leading role. In 1977, an android robot in George Lucas's film *Star Wars* was talkative and emotional, while another robot was intelligent, but not humanoid in form and unable to speak human language. An android robot was an important character in the popular television series *Star Trek: The New Generation*. The possibility that machines might think is surely in the mind of everyone who has grown up with these characters and stories, not only in the minds of philosophers and theoreticians.

Yet there is no consensus that thinking machines are a future reality. The unrestricted Turing test is very difficult, and no machine has come close to passing it. There is no general agreement as to whether it is possible for a machine to pass the Turing test, whether it is worth attempting to build such a machine, or whether such a machine would necessarily be able to think. Perhaps the most enduring result of Turing's proposal is the amount of thought about thinking that it has generated.

Unconscious Processes

Intermediate article

Howard Shevrin, University of Michigan, Ann Arbor, Michigan, USA

CONTENTS

The existence and nature of unconscious processes have been subjects of philosophical and scientific controversy for centuries. Only recently have scientific methods been developed that may resolve the controversy.

INTRODUCTION

To attempt to define unconscious processes is already to enter into philosophical, psychological, physiological and even theological controversies that have endured for centuries. Part of the problem is reflected in the fact that the very term 'unconscious' is defined by what it is not – not conscious – rather than by what it might be. Yet the scientific stakes are high, because what is at issue is how the mind itself will be conceived and understood. (*See* **Consciousness, Philosophical Issues about**; **Implicit Cognition**)

WHAT ARE UNCONSCIOUS PROCESSES?

The most intense controversy in recent times has been over whether unconscious processes of a genuinely mental, rather than a purely physiological kind, exist at all. Among those who believe that unconscious processes are mental, there are further differences: some believe that unconscious mental processes are dispositional in nature, like a bias or prejudice that remains latent in the mind until an occasion arises to act upon it; others believe that unconscious mental processes are continuously active and influencing our conscious minds and actions in various ways, often indirect and covert. Those who believe that unconscious processes are intrinsically physiological in nature assume, either explicitly or implicitly, that 'mental' and 'conscious' are equivalent terms: nothing mental exists beyond conscious experience. Often proponents of this view prefer to talk about 'nonconscious' processes, perhaps as a way to stress their non-mental nature. (*See* **Consciousness and Representationalism**; **Perception, Unconscious**; **Blindsight**)

Only since the 1950s have unconscious processes emerged as a field of empirical inquiry that can be conducted in the psychological and neurophysiological laboratory – not, however, without critics and skeptics. This period of empirical investigation has been made possible by the development of a method, subliminal stimulation, which permits the objective study of unconscious processes. 'Subliminal stimulation' refers to the presentation of stimuli so quickly or so faintly that they cannot be seen or heard consciously, but whose effects can be detected in various ways.

HISTORY

Throughout much of the history of the study of unconscious processes, two main themes are discernible: on the one hand, unconscious processes have been associated with cognition and normal functioning; on the other hand, with desire, emotion, and psychopathology. These two themes have yet to be harmoniously integrated.

Cognition and Unconscious Processes

The idea that stimuli that were not conscious could somehow register unconsciously and influence consciousness 'imperceptibly' can be traced back to Aristotle (384–322 BC). He observed that one could divide a grain of millet into small particles each of which singly would not be perceptible, and yet in the undivided grain each particle contributes to the conscious perception of the grain (Aristotle, 1902).

Centuries later, Leibniz (1646–1716) proposed a similar idea: minute perceptions, each of which escapes consciousness but which in the aggregate

contribute to a conscious perception (or in his terminology, an apperception). Each minute perception could be said to be below the threshold of consciousness, but if enough of them were aggregated they would become sufficiently strong that they could cross the threshold (Leibniz, 1908).

Herbart (1776–1841) was the first to exploit more fully the notion of a threshold implicit in Leibniz' thinking. He invested ideas (the German word refers to both perceptions and thoughts) with properties of strength and quality, resulting in a continual dynamic, competitive interplay of ideas, some of which would become conscious and others of which would remain in a state of inhibition, that is, unconscious (Herbart, 1891). An important notion in Herbart's theory is that ideas become unconscious not because they are too weak, but because they are inhibited by other ideas. This notion would reappear in a very different context in Freudian psychoanalysis.

For Helmholtz (1821–1894), unconscious inference played a vital role in perception. According to Helmholtz, our perceptions can be modified by repeated exposure to the same object, or by the laws of association (Helmholtz, 1962). At first these modifications are conscious and involve conscious inferences; ultimately these conscious inferences become unconscious, and can in some instances produce illusions or misperceptions. For example, we would tend to perceive a circle with a small segment missing as a complete circle because of an unconscious inference based on multiple conscious experiences with circles. Helmhotz' concept of unconscious inference is a forerunner of such current ideas as unconscious automaticity and procedural memory. (*See* **Automaticity**; **Memory, Philosophical Issues about**; **Memory: Implicit versus Explicit**)

The first cognitive subliminal experiments were conducted in the late nineteenth century. Generally, these experiments sought to demonstrate that, even though subjects were guessing at faintly presented stimuli such as letters or words and claimed that they were not consciously able to discriminate among the stimuli, their guesses were consistently better than expected by chance (e.g. Sidis, 1898). Many cognitive subliminal experiments have been modeled after this paradigm.

In this long line of theory and emerging experimentation extending to the present day, only cognitive processes, mainly perception, have been of interest, and only the normally functioning mind was the intended subject of explanation.

Desire, Emotion, and Unconscious Processes

Aristotle also observed how faint noises might appear in dreams as thunder and lightning. On the face of it, this would not seem to fit with Helmholtz' idea of unconscious inference, because faint noises are not ordinarily associated with thunder and lightning. Something different must be happening unconsciously for the laws of association to be violated. The difference, some have argued, has to do with the influence of desire and emotion. Many have seen these as of paramount importance in understanding unconscious processes and how they influence consciousness and action.

This view of the unconscious was forcefully expounded by Schopenhauer (1788–1860), who saw the individual as driven by an entirely unconscious impetus, which he called the will, originating from the same driving force that animates the universe (Schopenhauer, 1992). In people, the will is most manifest in the sexual instinct, for whose gratification, according to Schopenhauer, people invent deceptions and rationalizations. (*See* **Sexual Arousal**)

Following in Schopenhauer's footsteps, Nietzsche (1844–1900) redefined the will as the will to power, or the elemental unconscious force that was the one true impetus for experience and action (Nietzsche, 1967). Nietzsche was perhaps the first to identify what Freud would later call 'defenses'. Nietzsche talked about inhibitions that kept immoral but powerful desires from consciousness. In this way, he added a motivational and emotional dimension to Herbart's purely cognitive view of inhibition.

Meanwhile, there was a growing interest in people who were considered possessed, or who were in one way or another driven by uncontrollable urges, or suffered from strange physical torments and lapses. Such behavior seemed to be beyond conscious control. Cures were invented that ranged from exorcism, to the laying on of hands, to hypnotism.

With hypnotism, we arrive at the threshold of modern approaches to dealing with those unconscious emotional and motivational processes that can produce 'symptoms', or indicators of underlying psychological disorder. (*See* **Hypnosis and Suggestion**)

Throughout the twentieth century, these two perspectives on unconscious processes – cognitive, and motivational/emotional – existed side by

side, with very little exchange between them. (*See* **Emotion, Philosophical Issues about**; **Motivation**)

UNCONSCIOUS PROCESSES IN PSYCHOANALYSIS

Freud (1856–1939) was introducted to unconscious processes when he observed Charcot (1835–1893) hypnotize hysterical patients at the Salpêtrière. Among Freud's foremost contributions to the debate on unconscious processes was his elevation of unconscious processes to the status of the mental (Freud, 1915). For Freud, the extent of consciousness was tiny compared with the vast depth and extent of unconscious processes. He thus reversed the relationship between conscious and unconscious processes that had previously been advanced in psychology, in which unconscious processes were essentially tributaries to conscious processes. Freud placed motivation – in the form of powerful drives or instincts – at the heart of unconscious processes, and in this respect he aligned himself with Schopenhauer and Nietzsche. More importantly from a scientific standpoint, he initiated the development of a complex method of inquiry and treatment, which he called psychoanalysis, that no longer depended on hypnosis to reveal what was going on unconsciously and did not depend on suggestion as a curative agent. It was through the psychoanalytic method that Freud sought to discover the nature of unconscious processes and how they affected consciousness. (*See* **Motivation**)

The psychoanalytic method was based on two premises: unconscious processes existed and were both mental and causative; and unconscious processes influenced consciousness and actions in indirect and covert ways. The way to gain access to these unconscious processes was through free associations. The patient was encouraged to relax, assisted by lying on a couch and not facing the psychoanalyst, and to say everything that came to mind. Since it was assumed that unconscious processes were active and influencing consciousness but would only reveal themselves indirectly and in covert form, the psychoanalyst paid particular attention to discontinuities in the flow of free associations: omissions, elisions, slips, and illogical jumps.

Freud claimed to have discovered that patients unconsciously fight against, or resist, revealing what is at work unconsciously, and that this accounts for the indirect and covert ways in which unconscious processes influence consciousness. Freud called the various psychological mechanisms creating these distortions 'defenses', a generalization of what Nietzsche had called inhibitions. Repression, or unconscious motivated forgetting, would produce omissions in the free association process. Other defense mechanisms took the form, for example, of displacements, or endowing a trivial idea with undue importance as in an obsession. By shifting the emotional weight to a trivial idea the patient could avoid becoming aware of what was really bothersome unconsciously. An obsession contradicts the principle of saliency, one of the laws of association, according to which importance is determined by objective relevance.

Defense mechanisms did not appear to follow ordinary logical rules of thought, often violating the laws of association to such an extent that Freud hypothesized that unconscious processes were organized on the basis of entirely different principles from the normal waking conscious state (Freud, 1911). Because he further believed that this mode of thought appeared in childhood, he called this organizing principle the 'primary process', to be followed in time by the development of the 'secondary process', which referred to the logical, rational mode of adult thought. With maturity, the primary process more and more characterizes unconscious processes, and the secondary process conscious processes, although no exact equivalence emerges. Freud hypothesized that unconscious processes obeying the principles of the primary process tended towards immediate gratification, regardless of considerations of time or the identity of the gratifying object; thus unconscious processes were characterized by Freud as timeless and violating the principle of identity. The unconscious intent was to make some past pleasure immediate, no matter what constraints prevailed; thus it was necessary to develop defenses against this intent. According to Freud, the common experience in which all these contending forces are most evident is in dreams, which he conceptualized as primarily wish-fulfilling (Freud, 1900).

This powerful tendency for past gratifications to impose themselves on the present was nowhere clearer for Freud than in the phenomenon of transference. According to his observations, patients would often respond to him not as the helping physician he tried to be, but more in terms of some model transferred from the past, usually that of a parent. Often this unconscious press for immediate gratification of past desires in the present runs into obstacles or moral constraints, thus creating conflict and the symptoms for which the patient comes for treatment.

Freud divided unconscious processes into the dynamic unconscious and the preconscious. The dynamic unconscious was the powerful instinctual unconscious which was being defended against, and making itself felt through covert means. The preconscious is the repository of all those unconscious processes that can readily become conscious. In that respect it is similar to the unconscious studied by cognitive psychologists.

One could say that in psychoanalysis unconscious processes came to be recognized as powerful mental determiners of conscious experience. But since the theory was entirely based on anecdotal clinical evidence rather than systematic experimentation, many psychologists and other scientists have been skeptical of Freud's theories.

UNCONSCIOUS PROCESSES IN COGNITIVE SCIENCE

With the advent of behaviorism in the early twentieth century, psychology turned away from the study of unconscious processes, and indeed of consciousness itself. The discipline of psychology was narrowed to behavior, or what could be observed objectively rather than reported on introspectively. In time, however, a new approach emerged which returned psychology first to its older interest in consciousness itself and then to the study of unconscious processes. This new approach was called cognitive science because of its primary interest in cognition: perception, memory, judgment, and thought. (*See* **Cognitive Science: Philosophical Issues**; **Behaviorism, Philosophical**)

The underlying model in cognitive science was the computer (Simon, 1979). Once it had been programmed, quite complex processes could occur inside the computer, and these processes would eventuate in a useful print out. The mind could be conceptualized as a computer in which mental processes were the counterpart of the computer's programmed operations, and consciousness was the counterpart of the printout. And since only the outcome, not the operations themselves, were 'printed out', the counterpart of unconscious processes would appear to be the computer operations themselves. Advocates of what has been called strong artificial intelligence (AI) believed that computers would eventually be designed that would in essence be minds. The workings of the mind would then be equivalent to computer operations, or computations. This approach led many cognitive scientists to recast mental processes as computations which were set into operation by programs autonomously existing in the mind. (*See* **Turing Test**; **Artificial Intelligence, Philosophy of**; **Mental Disorders, Computational Models of**; **Social Processes, Computational Models of**; **Computation, Philosophical Issues about**)

The conception of unconscious processes inherent in this computer-based approach makes them coextensive with everything that occurs prior to consciousness. The function of these unconscious computational operations is to subserve consciousness by producing its contents in the form of solutions to tasks assigned to the mind. Strangely, consciousness thus becomes epiphenomenal, having no inherent purpose of its own. (*See* **Epiphenomenalism**)

Another cognitive approach to unconscious processes derived from earlier ideas about habit and voluntary action. Helmholtz' 'unconscious inferences', forming as a result of many consciously performed inferences, were in effect habits, while conscious inferences necessitated voluntary choices or actions. In contemporary cognitive science the notions of automatic and controlled processes replace 'habit' and 'voluntary action'. (Shiffrin and Schneider, 1977). Automatic processes are defined as involuntary, effortless (i.e. not requiring attention), unconscious, and unintentional. Controlled processes, by contrast, are voluntary, necessitating effort (i.e. requiring attention), conscious, and intentional. To complete the picture one needs to add the concept of semantic networks, the contemporary version of the 'associations' of earlier psychology (Rumelhart, 1999). A semantic network is a reticulation of nodes and weighted links built up between mental representations of stimuli based on experience with the stimuli. When a stimulus is processed automatically (unconsciously), activation spreads through the network solely as a function of the existing nodes and their weighted links. This automatic process is referred to as spreading activation, and is different from the more selective activation that is under conscious control, as in remembering a name, or performing some task.

With this kind of division between controlled (conscious) and automatic (unconscious), there could be no place for motivated unconscious processes. Motivation could only operate consciously. The division between the cognitive and motivational/emotional conceptions of unconscious processes thus persists to this day. Fortunately, we now have available experimental tools with which to test hypotheses derivable from each of these two different views of unconscious processes.

EXPERIMENTAL WORK ON UNCONSCIOUS PROCESSES

Although there had been a few sporadic experimental attempts in the first half of the twentieth century it was with the advent of research on subception (Lazarus and McCleary, 1951) in cognitive psychology and the Poetzl effect (Poetzl, 1960) in psychoanalytic research that experimental investigations of unconscious processes began in earnest. More recently there has been an increasing number of neuroscience-based investigations of unconscious processes.

Cognitive Studies

Lazarus and McCleary (1951) investigated the effect of obscene words on recognition thresholds. They hypothesized that if unconscious processing of words existed then most people would delay conscious recognition of obscene words, so that the recognition thresholds for these words would be higher compared with non-obscene controls. This unconscious perception was named subception. These studies were criticized because often differentials in word frequency were not taken into account, and also because even if people were aware of the obscene words, they might hesitate to say them.

Dichotic listening experiments, which involve presenting stimuli to both ears but requiring the subject to pay attention to one ear, were conducted (Lewis, 1970). It could be demonstrated that stimuli presented to the unattended ear influenced the perception of the stimuli in the attended ear. But the most widely used procedure was based on the masking effect. When a briefly presented stimulus is immediately followed by a longer-lasting stimulus, consciousness of the first stimulus is 'masked', that is, not reported as seen and presumably unconscious. Many experiments indicated that the masked stimulus, although unconscious, was registered and influenced subsequent conscious perception (Marcel, 1983). (*See* **Masking**)

Social cognitive researchers have demonstrated that subliminal emotional facial expressions can influence the way a neutral masking stimulus is consciously perceived (Winkelman *et al*., 1997). Others have shown that subliminal stimuli can reveal unconscious prejudices that are consciously disavowed (Banaji and Greenwald, 1994). (*See* **Emotion**; **Prejudice**)

More recently, a method has been devised called the process dissociation paradigm, whereby subjects are instructed in one condition to exclude stimuli previously masked, and in another condition to include them (Jacoby, 1991). The measure of unconscious perception is based on the failure to exclude the masked stimuli when instructed to do so. Positive results have been obtained from such experiments. (*See* **Dissociation Methodology**)

Psychoanalytic Studies

The Poetzl effect was named after a Viennese contemporary of Freud who devised a means for investigating how dreams were affected by stimuli that had not been present in consciousness (Poetzl, 1960). Poetzl flashed pictures for a duration of 10 ms, asked his subjects to describe what they saw, noted what had not been reported, and then discovered that the unreported and presumably unseen elements of the picture were present in dreams reported by subjects the next day. Freud was impressed by this means of experimentally investigating dream formation. (*See* **Sleep: Polyphasic**)

The Poetzl effect was replicated by a number of psychoanalytically oriented researchers who developed a variety of measures in addition to dreams, such as images and free associations (Fisher, 1954). These early Poetzl effect studies were often anecdotal and lacking in adequate controls, but more rigorous experiments were conducted later. On the whole, results were promising. For the first time it could be demonstrated that a stimulus not in consciousness had measurable effects on subsequent conscious experiences.

In addition to Poetzl effect studies, other methods were devised to more directly test psychoanalytic propositions. The subliminal psychodynamic activation method was developed to test quite specific psychodynamic hypotheses about the nature of unconscious conflict related to various disorders. In several studies the presence of unconscious oedipal conflict in young men was investigated by subliminally presenting the words 'Beat Dad' (Silverman *et al*., 1978). It was hypothesized that the 'Beat Dad' stimulus would activate an unconscious oedipal conflict that would lower dart-throwing scores in a subsequent competition. Positive results were obtained in some but not all studies.

Another approach sought to incorporate a brain response indicator of unconscious conflict (Shevrin *et al*., 1996). In these studies, unlike the subliminal psychodynamic activation investigations, stimuli were individualized for each subject based on intensive interviews and tests. Words were selected by a panel of psychoanalysts to reflect the subjects'

unconscious conflict, and were compared with words reflecting the subjects' experience of their symptoms. These words, and suitable controls, were flashed subliminally as well as supraliminally. It was found that the brain responses grouped the unconscious conflict words together only when they were presented subliminally. This fact was interpreted as supporting two conclusions: the existence of unconscious conflict (a defining characteristic of the dynamic unconscious); and the operation of some kind of inhibitory or defensive process so that the unconscious conflict words were no longer grouped together when presented supraliminally. This experimental effect correlated with a measure of repressiveness, providing additional convergent evidence that defensive behavior was involved. (*See* **Neural Correlates of Visual Consciousness**; **Event-related Potentials and Mental Chronometry**; **Electroencephalography (EEG)**)

Neuroscience Studies

We have already mentioned one study involving brain responses in subliminal research on unconscious conflict. Other brain response studies have demonstrated that emotional meanings can be processed entirely unconsciously, resulting in physiological arousal and appropriate expressive signs (Bernat *et al*., 2001; Bunce *et al*., 1999). The invention of neuroimaging, enabling us to picture neural activity in different parts of the brain, has made it possible to localize the response to a subliminal fear stimulus in the amygdala, a small brain structure known to be important in emotion (Morris *et al*., 1998; Whalen *et al*., 1998). Neuroimaging research is still in its infancy and there are complex methodological issues that remain to be resolved. It is, however, likely that a method combining brain responses with neuroimaging will offer exciting possibilities to future investigators of unconscious processes. (*See* **Emotion, Philosophical Issues about**; **Neuroimaging**; **Amygdala**)

FOUNDATIONAL ISSUES CONCERNING UNCONSCIOUS PROCESSES

The first conclusion one can reach on the basis of research in cognitive science, psychoanalysis, and neuroscience is that unconscious processes exist and must be taken into account in any theory of the mind and how the brain functions. The focus of research can now shift to determining the nature of unconscious processes. Some cognitive scientists believe that unconscious processes are relatively unimportant in the larger economy of the mind. Evidence is advanced, for example, that the effects of subliminal stimuli last only briefly and leave no memory trace. Other evidence suggests that the effects can last for hours, if not days. Most cognitive psychologists are not concerned with motivation and emotion. Research inspired by psychoanalysis, on the other hand, demonstrates that unconscious motivational and emotional processes play an essential role in conflict and symptom formation. From this standpoint, subliminal stimuli can leave memory traces that can last a lifetime and exercise a powerful influence on consciousness and personality.

Motivation is a particularly contested issue in the study of unconscious processes. According to the 'automatic versus control' theory, motivation can only be conscious. Psychoanalytic research (Shevrin *et al*., 1996) and social cognitive research (Bargh and Barndollar, 1996) have begun to cast doubt on this position. Other research suggests that complex motivational and emotional factors may be at work even in straightforward cognitive tasks. Snodgrass *et al*. (1993) and Van Selst and Merikle (1993), for example, have found that individual strategy preferences play an important role in cognitive subliminal effects. In their experiments, subjects were asked to guess which of four words had just been flashed subliminally under two conditions, one in which they were instructed to simply let one of the four words pop into mind, and another in which they were encouraged to base their guesses on whatever they could see. Importantly, they were asked which strategy they preferred. It was found that when the subjects who preferred the 'look' strategy were asked to follow the 'pop' strategy their performance in guessing the correct word was consistently below chance. In order to explain this finding, some form of unconscious inhibition of correct responses had to be inferred. (*See* **Social Cognition**)

How motivation works unconsciously, and how unconscious processes are qualitatively different from conscious processes, remain challenging questions for future research. Psychoanalytic theory would predict that different principles of organization govern unconscious and unconscious processes. Brakel *et al*. (2000) have provided some evidence in support of this hypothesis by demonstrating that similarity judgments based on subliminal categorization follow primary process rules.

In addition to issues bearing on the roles of cognition, motivation, and emotion, there are also issues bearing on whether unconscious processes

are to be considered mental or physiological, dispositional or active. Searle (1992) has taken the position that unconscious processes are physiological and dispositional in nature. Only consciousness is mental in the sense of being about things, or, in more technical terms, as possessing intentionality. Unconscious processes, insofar as they can become conscious, have what Searle called derived intentionality. Unconscious processes are dispositional in that they exist latently until such time as they become conscious. (*See* **Intentionality**)

It could be argued, however, that the evidence drawn from both cognitive and psychoanalytic subliminal studies suggests that unconscious processes are just as mental as conscious processes and are independently active. It would be difficult to account otherwise for unconscious registration of word meanings, which are inherently referential and result in spreading activation of semantic networks independently of any conscious task.

SUMMARY

For centuries, unconscious processes have been thought of either as purely cognitive and subserving consciousness, or as motivational/emotional and interfering with or independent of consciousness. We are now beginning to see some integration of these two seemingly distinct viewpoints.

Vagueness

Intermediate article

Achille C Varzi, Columbia University, New York, New York, USA

CONTENTS

Vagueness arises whenever a concept or word admits of borderline cases of application. It can be viewed as a feature of human thought and language (conceptual or linguistic vagueness) or as a characteristic of the world itself (ontic vagueness).

WHAT IS VAGUENESS?

The standard view is that vagueness arises whenever a concept or linguistic expression admits of borderline cases of application. The predicate 'bald', for example, is vague because there can be situations in which it is indeterminate whether or not it applies to (a name of) a certain object. Some people are clearly bald (Picasso), some are clearly not bald (the count of Montecristo), and some are borderline cases – our concept of baldness and our linguistic practices do not specify any exact number of hairs that marks the boundary between the bald and the non-bald. Similarly, a singular term such as 'Mount Everest' is vague because there is no determinate way of tracing the geographical limits of its referent. Some rocks are clearly part of Everest and some are clearly not, but some rocks enjoy a borderline status.

There is, however, dispute concerning this way of characterizing vagueness. For the statement that a term t admits of borderline cases of application – that it is indeterminate whether or not such and such objects fall within the boundaries of the entity designated by t – can be given a *de re* reading, as in statement 1 below, or a *de dicto* reading, as in statement 2:

> The term t designates an entity x such that it is indeterminate whether such and such objects fall within the boundaries of x. (1)

> It is indeterminate whether the term t designates an entity x such that such and such objects fall within the boundaries of x. (2)

On the first reading the indeterminacy is ontological. The predicate 'bald' is vague, on this reading, because it stands for a vague set: there is no objective, determinate fact of the matter about whether the borderline cases are included in that set (or about whether they enjoy the corresponding property). Likewise, on this reading 'Mount Everest' is vague because it stands for a genuinely vague thing: there is no objective, determinate fact of the matter about whether the borderline rocks are part of the mountain. There may also be no determinate fact of the matter about when the mountain itself came into being, for the temporal boundaries of an object may be vague too.

By contrast, the *de dicto* reading corresponds to a purely linguistic (or conceptual) notion of vagueness. On this view the set of bald people is not vague at all. There are exactly 2^n sets of people (where n is the number of people at the present time), each with a precise membership function; yet our linguistic stipulations do not fully specify which of those sets can serve for the extension of the predicate 'bald'. There is, similarly, no vague mountain on this view: instead there are plenty of aggregates of matter, each with a precise spatiotemporal boundary, and when we say 'Mount Everest' we are just being vague as to which aggregate we are referring to.

The two views are not strictly incompatible, at least in so far as one may be willing to treat some vagueness as ontological and some as linguistic. One could also construe some terms as involving both sorts of vagueness: it would be indeterminate which particular sets or objects those terms designate, and the relevant candidates would include vague specimens along with sharp ones. However, these ways of combining ontological and linguistic vagueness have attracted little attention and current views on vagueness divide rather clearly between one approach and the other. (See Tye, 1990 and Lewis, 1993, for two representative position statements, and Evans, 1978, for a much-debated way of setting up the issue.)

PROBLEMS AND PARADOXES

In so far as vagueness involves borderline cases, whether *de re* or *de dicto*, it manifests itself semantically in the generation of truth-value gaps. If Jones is a baldish person, then the statement that he is bald appears to lack a definite truth-value; if it is indeterminate whether this rock is part of Everest, then the statement that it is part of Everest is likewise neither true nor false. This has been a natural source of concern for philosophers and logicians since Frege, for the admission of truth-value gaps amounts to a failure of the classical principle of bivalence.

The main source of concern, however, is that vagueness generates a deep puzzle. For not only do vague terms involve borderline cases: they also seem to involve borderline borderline cases, or borderline borderline borderline cases. For example, just as there is no sharp line between the bald and the non-bald there does not seem to be any sharp line between the bald and the baldish (or the baldish-ish). In neither case can a single hair make a difference. Intuitively, this means that our notion of baldness satisfies the following principle:

> For every n: if a man with n hairs on his head is bald, then a man with $n+1$ hairs on his head is also bald. (3)

(Let us suppose that baldness supervenes exclusively on the number of hairs.) However, it is enough to combine this principle with

> A man with no hairs on his head is bald. (4)

to reach the paradoxical conclusion that

> A man with $500,000$ hairs on his head is bald. (5)

(This can be shown by 500,000 repeated applications of the rules of universal instantiation and modus ponens.) In other words, the intuition that the applicability of 'bald' cannot be a matter of a single hair seems to force us to reason from the true premise that Picasso is bald to the false conclusion that the count of Montecristo is also bald. A corresponding point can be made about the intuition that the applicability of 'Everest' is not a matter of millimeters. In both cases it is hard to reach a diagnosis, but the clash between logic and intuition is deep.

In its oldest form, this problem is known as the *phalakros* paradox (from the Greek work for 'bald') and is attributed to Eubulides of Miletus, a contemporary of Aristotle. Eubulides is also credited with the formulation of the *sorites* paradox, which builds in a similar way on the vagueness of 'heap.' There are also versions of the paradox that rely on a different way of expressing the inductive principle 3. For example, the Stoics considered replacing the embedded conditional 'if … then' with a negated conjunction (it is not the case that a man with n hairs on his head is bald and a man with $n+1$ hairs is not bald). This makes the paradox even harder, since one cannot just blame the material conditional for the problem. Another common variant involves replacing statement 3 with a long chain of conditionals (or negated conjunctions), one for each relevant n. Again this makes the paradox more robust, since one cannot blame the universal quantifier for the problem. All such paradoxes are collectively referred to as sorites paradoxes. The problem with the notion of vagueness is that it generates such paradoxes, in some form or other. And theories of vagueness are naturally compared on the basis of how successful they are in providing a systematic resolution.

THEORIES OF VAGUENESS

Broadly speaking, there are two strategies for dealing with the sorites paradox. Focusing on the version exemplified by statements 3 to 5, one can either reject the argument as invalid, or reject it as valid but unsound. (One could also bite the bullet and accept the conclusion, but few would be willing to go that far.)

There are two main varieties of the first strategy. On the one hand, one can insist that logically valid reasoning can only be formulated in a precise language. This was, for example, the response advocated by Russell (1923) in the first full paper devoted to the topic of vagueness. Today this is not a popular position because it enforces an intolerable restriction on the scope of logic: since many of the words that we use in ordinary discourse (and even in much scientific discourse) are vague, logic would be of little practical use.

On the other hand, one can question the validity of the sorites argument by questioning the adequacy of classical logic. A popular approach is to adopt some kind of many-valued logic in which statements are allowed to take intermediate truth-values and in which the validity of the inference of statement 5 from statement 4 decreases as the number of applications of modus ponens increases.

In fact, because the notion of a borderline case is itself vague, a natural implementation of this strategy allows for a continuum of intermediate truth-values. The result is a fuzzy logic in which sentential connectives, for example, are represented by operations on the real numbers in the

interval [0,1] rather than on the two-valued truth set {0,1} (e.g. Machina, 1976). If vagueness is thought of as an ontological phenomenon, this account is naturally combined with a fuzzy semantics in which a predicate, for example, is assigned an extension whose membership function is itself continuum-valued. The closer to 1 the value is, the more the argument is a member of the set (Zadeh, 1965). This approach allows one to resolve the paradox as follows. First, the connectives are characterized in such a way that a conditional of the form

> If a man with n hairs on his head is bald, then a man with $n+1$ hairs on his head is also bald. (6)

is sure to be true or nearly true. For example, the truth-value of a conditional may be set to 1 minus the surplus of the antecedent over the consequent (if any). Secondly, there will be values of n such that the truth-value of the antecedent of statement 6 is slightly higher than that of the consequent. The underlying intuition is that one hair does make some difference after all, albeit a very small and generally negligible difference. Thus, as long as validity is defined in such a way that the conclusion of a valid argument must be at least as true as each of the premises, the relevant instances of modus ponens will be invalid whenever the truth-value of the antecedent is less than or equal to the truth-value of the conditional but (slightly) greater than the truth-value of the consequent. The paradox arises because the error is so small as to be undetectable, and yet it increases each time modus ponens is invoked.

This account has a certain prima-facie appeal but it is open to a number of objections. First, the fuzzy-theoretic machinery appears to replace vagueness with extremely refined precision. To what degree, exactly, is it true that Jones is bald? To degree 0.6? Perhaps to degree 0.59? Or maybe 0.5999? Second, the assumption of a totally ordered set of truth-values is itself problematic. How does the degree to which Jones is bald compare to the degree to which Smith is tall? How does it compare to the degree to which a certain borderline rock is part of Everest? Thirdly, there is the embarrassing presupposition that a point must still exist where one goes from fully-fledged truth to partial truth, or from partial truth to fully-fledged falsehood. What is the maximum value of n such that a person with n hairs is truly bald, i.e., bald to degree 1? What is the last rock, along a continuous path descending from the peak of Everest, that is definitely part of the mountain? These questions may not have practical relevance, but they appear to undermine the theoretical force of the account.

Turning to the second strategy for dealing with the sorites paradox – to accept the validity of the argument but to reject one of its premises as false – one can again distinguish two main approaches. One can either reject the 'base step' expressed by premise 4, or one can reject the 'inductive step' expressed by premise 3. (In the version of the paradox where premise 3 is replaced by a chain of conditionals, this amounts to rejecting one of the conditionals. We shall not discuss this variant here.) A rejection of premise 4 amounts to a radical response to the effect that a vague term such as 'bald' is ultimately incoherent (e.g., Unger, 1979). Given the pervasiveness of such terms in natural language, this line of response seems to have few advantages over Russell's version of the first strategy. A rejection of premise 3, on the other hand, amounts to asserting the existence of a precise number n of hairs separating the bald from the non-bald. This appears to contradict the intuition that 'bald' is vague and, by generalization, that there are any vague words at all. Indeed, this problem is real and ineliminable if vagueness is understood entirely in ontological terms, for then the existence of a relevant cut-off value of n amounts to the existence of a sharp boundary around the relevant set or object. However, if vagueness is understood in linguistic terms there is a popular way of resolving this intuitive problem, using an approach that has come to be known as supervaluationism (Fine, 1975).

The basic idea underlying supervaluationism is that a vague term is one that admits of various alternative 'precisifications'. A vague predicate such as 'bald', for instance, could be made precise by deciding that a man is bald if and only if he has at most 10,000 hairs. Or it could be made precise by deciding that a man is bald if and only if he has at most 9,999 hairs. And so on. The predicate is vague precisely because there is indeterminacy between these various ways of picking out a precise cut-off value. Likewise, a vague singular term such as 'Everest' could be made precise by drawing a precise boundary around its referent, but there are many ways of doing this and all of them are compatible with the way we use the name. Given this understanding of vagueness, supervaluationism says that the truth-value of a statement involving vague terms is a function of its truth-values under the various admissible precisifications of those terms. If the statement is true under all such precisifications, then it is true *simpliciter*: the unmade linguistic stipulations do not matter. In other words, it makes no difference to suppose that the meaning of those expressions could be defined

more precisely: what the statement says is true regardless ('super-true'). Likewise, if the statement comes out false under every precisification then we may regard it as false (or super-false) in spite of its vagueness. This explains, for example, why we can confidently assert sentence 4 and deny sentence 5. On the other hand, when a statement comes out true under some precisifications and false under others, the unmade linguistic stipulations become relevant. In such cases, the statement falls into a truth-value gap. This is why, for example, we must suspend judgment when it comes to statements of the form

A man with n hairs on his head is bald. (7)

for various intermediate values of n: the truth-value of such statements depends crucially on how we imagine the extension of 'bald' to be precisified.

This account preserves all theorems of classical logic even though it violates some of its fundamental semantic presuppositions, such as bivalence and truth-functionality. For example, an instance of the law of the excluded middle, such as

Either a man with n hairs on his head is bald, or he is not bald. (8)

is sure to be true even when both disjuncts fall into a truth-value gap. It is precisely this sort of property that allows supervaluationism to resolve the sorites paradox. Supervaluationally the inductive premise 3 is false, because it is false on every precisification. However, contrary to the standard semantics for the quantifiers, its falsity does not imply the existence of a specific n for which the corresponding conditional (statement 6) is false, and this is what allows a supervaluationist to preserve the intuition that 'bald' is vague. Supervaluationally it is true that there is a number of hairs that marks the boundary between bald and non-bald, but there is no number of hairs such that it is true of that number that it marks the boundary. (The same account applies, *mutatis mutandis*, to a sorites for a singular term such as 'Everest'.)

This account is attractive because it reflects a deep, preanalytical intuition concerning vagueness as it arises in ordinary language: we speak vaguely because in ordinary circumstances the vagueness of our words does not matter. Still, various objections have been raised. For example, some critics consider the supervaluationist account of the logical operators in statements 8 and 3 unacceptable. Moreover, supervaluationists have been pressed to provide an account of the phenomenon of higher-order vagueness. This difficulty manifests itself not only in the supposition that there is a clear demarcation between the clear cases and the borderline cases (as in fuzzy logic) but also in the supposition that each vague term is associated with a precise set of precisifications. Presumably, if 'bald' could be made precise by deciding that a man is bald if and only if he has at most n hairs, then it could be made precise by deciding that a man is bald if and only if he has at most $n+1$ hairs – and this yields immediately a sorites paradox for the semantic predicate 'could be made precise'. For a supervaluationist this only shows that the metalanguage within which the semantics is formulated is itself vague, but some critics find this line of response unsatisfactory. Lastly, the assumption that every vague expression can in principle be precisified, or that any number of vague expressions can in principle be simultaneously precisified, has sometimes been regarded with suspicion.

VAGUENESS AND COGNITIVE SCIENCE

To the extent that vagueness is not entirely a matter of ontology, it falls naturally within the range of interest of the cognitive sciences. Supervaluationism, for example, may be viewed as implementing a certain view about how ordinary speakers manage to communicate and reason even in the absence of a precise language. We speak vaguely because in normal circumstances the vagueness of our words does not matter. In normal circumstances what we say is true under all the admissible interpretations of our words, hence we do not need to be more precise (Lewis, 1993).

More generally, the linguistic conception of vagueness has often been associated with the idea that language is but one of many different representation systems. Thoughts and mental images, for some authors, can likewise be vague, and so can every privately or publicly accessible representation. Russell combined his conservative views on logic with the view that all vagueness is analogous to the vagueness that may exist even in a photograph, let alone an impressionist painting.

It is not clear, however, whether a single account can indeed be made to fit all these different cases (Dummett, 1975). Compare the vagueness of 'bald' with that of 'looks bald'. If Jones is a borderline case of the latter predicate, a linguistic account would have to say that on certain precisifications Jones will look bald (to me) even though his identical twin, who has just one more hair on his head, will not look bald. Since the two men look exactly alike to me, this seems to contradict the idea that the

predicate 'looks bald' is entirely observational, i.e., that it applies only by virtue of appearances. A similar point can be made for observational predicates such as 'looks square' (where 'square' is non-vague), or for any other predicate expressing properties whose reality, as some say, *is* their appearance – such as color predicates.

For another example, if there is such a thing as the language of thought, or 'Mentalese', then it would seem to suffer from a different sort of vagueness from that of public languages, at least to the extent that the meaning of Mentalese expressions does not depend on their use. A supervaluationist account would therefore seem unjustified in this case. A fuzzy-theoretic semantics would also be inadequate because of the psychologically unrealistic fineness of definition in the underlying space of truth-values. In the case of public languages one may try to base a fuzzy truth-value assignment on statistical measurements, but Mentalese would defy this way of proceeding. (There is a tradition of psychological studies aimed at measuring the degree to which people are inclined to classify a penguin as a bird, say, but this is irrelevant here: something may fail to be a typical P without being a borderline case of P, just as a perfectly clear case of prime number may fall short of typicality (Armstrong *et al*., 1983).)

Sorensen (1991) has suggested that cases such as these are more amenable to an epistemic account whereby vagueness is a kind of ignorance. On this account, the indeterminacy associated with a vague expression stems primarily from our inability to determine its exact reference (extension). More generally, the epistemic account has been proposed as an alternative to all the theories mentioned above because it provides a straightforward resolution of all sorts of sorites paradoxes. If the vagueness of 'bald' is a matter of ignorance, then a critical cut-off value of n does exist which separates the bald from the non-bald, but it is unknown to us. Moreover, the relevant value cannot be known to us. This would explain our inclination to regard statement 3 as true when it is, in fact, false. In this sense, epistemicism can be viewed as an alternative to supervaluationism in providing an implementation of the second of the two strategies for resolving the sorites paradox. Like supervaluationism, epistemicism validates all theorems of classical logic; unlike supervaluationism, however, it also validates all classical semantic presuppositions, including the principle of bivalence.

The epistemic account of vagueness is generally met with astonishment. How can there be a sharp boundary demarcating the extension of 'bald' if nobody has ever made the necessary semantic stipulations? What could possibly be the explanation of our general ignorance? One response, articulated in some detail by Williamson (1992), is that the boundaries associated with vague terms are unknowable because they violate a general principle that characterizes reliable knowledge. Briefly, this is a principle to the effect that our beliefs are reliable only if we leave a margin for error. For example, the belief that a general condition obtains in a particular case can be reliably true only if that condition obtains in every similar case (the relevant notion of similarity depending on context and cognitive capacities). In the case of baldness this would mean that we cannot *know* that a certain person is bald if people with just one more hair on their head *are not* bald. The vagueness of a predicate such as 'bald' would then be captured, intuitively, not by the inductive principle 3 but rather by a margin-of-error principle such as:

> For every n: if a man with n hairs on his head is known to be bald, then a man with $n+1$ hairs on his head is bald. (9)

And this principle does not combine with statements 4 and 5 to generate a paradox even if classical logic is retained altogether.

Some support for the epistemic conception of vagueness derives from recent experimental data. Notably, Bonini *et al*. (1999) have found that ordinary speakers react to questions about vague predicates as if they were not sure about their boundaries, which leads to the hypothesis that vague predicates are mentally represented like sharp predicates with crisp true–false boundaries of whose location one is uncertain. On the other hand, such findings seem compatible also with the view that vagueness is a phenomenon that reflects the fluid judgmental spreadings involved in human categorization. According to Raffman (1994), ordinary subjects are always likely to break the slippery slope of a sorites series precisely because a sharp category shift is likely to occur at some point on each run of judgments. The point of shift varies with the judgments of different speakers, and those judgments in turn vary with the contexts in which they are made. Rather than explaining this phenomenon in epistemic terms, however, Raffman conjectures that the point of shift is determined by a set of psychological factors, such as the strength of the judgmental inertia induced by the anchoring heuristics (Tversky and Kahneman, 1974) employed by the subjects as they proceed along the series. (One will categorize a greater number of people as bald if one begins

from the hairless side of a corresponding sorites series than if one begins from the hairy side.) In other words, the relevant category shifts are not to be viewed as boundary crossings but as Gestalt-like changes of perspective. If this is right, then it is also plausible to suppose that a subject's judgments may vary depending on whether the items in a sorites series are considered individually or in pairs. Both the basic premise and the conclusion of a sorites argument derive their plausibility from individual judgments. But only the second, pairwise, type of judgment satisfies the inductive premise of the sorites paradox. This means that statement 3 would have to be rewritten as

> For every n: if a man with n hairs on his head is bald then a man with $n+1$ hairs on his head is also bald, in so far as the two men are judged pairwise. (10)

With premise 3 replaced by statement 10, the paradox would dissolve into a fallacy of equivocation.

It is indeed regretful that the available experimental data are still too scarce to throw light on these conjectures. A psychologically plausible account can hardly fail to include some hypothesis about the mental representations that underlie our usage of vague words. Still, few theorists seem inclined to believe that the paradox can be resolved by purely empirical considerations, just as few are willing to accept a purely epistemic account. For the majority, the paradox is a genuine one. Vagueness remains a deep philosophical conundrum.

Zombies

Intermediate article

Güven Güzeldere, Duke University, Durham, North Carolina, USA

CONTENTS

A zombie is a creature that is indistinguishable in behavior as well as in certain physical or physically specifiable respects from a human being, yet which lacks certain mental features that a human being possesses.

INTRODUCTION

The folkloric notion of zombies (which came from the West Indies and has been popularized by Hollywood horror movies) attributes life, or at least lifelike behavior, to them, in a resurrected body, while denying them a soul. The philosophical notion postulates the zombie body as identical to a human body characterized at a particular level of abstraction (molecular or functional), and replaces the 'absence of soul' with the absence of mind, or particular kinds of mental states. As such, zombies are used as an illustrative element in thought experiments in the philosophy of mind that explore the nature and modality of the relation between bodily properties and mental attributes, as well as the relation between different kinds of mental states (propositional attitudes such as beliefs and thoughts versus conscious experiential states such as visual sensations and pains).

HISTORY AND BACKGROUND

Because there have been several different ways in which zombies have been described in the philosophical literature as being indistinguishable from humans, and several different features they have been described as lacking, it is necessary to characterize the idea of zombies in general terms. It is possible to come up with at least nine different philosophically relevant notions of a zombie (see Figure 1). However, in most of the notable discussions, zombies are taken to be identical to human beings either in complete physical make-up or in functionally specifiable internal constitution, and in behavior, and they are taken to lack either conscious qualitative (experiential) mental states or mentality altogether.

Although both the term "zombie" and its core notion had been used in the philosophical literature in a less specific sense earlier (e.g., Martin and Deutscher, 1966; James, 1879, and Campbell, 1970, respectively), it was introduced in its modern form by Robert Kirk (1974) as 'an organism indistinguishable from a normal human being in all anatomical, behavioral and other observable respects, yet insentient'. Although more general conceptions have since been formulated, Kirk's discussion, in its aim to refute materialism, not only led the way but also anticipated much of the discussion on zombies that followed in the next three decades. Kirk's strategy is a familiar one: using a hypothetical argument based on the conceivability of mind, characterized in terms of its cognitive or experiential attributes, and body, characterized in terms of its physical attributes, as having distinct existences. The possibility of body and mind as being thus separable is then used to draw the conclusion that any materialist ontology, however successful in providing an account of the physical world, necessarily falls short of providing a complete account of the mind.

One of the most influential examples of this kind of argument in the history of philosophy is employed in Descartes's *Meditations*. From the clear and distinct conception of mind, characterized as thinking substance, as existing independently of the body, characterized as extended substance, Descartes concludes that body and mind are in fact ontologically separate and independent. The zombie argument employs the converse of the Cartesian argument. From the self-consistent conception of the body and its full behavioral repertoire as existing in the absence of the mind, it is concluded that a complete theory of bodily attributes and behavior, by itself, is silent about the nature of mind, and the relation between body and mind. It then follows, it is argued, that

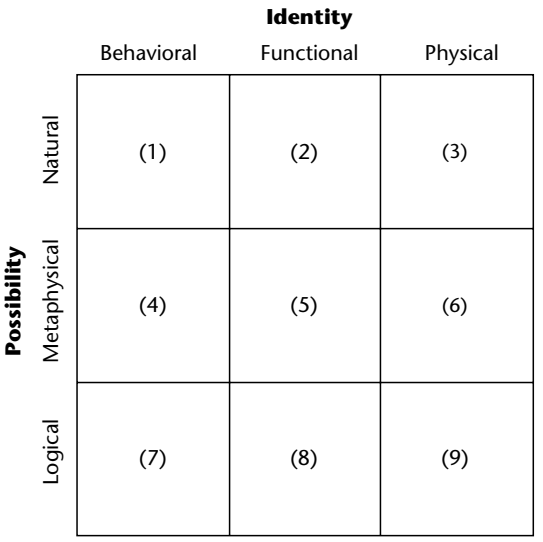

Figure 1. The 'zombie scorecard': nine distinct notions of zombie, classified according to the respects in which the postulated creature is the same as a human being (the 'identity' parameter) and the kind of possible existence the creature is granted (the 'possibility' parameter). (Adapted from Polger (2000).)

the accounts provided by materialist theories at best explain the constitution and nature of our zombie twins, not of complete human beings. Lacking the theoretical machinery to talk about the mind, or about how body and mind are related, they fail to distinguish between us and our zombie replicas.

Notice that these two versions of the conceivability argument can be, and often are, proposed independently of one another. Descartes, for example, never employed the 'zombie argument' (even though he toys with the idea in his discussions on automata and animals), and, despite the fact that he is generally cited in support of it, it is not obvious that his interactionist substance dualism could indeed permit the metaphysical possibility of a zombie. On the other hand, most anti-materialists today shy away from the Cartesian argument, because of well-known difficulties about the nature of mind–body interaction that have plagued Cartesian theory from the very beginning, and use the zombie argument only in favor of a milder version of dualism, 'property dualism'.

A few variants of Kirk's thought experiment have since been proposed as responses to various versions of materialist theories in the philosophy of mind. Most prominently, in the 1980s, the 'absent qualia' thought experiment was defended, primarily by Ned Block, contra functionalist materialism. In the 1990s, David Chalmers brought the notion of zombies to bear against materialism of all stripes, including the identity theory and materialist theories of supervenience. But in terms both of the particulars of the zombie notion employed and of the modal character of the possibility claim, there are important differences between those arguments. In order to better locate these two arguments, I will first sketch a broader framework for discussing zombies.

KINDS OF ZOMBIE

In general terms, zombies can be classified on the basis of two parameters: physical and mental properties, in virtue of which they are identical to humans in certain respects and different from them in certain others, and the modal strength of their possibility of existence. Güzeldere (1995) explored different kinds of zombies in terms of their postulated constituency, and called them 'behavioral', 'functional', and 'physiological' (or 'physical') zombies. Polger (2000) extended the discussion by examining these three kinds of zombies under natural, metaphysical, and logical possibility, producing a 3×3 'zombie scorecard' (see Figure 1).

In the first category of identity are creatures that are behaviorally indistinguishable from human beings, but may be made up of completely different, non-carbon-based stuff, with no bodily mechanism, and no functional or computational internal structure, on the basis of which there could be attributed to them a true psychology. They are candidates for 'behavioral zombies'. It may be that the behavioral zombie goes through the bodily movements that we take to be sophisticated human behavior by a miracle; those movements should not therefore be construed as anything beyond 'as-if behavior'. Nevertheless, a behavioral zombie is so sophisticated in its mimicry of human behavior that it is, by stipulation, impossible to distinguish it from a normal human being solely on the basis of what (it seems as if) it does. This 'as-if behavior' includes, of course, speech acts of the most sophisticated form, which would be sufficient for the behavioral zombie, for example, to pass the Turing Test. However, a behavioral zombie has no internal structure or mechanism that would support a functional description of its psychology, and it would also immediately fail the physical-indistinguishability test once it is internally examined beyond its skin-deep appearance.

In the second category of identity are creatures that are not just indistinguishable from human beings in behavior, but can also be attributed a belief–desire psychology at the right level of

functional characterization. Nonetheless, they may be made not of flesh and bones but of entirely different kinds of matter. This would be the characterization of a 'functional zombie', if it is also postulated that its psychology is incomplete, lacking, in particular, qualitative conscious states. A functional zombie is also a behavioral zombie, but not vice versa.

In the third category of identity are creatures that not only fulfill the criteria of behavioral and functional zombies, but also have the same bodily constituency as human beings, including flesh, blood, bone, nerve cells, and even microtubules – down to the minutest component. We may tentatively regard this kind of creature a candidate for a 'physical zombie'. Of course, a physical zombie is also a functional (and behavioral) zombie. The strongest metaphysical claim based on the possibilities of zombiehood is based on physical zombies.

To recapitulate, at one end of the scale, a behavioral zombie is a creature that is indistinguishable from human beings in its behavior but is unlike a human being in other (physiological and psychological) respects. At the other end, a physical zombie is a replica of a normal human being, identical in all its physical aspects, the psychological attributes of which are, nonetheless, being questioned. A functional zombie lies somewhere in between these two.

A brief examination of which view in the philosophy of mind favors which kind of zombie serves to reveal some of the prior ontological commitments of the various views of the mind. Physicalists, for instance, would need to claim that physical zombies lack nothing at all: that whatever is true of the psychology of humans, including the experiential states and their qualitative phenomenology, will also be true of their physical-zombie counterparts. Functionalists would further assert that functional zombies have a complete mental life, much as we do, because their psychology is functionally equivalent to that of human beings. And metaphysical behaviorists would be committed to the claim that behavioral zombies are just as conscious as any human being, since all mental states are characterizable in purely behavioral and dispositional terms.

Conversely, non-behaviorists, including functionalists and physicalists, may claim that a behavioral zombie would lack crucial aspects of the psychology of a human being; a non-functionalist physicalist may claim that a functional zombie would lack qualia-laden mental states; and property and substance dualists may claim that physical zombies, no matter how perfect molecular replicas they are, can still be 'mindless automata'.

To put the matter differently, for the behaviorist, there are (or can be, in the strongest modal sense) no zombies at all. For the functionalist, the possibility of a behavioral zombie can be admitted, but the possibility of a functional zombie (as well as that of a physical zombie) cannot. And the physicalist has to deny the possibility of a physical zombie.

In addition to the three kinds of zombies distinguished along the identity axis, one can distinguish kinds of zombies along the possibility axis of Figure 1, on the basis of the modal strength of the possibility of their existence. Among the culminating nine elements, I will focus on two particular cells of the zombie scorecard, namely (2) and (9). In recent years, on the basis of the above kind of analysis of zombie kinds vis-à-vis ontological theories, two kinds of zombies in particular, functional and physical, have been used to argue against materialist functionalism under natural possibility and physicalism under logical possibility, respectively.

ZOMBIE ARGUMENTS AGAINST MATERIALISM

Kirk's zombie argument emerged in the early 1970s at a time when similar ideas were in circulation (e.g. Campbell, 1970; Nagel, 1970; Kripke, 1972), in response to the then-dominant thesis of topic-neutral identity between physical (brain) states and mental states. Campbell's 'imitation man' is an early version of a zombie, and Kripke's contention that God would have additional work to do in order to make the mental properties instantiated after having created and set in place all the physical features of the world evokes, in effect, a complete 'zombie world'.

Materialists, by and large, took this identity relation as contingent, subject to empirical *a posteriori* discovery (Smart, 1959; Armstrong, 1968), although some argued that the identity of brain states and mental states was an analytic truth (Lewis, 1966). Kripke's attack on the identity thesis, based on his theory of rigid designators, was closely related to the zombie-based arguments of the 1970s, which were based on the logical or metaphysical possibility of zombies that were physical replicas of humans but lacked minds altogether.

The debate shifted in the 1980s, as the identity theory by and large gave way to functionalism, and zombie arguments became transformed into arguments about 'absent qualia' and 'ersatz pains'. While the notion of zombies was rarely invoked explicitly during this period, the underlying idea of absent-qualia arguments was the same. Critics of

materialism argued that minds (or mental states) could not be fully characterized in terms of their causal or functional roles, on the basis of thought experiments involving functionally equivalent constructs of brains that, intuitively, did not seem capable of underpinning mental events.

One of the best-known examples of such thought experiments is Ned Block's 'China head' argument for the impossibility of mental states emerging from a brain-like, functionally identical but spatially distributed system (Block, 1978). Block asks us to imagine the functional simulation of a human brain by the Chinese nation, by connecting each of the billion inhabitants of China in appropriate ways through radio links, and having them communicate from a distance like neurons in a brain and thereby animate an artificial body for a certain period of time. According to Block, while this system is 'nomologically possible' and 'could be functionally equivalent to [a human being] for a short time', it is doubtful 'whether it has any mental states at all – especially whether it has "qualitative states", "raw feels", or "immediate phenomenological qualities" '.

The system that Block describes is very much like a functional zombie: it can behave in ways similar to a human being, in virtue of having functionally identical but physically very different internal causal states, and it is Block's contention that it will lack mental states, at least qualitative conscious states. Natural, or nomic, possibility is at issue here. That is, the thought experiment aims to show that there can in fact be systems functionally identical to a human being (or the nervous system of a human being) and that these systems would in fact lack qualitative mental states (cell 2 of the scorecard).

A second type of zombie argument is stronger in its claim: it is based on the logical possibility of physical zombies, and it purports to show that all types of materialist theories are bound to fail (Chalmers, 1996; cell 9 of the scorecard).

Materialists, in response, reject the zombie arguments, either on the basis of differing intuitions on what is logically possible, or by resisting metaphysical conclusions drawn from mere logical possibility claims.

EPIPHENOMENALISM AND ZOMBIES

Finally, let us examine epiphenomenalism, a view implied by the possiblity of zombies. The doctrine of epiphenomenalism has a long history. The philosophers and psychologists of the nineteenth century hotly debated the question of whether consciousness was part and parcel of the causal network that was responsible for the decisions we make, actions we take, etc., or whether it was just an 'idle spectator', 'riding on' the causal processes, perhaps being caused by them, but without itself exerting any causal force on those processes. Perhaps, some argued, we are all 'automata', since all of our mental life and behavior seems to be determined by our nervous systems, in a purely mechanical framework, with no respectable place in it for consciousness.

This view does not deny that we are conscious. It comes close, however, in positing that consciousness, in itself, makes no difference. Thus it prepares the way for the concept of zombies.

Thomas Huxley was one of the most influential advocates of such a thesis, known as the 'automaton theory of consciousness'. The thesis was first formulated as applying to animals, in agreement with Cartesian intuitions. Huxley (1902) advanced the claim that 'the consciousness of brutes would appear to be related to the mechanism of their body simply as a collateral product of its working, and to be as completely without any power of modifying that working as the steam whistle which accompanies the work of a locomotive engine is without influence upon its machinery'. But the real target was human beings and the nature of human consciousness. This was where Huxley's automata theory differed from Descartes' interactionist dualism. Huxley's account of the 'brutes' was just a lead, to make the same point for humans and maintain that 'in men, as in brutes, there is no proof that any state of consciousness is the cause of change in the motion of the matter of the organism'.

For Huxley, consciousness plays no contributory role in the causal chains in the nervous systems, which totally determine the behavior of an organism; consciousness is merely affected by the neural interactions. In contrast, Descartes' idea of consciousness was of a causally efficacious parameter in the formula of mind–body interaction. Just as Descartes is taken to be the founder of interactionism, Huxley laid a clear foundation for epiphenomenalism with respect to the mind.

CONCLUSION

Could there be beings who behave like us in every possible way and yet lack consciousness (or possibly all mental life)? Could such beings be not only behaviorally, but also physically identical to us, on a molecular level, and still not have conscious life? On which modal sense of 'could' are we offering our answers – is this a nomic possibility that

can accommodated within the laws of nature in our world, or is it a metaphysical, or a logical possibility?

The answers one gives to questions of this sort is usually a good indicator of where one stands with respect to a variety of issues regarding consciousness: its ontology, nature, function, evolutionary role, and so on. One's belief in a particular modal possibility of a particular kind of zombie often helps reveal one's implicit metaphysical assumptions, rather than grounding them. As such, the notion of zombies should be considered more of a useful rhetorical tool than the basis of any knockdown argument in philosophy of mind.

Academic Achievement

Introductory article

Harold W Stevenson, University of Michigan, Ann Arbor, Michigan, USA

CONTENTS

Worldwide studies of academic achievement in children and adolescents strengthen our understanding of the factors underlying differences in performance.

CONDUCTING CROSS-CULTURAL RESEARCH

This article describes the methodology and findings of several studies of academic achievement of children and adolescents in the US, Taiwan, China, and Japan. In the mid-1980s, when many of these studies were begun, large-scale studies of academic achievement in the US and East Asian countries were still rare, in part because China had not until then opened its doors to foreign researchers. Since then, there has been increasing interest in cross-cultural studies of academic achievement comparing East Asian children with their US peers.

The main purpose of most of these comparative studies is to identify factors that underlie cross-cultural differences in children's performance in academic subjects such as mathematics and science. Such research can generate ideas about what is possible in one's own culture, by drawing attention to those environmental conditions and strategies that have been found to be productive in others. East Asian societies have attracted the interest of many educators and researchers because of the excellence of their students' academic performance. International test results show that the academic performance of American children is consistently below that of their East Asian counterparts.

We begin with a consideration of several important methodological and interpretive issues, and then review some findings that illustrate the importance and relevance of cross-cultural research to educational policy and practice in the United States.

Methodological Issues in Developing Tests

Cross-cultural research is difficult to conduct, for it requires instruments that are culturally specific but are also capable of producing findings that can be applied meaningfully across cultures. Perhaps the greatest problem encountered in cross-cultural research in the social and behavioral sciences has been the use of materials that were initially developed for one culture and then applied inappropriately to other cultures. For example, a scale devised in New York for measuring depression would not necessarily be equally valid in East Asian cultures. Great care must be taken, therefore, in ensuring that research materials and procedures are culturally relevant, reliable, and valid for all cultures being studied.

Another problem often encountered in cross-cultural research is that sample sizes are too small to permit generalization to the larger population being studied. One must ensure that samples are representative of the larger population, and that study materials are prepared in the language of the culture under study. For example, an intelligence test such as the Stanfordu–Binet test developed in the US is not equally useful in China when translated into Chinese. Problems such as these make the research difficult to replicate and to apply.

Measuring Personality and Social Attributes

It is often difficult to translate psychological terms such as 'dependency', 'aggression', or 'anxiety', because of differences in the nuances or meanings of these concepts across different languages. Some researchers measure personality and social attributes through survey research, where large numbers of participants fill out scales designed to record subtle aspects of their reactions to, for example, mathematics instruction. Alternatively, researchers may conduct personal interviews with subjects, making it possible to probe and clarify subjects' responses through questions such as: 'How satisfied were you when you received your last semester's grade in math? Can you tell me

more about why you felt this way?' Another technique for investigating differences in the meanings of terms for personality and social attributes across cultures involves the development of vignettes, prepared by residents of each country, to provide a detailed look at differences in the meanings of the terms across languages.

Studying Classroom Behavior

Studies of the classroom behavior of students and teachers require many hours of observation by researchers and thorough checks of the validity and reliability of their interpretations and conclusions. The advent of videotaping has significantly streamlined the process of observing children and teachers in action, as it has enabled researchers to gather substantial amounts of data without incurring the cost of observation on site. However, it is essential that videographers understand the purposes of the study, and the languages and cultures being studied, to ensure that the tapes are relevant to the research.

CULTURAL DIFFERENCES IN SCHOOLING

Here we briefly describe some results from a series of comparative studies concerned with differences in performance in mathematics and science of students in the US, Taiwan, and Japan.

Main Results

US students generally perform at lower levels at each grade level – from first grade through entrance into college – than do Chinese and Japanese students on a range of tests of cognitive development and academic achievement. Children's academic performance across countries bears little relation to the amount of money the countries spend per child on education. For example, the US spends a greater proportion of its gross national product on education than does China, yet consistently produces lower scores on tests and other indicators of children's cognitive development and academic achievement. Interestingly, the Chinese students who performed better than the American students were less satisfied with their performance than were the American students with theirs. This finding is consistent with the generally higher standards that Chinese and Japanese schools, parents, and students themselves, tend to set for students.

Thinking about Thinking

One explanation of the observed superiority among Chinese and Japanese students on academic tests concerns the manner in which problem-solving is presented. The East Asian teacher guides children through a problem presented in a lesson plan by encouraging them to define the problem in their own words, to determine an acceptable solution to the problem, and then to create additional methods for solving the problem. As the teacher walks around the classroom to observe students' efforts, he or she may offer hints to a confused child. After one acceptable solution is found, the child is asked if another one can be found. Depending on the child's reaction to this challenge, additional solutions may be requested of the student. The child quickly learns that problems can be approached in more than one manner, and that the way to success in solving problems is through close attention, careful thought, creative thinking, and discovery of alternative strategies.

In the US, students are typically expected to learn a prescribed strategy for solving problems and then to apply the strategy in new contexts. Less emphasis is placed on having children define the problems and then develop multiple approaches to their solution.

East Asian students commonly characterize mathematics as something they need to understand, not as something to memorize. The emphasis on problem-solving, rather than rote learning and memorization, is evident in the types of problems included in contemporary curricula in mathematics. Teachers are encouraged to present the questions in a meaningful context so that students become able to understand a rule, to provide a number of problems that are solvable by the same general rule, and to extend the discussion, opening it up for further comments.

Innate Ability

Children's own perceptions of the role that several factors play may also influence their level of academic achievement. These factors include the strength of the teacher, the level of effort students expend, their level of ability, their aspirations for educational achievement, their reasons for working hard, and their dissatisfaction with current performance. A common finding among East Asian participants is the belief that a child's behavior is highly malleable and can be readily changed, depending on the quality, interest, and relevance of the child's experiences. East Asian participants

stressed the importance of the level of effort students apply to their studies, as an important predictor of their level of academic achievement – rather than their natural or innate ability, which US respondents favored as a stronger predictor. Thus, according to East Asian participants, students' test scores may rise or fall according to the quality of their experiences and the effort they apply to their studies.

Development and Expansion of Academies

What happens in the classroom constitutes only a part of the academic training that occurs in schools. A second group of educational institutions provides supplemental training to many students. These are called 'buxiban' in Taiwan, and 'juku' and 'yobiko' in Japan. These academies were set up to ensure that children would be taught aspects of the curriculum that could not be covered during the ordinary school hours. They may be especially relevant now that the school week in East Asia has been reduced from five and a half days to five days.

East Asian educators have developed a variety of extracurricular programs to accommodate differences in students' levels of academic, social, and personality development. Yobiko in Japan, for example, are academies designed specifically to help students who fail the college entrance examination to pass it in subsequent efforts. Buxiban in Taiwan, and yobiko in Japan, provide students with additional practice and review of the content of academic courses, and help them to prepare for college entrance examinations. Buxiban and juku may include activities for students with special abilities who wish to undertake projects of unusual complexity: for example, making their own communications equipment, developing their own pharmaceuticals, or presenting programs of folk dances from various regions of China. Children and young people who wish to become more involved in sports or the arts, or who are interested in filling a void of social experiences, are also often served by these institutions. They provide opportunities for athletics and art, and a meeting place for fostering social interactions among schoolmates in after-school activities.

In the past, admission to colleges and universities in Japan depended solely on students' scores on college entrance tests. The emphasis on test scores as the main basis for college admission guided many aspects of higher education in Japan, including the *Course of Study*, a guidebook that describes the content of the curriculum and what students should know in preparing for the examinations. While this practice may have served the purpose of selecting highly able college students in the past, many Japanese have responded to it unfavorably, claiming that its narrow focus on only one aspect of children's academic achievement is 'elitist'. Following the general practice in the United States, admission procedures have changed to permit grades in high school and letters of recommendation, as well as test results, to be considered as important factors in admission decisions. This 'recommendation' method has resulted in the introduction of personal and social aspects of achievement, such as extracurricular activities and other distinguishing characteristics of children, into the criteria for selecting high school and college students. A negative feature of these changes is that students have less time than was available earlier for traditional academic work. There is increasing interest in transforming the system of education so that lessons place less emphasis on memorization and more on thoughtful, creative problem-solving.

CONCLUSION

It has become increasingly clear that understanding a single culture is not sufficient to create new methods of educating students. Cross-cultural research on cognitive development, conducted with sound methodology, can give researchers and educators substantial insight into methods for improving educational practices and students' academic performance. Recent technological advances, such as fast computers and videography, as well as recent political developments, such as China opening its doors to foreign researchers, have enabled much data to be obtained and analyzed across a wide range of cultures. The findings from cross-cultural research on children's academic achievement have far-reaching implications for US education policy and practice. These findings identify mechanisms to help strengthen children's understanding of academic information and may help to narrow the gap between western and eastern children's performance in mathematics and science.

Action

Intermediate article

Jos J Adam, Maastricht University, Maastricht, Netherlands
Martinus J Buekers, Katholieke Universiteit Leuven, Leuven, Belgium

CONTENTS

Action is the ability to move the body or body parts in a purposeful, coordinated manner in order to physically interact with the environment. It is based on the integration and cooperation of sensory and motor systems.

INTRODUCTION

A characteristic of humans is their ability to perform skilled motor actions. Some of these motor actions are carried out to perform mundane tasks such as walking, picking up a pencil, drinking a glass of water, or buttoning a shirt. Other motor actions accomplish more sophisticated tasks such as painting a picture, flying an airplane, and performing brain surgery. How does the brain generate and control motor actions? This is not a trivial question, as the body contains hundreds of muscle groups that act on scores of joints, thereby introducing a very large number of 'degrees of freedom' in movement. This article discusses some of the variables that shape human motor performance, and describes its main underlying control principles. (*See* **Motor Control and Learning**; **Performance**; **Reaction Time**)

STARTING, STOPPING, AND SEQUENCING ACTIONS

Starting Actions

To start an action, preparatory processes are first needed in order to formulate a movement plan. These preparatory processes include the processing of sensory information in order to perceive the state of the environment and the state of the actor. Based on this information, an action plan is formulated. For instance, when driving a car, one needs to visually scan the environment in order to detect significant environmental changes, such as a traffic light changing to amber. When reaching for a pencil, one first needs to determine its position in space. This kind of perceptual information is then related to the state of the actor (the effector), and a decision is made about what to do and how to do it. These preparatory processes take time, which can be measured by means of the reaction-time paradigm.

In a typical reaction-time task, the actor is first presented with a warning signal in order to increase alertness. Then, after a variable time interval (which can range between 0.2 s and 5 s), the imperative reaction signal (the stimulus) is presented, calling for a physical response. In the laboratory, the response is often a button-press or button-lift movement. The time that elapses between the presentation of the reaction signal and the start of the overt response defines the reaction time. Many variables influence reaction time. Some of the most influential are: the number of response alternatives; the complexity of the response; the spatial compatibility between the possible stimuli and responses; and the performer's subjective preference for speed or accuracy of responding.

Number of stimulus–response alternatives

In some situations, there is only one possible stimulus and only one correct response. The reaction time in this situation is called the 'simple' reaction time. For example, an athlete just before the start of a 100-meter race knows in advance what to expect and what to do, and the reaction time is typically short (less than 200 ms), representing the minimal time needed to perceive and act.

Other situations confront the performer with more uncertainty. For example, a boxer facing an opponent who can attack with the left or right fist must make a fast decision about what to do. In situations like this, the 'choice' reaction time is

substantially longer, mainly reflecting the increased processing demands associated with selecting and programming the appropriate action. In general, as the number of stimulus–response alternatives increases, the choice reaction time increases. The exact relationship between reaction time and the number of stimulus–response alternatives is given by the Hick–Hyman Law, which states that reaction time increases linearly with the logarithm of the number of stimulus–response alternatives.

Response complexity

The nature of the response to be executed is an important determinant of reaction time. A complex action needs more programming time than a simple action, and therefore a longer reaction time. Increased response complexity can be defined in terms of additional movement parts, increased accuracy demands, and longer movement durations (e.g. Klapp, 1996).

Stimulus–response compatibility

The (spatial) relationship between the set of potential stimuli and the set of potential responses is one of the most important determinants of reaction time. For example, choice reaction time in a task involving left and right stimuli and left and right responses is slower when the stimulus and associated response are on opposite sides (i.e. a left stimulus requires a right response and a right stimulus requires a left response) than when they are on the same side (i.e. a left stimulus requires a left response and a right stimulus a right response).

In general, performance tends to be faster when there is a close, natural correspondence or association between the stimulus and its required response. According to recent theories of stimulus–response compatibility, when there is some kind of correspondence or similarity between the stimulus and response sets, each stimulus will automatically activate its natural – or habitually associated – response (e.g. Kornblum *et al.*, 1990). If this response is the correct one, it can be executed immediately and the reaction time is short: this situation represents a compatible or congruent stimulus–response assignment. If, however, the automatically activated response is incorrect – as is the case in a 'crossed' or incompatible stimulus–response assignment – then the automatically activated response must be aborted and inhibited, and consequently reaction time is lengthened.

The notion of automatic response activation has been confirmed by evidence from psychophysiological studies that recorded lateralized event-related brain potentials on the basis of electroencephalogram recordings (e.g. Eimer, 1995). These studies indicate that action control processes may proceed very fast and without conscious awareness.

Speed–accuracy bias

Human task performance can be error-prone. In fact, there is a trade-off between speed of responding and accuracy of responding: improvements in reaction time often co-occur with an increase in the number of errors, and improvements in accuracy with slower responses. Task constraints and subjective biases for speed or accuracy jointly determine the position on the speed–accuracy continuum.

Stopping Actions

Once the motor program has been formulated, it is implemented and executed. 'Movement time' is the time that elapses between the start of the movement and its termination. A movement stop may be incorporated in the motor program before execution. This is the case for extremely fast, ballistic movements that are executed to maximize speed (e.g. a boxer's punch). However, a movement stop may also be planned 'online', that is, during the execution of the movement. This is the case when accuracy is an important task requirement. Under such circumstances, feedback-based modifications of the movement are implemented during the latter parts of the movement – that is, when the movement approaches the target zone – in order to ensure that the movement terminates accurately.

Thus, for ballistic actions movement time is very short and mainly a function of the parameters specified by the motor program; while for accurate actions movement time is typically longer and a function of motor program specifications and feedback-based movement modifications. Note that this distinction describes two modes of motor control: open-loop and closed-loop control. Open-loop control is fast, but inflexible, because it just follows the instructions laid down in the motor program without the possibility of modification. Closed-loop control is more flexible, but slower, because of feedback processing and the implementation of movement corrections.

Research using the manual-aiming paradigm (whereby the hand is moved from a 'start' position to a 'target' position) has identified several important variables that influence movement time: movement distance; target size; the presence

of non-targets (distractors); and the actor's subjective preference for speed or accuracy of moving.

Movement distance and target size

Increasing movement distance and decreasing target size both result in longer movement times. The exact relationship is expressed by Fitts' law. Fitts' law states that movement time increases linearly with the 'index of difficulty', defined as $\log_2(2A/W)$ where A is the movement amplitude (or distance) and W is the width or size of the target (Fitts, 1954). According to the 'optimized submovement' model (Meyer *et al*., 1988), Fitts' law is a consequence of a particular hybrid way of controlling movements: a preprogrammed, initial-impulse phase followed by a feedback-based control phase that allows the implementation of corrective submovements. This model allows actors either to make submovements in order to optimize spatial accuracy or to keep submovements to a minimum in order to maximize speed.

Presence of non-targets

Often, the target for an action does not appear in isolation but is surrounded by other objects (sometimes called non-targets or distractors). An example is the act of picking a particular apple from a basket full of fruit. Research has shown that the presence of additional objects slows down reaching performance (Tipper *et al*., 1992). Moreover, there is an important asymmetry in the spatial nature of this interference effect: distractors close to the starting position of the hand interfere more than distractors further away (the 'proximity-to-hand' effect). According to the visuomotor account of distractor interference (Meegan and Tipper, 1999), both target and distractor automatically trigger the planning of movements towards their locations. Distractor interference, then, reflects the need to suppress or inhibit responses towards the distractor.

Speed–accuracy bias

It is not only external, physical constraints (e.g. size and distance of the target) that influence the control of movements; the intention or goal of the performer is important too. Individual performers may opt to emphasize speed or accuracy. It has been shown that the kinematics of the movements produced under these two strategies are different (Adam, 1992). Whereas a speed strategy results in a more or less symmetric movement profile (i.e. similar durations for the acceleration and deceleration phases), an accuracy strategy results in a much longer deceleration than acceleration phase. The longer deceleration phase associated with an accuracy strategy allows feedback information concerning endpoint accuracy to be monitored and used for movement adjustments.

Sequencing Actions

So far, we have considered discrete or one-element movements which have a single start and a single stop. Often, however, actions involve a series of consecutive movements that occur through time: for example, writing, speaking, piano playing, dialing a phone number, and entering a security code in a bank terminal.

The 'one-target advantage' phenomenon sheds some light on how the brain controls sequences of movements. A rapid aimed hand movement is executed faster when it is performed as a single, isolated movement than when it is followed by an additional movement. The one-target advantage phenomenon may be demonstrated by comparing performance in two conditions: participants are asked either to move as quickly as possible to the first target and stop (the one-tap condition) or to strike the first target and then immediately move on and hit a second target (the two-tap condition). Typically, movement time to the first target is about 20 ms shorter in the one-tap condition than in the two-tap condition, indicating that one of the effects of making a second movement is to slow down the first. This observation implies that the two movements are functionally interdependent.

According to the 'movement integration' account, the one-target advantage results from an anticipatory motor control strategy whereby the two movements in the two-tap condition are planned together in one overall response program before response initiation (Adam *et al*., 2000). This overall response program specifies that the second movement should be implemented during the latter parts of the first movement so that a smooth and quick transition of the first movement into the second can occur. In other words, implementation of the second movement does not await termination of the first movement, but, rather, overlaps with and is superimposed on the execution of that first movement. The movement integration account of the one-target advantage is based on the notion that the serial ordering of movements is controlled by a motor program that represents an integrated series of movements.

Sequences of movements involving more than two elements may be represented hierarchically. This means that the mental representation of a sequence is not just a linear string of event-to-event

associations; rather, elements are organized in groups, and superordinate relationships may exist among them, so that there are distinct (i.e., higher and lower) levels of control mediating the temporal structure of the movement sequence. Consistent with a hierarchical conception of motor control, interresponse times of individual elements in a movement sequence are not identical, but follow closely the hierarchical (or tree-like) structure of a sequence of keyboard responses (Rosenbaum *et al*., 1983).

ACTION AND PRACTICE

As the proverb 'practice makes perfect' implies, high-level performance appears to be a function of repeated rehearsal of motor acts. Indeed, the elegance, speed, and accuracy of actions performed by experts (e.g. athletes, musicians, craftspeople) derive from many years of deliberate practice. The observation that repetition exerts a powerful influence on the quality of the motor act (e.g. Ericsson *et al*., 1993; Helsen *et al*., 1998) has inspired many researchers to concentrate on the mechanisms underlying skill acquisition. (*See* **Expertise**)

The Three-Stage Theory of Practice

Regarding actions as the overt consequences of the interactions of the human neuromuscular system with the environment, one can regard the learning of new motor skills as adaptations of the implemented input–output connections. Apparently the cerebellum plays an important role in this adaptation process, as the repeated soliciting of its circuits establishes, modifies, or strengthens the required input–output connections. The learning of motor skills has a strong biological foundation (this observation is supported by recent research using magnetic resonance imaging). Within these structural boundaries, the learning process can materialize in different ways. Regarding the mental representations of the action to be executed as the controlling and driving forces of movements, the observed practice effects appear to express the enhancement of these 'dynamical' representations. Actually, the adaptability of these representations (which illustrates well the plasticity of the brain functions) is a prerequisite for learning.

What form does this learning process take? The progress made by humans trying to learn new skills does not appear to follow a linear function. Ever since Fitts (1964) formulated his observation that learning follows a triphasic path, it has been clear that learning phases are fundamental features of long-term behavioral adaptations. Indeed, distinct learning phases have been described, each embodying specific characteristics and properties of motor behavior. The amount of mental effort put into the action by the performer is an important determinant of these phases. A strong cognitive involvement is observed in the initial ('cognitive') phase of the learning process, but the need for this cognitive activity gradually decreases as learning progresses. Numerous repetitions are required to pass from the second ('associative') phase, in which performers continually adjust and improve the movement pattern, to the last ('autonomous') phase in which real expertise appears. This final phase, with its smooth, elegant and parsimonious motor behavior, is the automated expression of years of deliberate practice, which has enabled the actor to eliminate cognitive interference and to use higher-order mental processes only to develop and implement strategic elements. A highly skilled performer transforms action into art.

The Importance of Feedback

Various mechanisms are available to facilitate and possibly shorten the route to expertise. Apart from verbal instructions and visual models (which are most effective during the cognitive phase), the most widely used strategy is to inform the actor about his or her performance after completing the action. This feedback can engender positive learning effects; however, neutral or even negative effects have also been reported, showing that the effectiveness of feedback strongly depends on the nature of the task. For example, when a player tries to score a goal, information about the result of his or her kick or throw is redundant as this information is intrinsically available in the task. Moreover, false or conflicting feedback information may engender incorrect behavioral adaptations (Buekers *et al*., 1992). Nevertheless, the crucial element in learning appears to be the availability of (correct) information about the errors produced by the learner. On the basis of this error information the learner can adjust his or her movement in a subsequent trial and better meet the criteria of the task.

How should this feedback information be transmitted to the learner? Knowledge of results is an obvious form of feedback, but it is actually less efficient than one might expect. Knowledge of performance (information about the movement itself) appears to have a more pronounced facilitating effect on the learning of new motor skills. This form of feedback is primarily focused on movement characteristics (form, spatial, and temporal

characteristics, etc.), and aims to change the movement errors that led to performance failure. The term 'transition feedback' has been proposed, referring to how specific elements of the movement must be changed to produce a successful outcome.

MOTOR IMAGERY

Many experiments have shown that performance can improve as a result of purely mental activity, in the absence of the actual action – for example, imagining oneself performing a perfect golf swing, lifting a heavy weight, or throwing a dart at the bullseye. This improvement has been observed for a variety of motor skills, such as tracking in a pursuit task, walking on a balance beam, hitting golf balls to a target, and muscular strength. However, although these effects are substantial, motor imagery cannot replace physical practice.

The observed performance benefits of motor imagery have sometimes been ascribed to motivational factors; however, it has been shown that motor imagery and overt practice stimulate – at least in part – common neural substrates. Apparently, motor imagery and overt practice rely to a large extent on the same cortical structures. For example, qualitatively similar event-related brain potentials have been reported when subjects imagined or executed specific hand movements. More recent studies using positron emission tomography or magnetic resonance imaging confirm this finding and support the hypothesis of functional equivalence, that movement preparation and motor imagery use the same brain processes. Thus, there seem to be relevant mental representations that are accessible to the actor even in the absence of external stimulation and overt action.

ACTION AND CONSCIOUSNESS

Consciousness is very difficult to define, but phenomenologically it refers to experience (Flanagan, 1998). Consciousness often, but not always, plays a role in the control of action. When learning a new motor skill, a substantial amount of conscious attention is typically needed to learn the basic procedures involved. In this early cognitive stage, verbal cues are often used. However, once actions are highly practiced they may no longer require conscious control; indeed, when automated, actions like writing or driving a car can be performed without conscious awareness at all. Thus, skilled actions that have progressed to Fitts' autonomous stage can be performed without consciousness; they are automatic in the sense that they can be carried out concurrent with other mental or motor activities.

The phenomenon of 'blindsight' also illustrates that consciousness is not always necessary for the control of action. Patients with cortical blindness in one hemifield can perform eye movements or pointing gestures towards visual information presented in their blind field even though they report that they are unaware of this information. Furthermore, the Ebbinghaus (or Titchener circles) illusion (a target circle surrounded by smaller circles appears to be larger than a target circle surrounded by larger circles) affects the conscious visual perception of the size of the target but not grasping movements towards it: the grip aperture of the grasping hand is determined by the actual and not by the subjectively perceived size of the target (Agliotti *et al*., 1995). Observations like these indicate that actions are not always controlled by the conscious experience of objects. Indeed, Milner and Goodale (1995) argue that (conscious) visual perception and visuomotor control are separate functions, sensitive to different constraints, and mediated by different neural pathways. According to this view, visual information may affect action directly, without mediation by consciousness. (*See* **Blindsight**; **Visual Scene Perception**)

CONCLUSION

Motor actions are the principal means by which we interact with the world. Brain processes compute an abstract representation of the intended action. The time to prepare a motor representation or motor program is reflected in the reaction time, which is sensitive to factors such as the number of response choices, the complexity of the response, the compatibility between the potential stimuli and responses, and the performer's bias towards speed or accuracy. The time needed to complete a movement depends on variables such as movement distance, target size, the presence and spatial nature of non-targets, and, again, the actor's bias for speed or accuracy.

Movements can be fully preprogrammed and executed as such (open-loop control); the advantage is speed, though sometimes at the cost of accuracy. Accurate (and slower) movements are constrained by feedback processes that allow corrective submovements (closed-loop control).

Motor skill acquisition progresses via three phases: in the first, cognitive phase, conscious attention is required to understand and practice the basic procedures and movements involved; in the second, associative phase, feedback in the form of knowledge of performance is particularly effective

in shaping successful movement patterns and eliminating errors; in the last, autonomous phase, motor performance is automated and freed from the involvement of conscious control, allowing the concurrent engagement in other tasks. Mental practice – especially in combination with physical practice – can improve motor performance. But even though consciousness is necessary for mental practice, and is very involved in the first two phases of skill acquisition, skilled motor action can, and often does, proceed unconsciously.

Addiction

Introductory article

George V Rebec, Indiana University, Bloomington, Indiana, USA

CONTENTS

The essence of addiction is persistent performance of a behavior despite increasingly aversive consequences. This definition is most commonly used to describe the compulsive taking of drugs. An addict endures deteriorating health, social isolation, and other setbacks in maintaining a drug habit. In effect, addiction is the loss of control over drug use.

ADDICTIVE PROPERTIES OF DRUGS

Many substances, whether they occur in nature or are synthesized in laboratories, are potentially addictive. Intravenously administered heroin and the smokable forms of cocaine ('crack') and methamphetamine ('ice') stand out as drugs that pose a high risk of addiction. But the risk also extends to routinely available substances, such as nicotine and alcohol.

What makes drugs addictive? Part of the answer involves rapid entry into the brain. For a drug like heroin, rapid brain entry often elicits a brief, but intense, rush or 'high' that can drive the search for more of the drug. In fact, heroin has a higher potency than morphine even though heroin is converted to morphine once it enters the brain. The difference is that heroin has additional methyl groups that allow it to slip across membrane barriers more readily than morphine. The invention of the hypodermic syringe, which can deposit drugs directly into the bloodstream for ready access to the brain, became a key factor in the spread of heroin addiction at the end of the nineteenth century. Drugs that are inhaled or smoked also gain rapid access to the brain. Alcohol, because of its relatively simple molecular structure, is absorbed across mucus membranes and begins entering the blood and brain even before it reaches the stomach.

But rapid brain entry of a drug is not the only factor contributing to addiction, nor is the drug itself. Not all heroin and cocaine users become addicts. Many tobacco smokers and social drinkers also avoid compulsive use. Addiction develops only after regular, repeated exposure to a drug on a chronic basis. The factors that control such behavior are many, ranging from physiology to family history, and they interact in complex ways that thwart the search for a simple explanation.

There are certain features of addictive drugs, however, that make them more likely to be abused than other substances. One of these features is the ability to elicit pleasure or reward.

The Reward Model

That drug reward might play a role in addiction gained widespread acceptance after the demonstration that animals, equipped with appropriate catheters, would work to obtain drugs given intravenously. Rats, for example, will readily and repeatedly press a lever to self-administer many of the same drugs as humans. This was an important demonstration because it showed that there was nothing uniquely human about compulsive drug use. In fact, the animal experiments showed that drugs shared many similarities with naturally occurring rewards such as food, water, or sex. A hungry rat, for example, will work very hard for food just as it will go to great lengths for an intravenous injection of heroin or cocaine. Thus, drugs came to be viewed as positive reinforcers, subject to the same principles that govern the behavioral response to other positive reinforcers like food.

It should be noted that positive reinforcement is not necessarily the same as pleasure or reward. Reinforcement simply refers to a procedure that strengthens or increases the likelihood of a given behavioral response. It is impossible to know what the rat actually experiences. Although discussions of drug addiction often use 'reinforcement' and 'reward' interchangeably, these terms are not always equivalent.

When animal research revealed the powerful reinforcing properties of addictive drugs, the next step was to investigate the brain mechanisms underlying this behavior. Research revealed that

the brain was equipped with a circuit that appeared to mediate the behavioral response to natural reinforcers as well as drugs. Although the investigation continues, now bolstered by powerful brain imaging techniques applied to human subjects, the reinforcing effects of drugs have been linked to specific neuronal and biochemical changes.

The Reward Circuit

The brain circuit that appeared to signal reinforcement, and that now has become known as the reward circuit, was identified in the 1950s when it was shown that rats would work to stimulate electrodes implanted in the medial forebrain bundle. Although this bundle contained fibers connecting a wide array of structures, attention centered on a group of axons extending from the ventral tegmental area in the midbrain to several forebrain structures in the limbic system and cerebral cortex. The axons were found to release dopamine as a transmitter, and it was dopamine that seemed to play a key role in virtually all forms of motivated behavior. In fact, the mesocorticolimbic dopamine pathway, as it came to be known, also appeared to be highly sensitive to drugs of abuse. Opiates, like heroin and morphine, and psychomotor stimulants, like cocaine and the amphetamines, all increased dopamine transmission. The same was found for nicotine and alcohol. Not only did all these drugs appear to elevate the synaptic level of dopamine, they were most likely to have this effect in the nucleus accumbens, an important target of the mesocorticolimbic pathway known to process autonomic, emotional, and cognitive signals. When blockade of the accumbal dopamine system was found to block drug self-administration behavior in rats, the link between drug reinforcement and accumbal dopamine transmission was firmly established.

Although all the major drugs of abuse increase dopamine transmission, they do so in different ways. Opiates promote the release of dopamine by stimulating receptors that normally respond to opiate peptides found naturally in the brain, the so-called endorphins. Although there are at least three different receptors that respond to endorphins, opiate drugs primarily activate the mu receptor. One effect of this activation is an increase in dopamine release. Nicotine and alcohol promote dopamine release by acting at different receptors: nicotine stimulates a group of receptors that respond to acetylcholine, and alcohol interacts with the major receptor for GABA, an amino acid found throughout the brain. Both acetylcholine and GABA, like many of the endorphins, are transmitters that play a role in dopamine release. When opiates, nicotine, or alcohol are introduced into this system, their receptor effects overwhelm any naturally occurring activity and dopamine is released in abnormally high amounts.

Psychomotor stimulants, on the other hand, increase dopamine transmission by interacting with a protein that transports newly released dopamine back into the neuron for re-release. Cocaine prevents the transporter from working and amphetamine forces it to operate in reverse. Thus, cocaine allows dopamine to accumulate outside the neuron and amphetamine causes dopamine release. The net effect of either drug is an increase in synaptic dopamine.

A drug-induced increase in dopamine transmission, however, is only the beginning of the reinforcement story. The mesocorticolimbic pathway is embedded in a complex network of structures, each of which processes information relevant to drug-induced behavior such as emotional state, environment, past experience, and many other key variables. Investigations at the membrane level, moreover, reveal that rather than exerting a powerful excitatory or inhibitory influence on individual neurons, dopamine modulates the effects of other transmitters, serving more as a filter or gain mechanism than as a conveyor of specific information. In addition, some neurons, such as the endorphin system, may respond to drugs of abuse independently of a change in dopamine. Thus, the drug-induced dopamine signal may be only one of many that contribute to what might become a sense of pleasure or reward. The reinforcing effects of most drugs are likely to involve both dopamine-dependent and dopamine-independent neuronal systems.

Whatever role dopamine, endorphins, and other transmitters play in drug reward, the reward model itself is simply a starting point for understanding addiction. Compulsive drug use is not driven by euphoria alone. Many addicts actually report a loss of pleasure after chronic drug use, but the habit persists. A case can be made that liking a drug, which may parallel drug-induced reward, is entirely different from wanting a drug, sometimes described as the craving that overwhelms an addict's behavior. Noteworthy in this regard is evidence that the transition to compulsive drug use may reside in the neuronal changes that occur when the brain reward circuit is exposed to drugs on a chronic basis.

Neuroadaptations Underlying Addiction

One effect of chronic administration of drugs of abuse is a change in the responsiveness of dopamine receptors. Although these receptors exist in multiple forms, they can be grouped into what are known as D1 or D2 families. Both families are *metabotropic* in that their activation leads to intracellular metabolic changes that regulate membrane excitability and gene expression. Whereas the D2 group appears to be critical for normal motor behavior, the D1 family may play a greater role in the neural adaptations that accompany learning. These same adaptations may also be involved in the behavioral changes that accompany repeated exposure to drugs of abuse. In fact, addiction itself is likely to involve some type of learning-related change in the behavioral response to a drug. By disrupting the normal flow of dopamine transmission, and thus changing D1 receptors, drugs of abuse may set in motion a series of neural events that can lead to addiction. A drug-induced change in this receptor, such as a down-regulation or loss of sensitivity, can occur within minutes of an amphetamine injection. This may explain why the first administration of psychomotor stimulants, which are typically taken in a series of administrations known as a run or binge, has the greatest euphoric effect. As the run continues, the drug-induced high loses its intensity. Over a series of runs, however, prolonged stimulant exposure appears to up-regulate or enhance the sensitivity of D1 receptors, and this effect may persist for weeks after the last drug administration.

Stimulation of the D1 receptor family also leads to a change in gene expression and ultimately the production of cellular proteins. Up-regulation of these receptors, therefore, could mean not only an increase in synaptic transmission but also long-term structural changes. In fact, changes in dopamine synaptic structure have been reported in rats after amphetamine exposure. By usurping the dopamine system and driving it to excess, addictive drugs may permanently alter the flow of information through limbic and cortical circuits in a way that increases the likelihood of further drug use.

CONTROL AND TREATMENT OF ADDICTION

By the time an addict appears for treatment, the drug habit is likely to have persisted for years. During this time, there has been ample opportunity for the problems that typically accompany addiction – family, legal, medical, occupational, and social troubles – to complicate and confuse the treatment process. The greater these accompanying problems are, the more difficult it will be for treatment to succeed.

The first step towards rehabilitation involves detoxification, the removal of the addictive drug from the patient's system. The next step, preventing a relapse, is far more difficult, but various behavioral approaches can be effective. These include teaching coping skills or attempting to desensitize an addict to the cues associated with drug-taking. But if chronic exposure to addictive drugs causes lasting changes in critical brain circuits, as ample evidence suggests, then medication may occupy an important place in the rehabilitation effort.

Detoxification

For heroin addicts, detoxification is best accomplished in conjunction with a drug such as methadone, which acts as a mild heroin substitute. Gradually decreasing the maintenance dose of methadone is part of the detoxification strategy. For nicotine addicts, detoxification can be achieved relatively simply by gradually reducing the dose of nicotine delivered by skin patch, chewing gum, or nasal spray. In some cases, a low, maintenance dose of nicotine may continue for several months to encourage abstinence. Detoxification is especially important for alcoholics because there is danger of death from overdose. In addition, an alcoholic suffers convulsions and other life-threatening reactions that increase in severity each time the drug is withdrawn. To minimize these effects, alcohol detoxification includes treatment with one or more benzodiazepines, which act as sedatives or minor tranquilizers. For cocaine or amphetamine addicts, detoxification becomes important in the event of an overdose, which can be lethal. Drugs can be used to counteract the racing heart, high blood pressure, and other dangerous effects associated with stimulant overdose.

Medication Strategies

Medication is used in one of three basic strategies to keep an addict off drugs: antagonizing or blocking the effect of the addictive drug; substituting another drug from the same class as the addictive drug but with less powerful effects; or the use of medication specifically designed to reduce craving. Medication is now available for patients dependent on opiates, nicotine, and alcohol.

In the treatment of opiate addiction, the antagonist strategy involves administering a drug that has a high affinity for the mu receptor but does not cause the same cellular reaction as heroin or morphine. One such drug is naltrexone. Rather than activating the mu receptor, naltrexone acts as a mu antagonist, binding to the mu receptor but preventing it from working. When given to heroin addicts, for example, naltrexone blocks the effects of a subsequent heroin injection. The problem with such treatment, however, is that all the subjective effects of heroin that an addict has come to expect are prevented. Another problem is that if heroin is still present in the body, naltrexone creates an immediate withdrawal syndrome. Thus, unless an addict is firmly committed to overcoming the habit, the antagonist strategy is rarely successful.

Most heroin addicts prefer the substitution strategy. In this case, the drug substituted for heroin acts like heroin itself in that it also stimulates the mu receptor. Unlike heroin, however, the substituted drug has a relatively slow onset of effects and stays attached to the receptor for prolonged periods of time. Thus, the addict experiences some heroin-like effects but in relatively mild form. Moreover, because the substituted drug stays attached to the receptor for a day or more, a subsequent injection of heroin during this time will not elicit the intense rush or high likely to trigger more craving. Methadone was introduced in the 1960s as the first such substitution drug for heroin addicts. Now, even longer-lasting substitutes, such as buprenorphine and L-acetylmethadol (LAAM), have been developed, which may attach to the mu receptor for up to three days. More than 100,000 heroin addicts in the USA are currently being treated with methadone or long-acting opiate substitutes.

Naltrexone is sometimes used in the treatment of alcoholism to reduce craving. This strategy emerged from evidence that endorphins play a role in reward and that blockade of mu opiate receptors decreased responding for alcohol in animals. It may be that the GABA system, which is sensitive to alcohol, interacts with endorphins in the forebrain reward circuit. That naltrexone can reduce craving in human alcoholics supports this view. Another anti-craving compound is acamprosate, which is used in Europe to reduce relapse in detoxified alcoholics. Although some of its brain actions are still obscure, acamprosate is known to modulate neuronal excitability in the nucleus accumbens by interacting with specific groups of glutamate and GABA receptors. Interestingly, nicotine craving can be reduced by bupropion, a drug commonly used to treat mild to moderate cases of clinical depression. Bupropion has a wide range of effects, but its ability to block nicotine receptors and modulate dopamine transmission may play key roles in reducing nicotine craving.

A fourth medication strategy, the use of nausea-inducing drugs, is available for treating alcoholics. They can obtain a prescription for disulfiram (antabuse), a drug that interferes with the normal metabolism of alcohol, creating an abundance of acetaldehyde. A high level of acetaldehyde causes headache, vomiting, disorientation, and other signs of nausea that are so repulsive that the impulse to drink disappears. The problem with this treatment strategy is compliance; an alcoholic who wants to drink again can simply stop taking disulfiram.

The development of medication for treating an addiction to cocaine or other stimulants is still in its infancy, but several possibilities are being explored. One is akin to the methadone strategy for heroin addiction and involves developing a drug that activates dopamine receptors to produce a partial stimulant-like effect with the hope that the addict could be gradually weaned away from the medication without a reinstatement of craving. Another approach is to interfere with the ability of cocaine or amphetamine to reach their main site of action, the dopamine transporter protein. In this case, the drugs would lose the dopamine-enhancing effect that may underlie addiction. No dramatic successes have emerged with either approach in clinical trials, but there is still much to be learned about the neuropharmacology of the dopamine system and how this system interacts with other transmitters. New medications continue to be developed, and further study of their mechanism of action is likely to lead to new strategies for treatment.

PHYSICAL AND PSYCHOLOGICAL ADDICTION

For most of the twentieth century, addiction was explained in terms of how the body responded when the drug was no longer available. The more severe the response, the stronger the addiction. Consider heroin, a drug that causes a wide range of effects, including analgesia, muscle relaxation, suppressed gag reflex, low core body temperature, and constipation. When the drug is stopped or withdrawn, an addict experiences exactly the opposite sensations: pain, tension, retching, fever, and diarrhea. These withdrawal symptoms, which could last for days or weeks depending on how much and for how long the drug was used, were

considered a sign of addiction or, more appropriately, physical dependence. Without the drug, the body became physically sick. To avoid this condition, more of the drug was required, thus perpetuating addiction.

Physical dependence was also used to explain addiction to alcohol and nicotine because of the unpleasant physical reactions that occur when these drugs are withdrawn. In fact, a drug was not considered addicting unless there were clear and profound signs of physical dependence. The problem with this model is that it cannot explain addiction to many drugs, including stimulants like cocaine and the amphetamines. Apart from fatigue or depression, there are no profound withdrawal symptoms associated with these drugs, yet they are strongly addicting. To deal with this issue, some theorists proposed the concept of psychological dependence, the notion that drug withdrawal could lead to a mental or psychological state that triggered addiction. This model was even more difficult to accept because the concept of a mental or psychological addiction was impossible to define and thus impossible to study empirically. It never caught on as a useful model of addiction.

Remnants of the psychological dependence model, however, are apparent in the use of such terms as 'reward' or 'positive reinforcement' to explain a drug habit. Such terms are invoked when the compulsion to take drugs cannot be explained by physical dependence. In fact, even the physical dependence model cannot explain why former heroin addicts or alcoholics can relapse months or years later, long after the withdrawal syndrome has passed. Interesting in this regard is evidence that animals will work very hard to obtain addictive drugs, even at doses that fail to elicit signs of physical dependence. Thus, although physical dependence is a legitimate reason for why some addicts maintain a drug habit, the model has limited applications. As brain research has revealed, drug craving is a long-term process that most probably involves a dysfunction of the neural circuitry underlying motivational behavior. An overriding question is why only some persons exposed to addictive drugs become addicts.

PREDISPOSITION TO ADDICTION

There appear to be certain risk factors that make some individuals especially vulnerable to addiction. These include age, mental state, and personality type, as well as a variety of environmental and genetic conditions. No single factor by itself is a good predictor of addiction but as the number of risk factors increases, the likelihood of addiction also increases.

The highest rates of illicit drug use occur among 18- to 25-year-olds. Experimenting with drugs of abuse at earlier ages, including the pre-teen years, increases the chance of addiction. Some addicts also have co-existing psychiatric conditions, such as depression or schizophrenia, that may impair judgment. Although the psychiatric problem sometimes precedes the addiction, it is most often the case that the addiction develops first. Personality traits may also contribute to addiction, but the relationship is difficult to specify because, as with psychiatric problems, it is not clear if abnormalities in personality are a cause or a consequence of the addiction. In some cases, however, personality influences on drug-taking behavior have been studied in controlled laboratory settings, and the data suggest a problem for adventurous and antisocial personalities, the so-called novelty-seekers or risk-takers. Their lack of impulse control not only puts them in vulnerable situations with respect to drug use but may also complicate rehabilitation. The antisocial personality, for example, correlates with poor outcome in methadone maintenance programs.

Environmental influences on drug-taking behavior take many forms and range from parenting practices to the prevalence of public education efforts. In fact, efforts at informing people about the dangers of drugs are at their peak during times of peak drug abuse and then decline as drug abuse declines, which may help pave the way for the start of another peak period of drug abuse. Wide swings in drug use, such as a sixfold variation in alcohol consumption in the United States over the course of the twentieth century, largely reflect changes in social attitudes and public policy. The context in which drugs are taken is also important. This point was nicely illustrated during the Vietnam war in the 1960s and 1970s. Many United States servicemen became addicted to heroin while serving in Vietnam but either stopped the habit completely or dramatically lowered their heroin use when they returned home. In Vietnam, high-quality opiates were readily available at a cheap price, and any disapproving family members were likely to be thousands of miles away. These factors, combined with the high stress of battle conditions, made it easy to justify drug use. Many servicemen, moreover, disconnected their one-year tour of duty in Vietnam from the rest of their lives. Most, if not all, of these

contributing factors disappeared when the tour of duty ended.

Genetics also may contribute to drug addiction, but genes alone are not destiny. In fact, only one in five of those genetically at risk for alcoholism actually become alcoholic. Another consideration is that even if the genetic influence to addiction is critical, there is likely to be more than one genetic factor involved. Genetics, for example, can contribute to the rate and efficiency at which a drug is metabolized as well as to how receptor proteins in the brain respond to a drug. Both of these factors will influence how a drug alters behavior. The strength of that influence, moreover, will depend on the influence of all the other risk factors that contribute to addiction.

Some attempts to specify the potential influence of genetic and nongenetic risk factors involve work with animal models. In this type of research, mice and rats are strategically bred to establish genomic correlations with drug-induced behavioral responses, to identify neurobiological mechanisms, and to localize the chromosome associated with specific drug-induced behavioral traits. In many cases, the identification of drug-response genes in mice indicates the appropriate gene location on human chromosomes. This work is being carried out for all major drugs of abuse and holds promise for assessing the genetic and environmental risk factors underlying addiction.

Affective Disorders: Depression and Mania

Introductory article

Michael T Compton, Emory University School of Medicine, Atlanta, Georgia, USA
Charles L Raison, Emory University School of Medicine, Atlanta, Georgia, USA
Charles B Nemeroff, Emory University School of Medicine, Atlanta, Georgia, USA

CONTENTS

Affective disorders are psychiatric illnesses characterized by disturbances of affect or mood, which cause emotional, cognitive, and behavioral symptoms that significantly impair functioning. They are classified according to polarity (the degree of mood elevation or depression), and are treated with pharmacological and/or psychotherapeutic interventions accordingly.

INTRODUCTION

Affective disorders have been described and treated since the age of ancient Greco-Roman medicine. Hippocrates described melancholia (an excess of 'black bile') around 2400 years ago. Affective excitement, or mania, was also described by ancient physicians. Aretaeus of Cappadocia recognized that mania and depression were usually connected in the same individuals, indicating that the concept of bipolar disorder was anticipated in antiquity. Affective disorders continue to be subdivided according to polarity: unipolar disorders are characterized by depressive episodes only, whereas bipolar disorders are marked by the presence of hypomanic, manic or mixed episodes, with or without intervening depressive episodes.

CLASSES OF AFFECTIVE DISORDERS

Affective disorders are currently diagnosed using four specific mood episodes as building blocks: major depressive episode, manic episode, hypomanic episode, and mixed episode.

Mood Episodes

A major depressive episode consists of a period of at least 2 weeks during which five or more specific symptoms are experienced, representing a change from previous functioning. At least one of these symptoms must be either depressed mood, or loss of interest or pleasure (anhedonia). Other potential symptoms include significant change in appetite or weight, insomnia or excessive sleeping, psychomotor agitation or retardation, fatigue or loss of energy, feelings of worthlessness or inappropriate guilt, poor concentration or indecisiveness, and suicidal thoughts. Patients suffering from a major depressive episode often experience negative cognitive patterns, including helplessness, hopelessness, and preoccupation with inadequacy. Low self-esteem is commonly present. Psychotic symptoms accompany approximately 15% of depressive episodes.

A manic episode is a distinct period of abnormally elevated, expansive, or irritable mood lasting at least a week or requiring hospitalization. During this period, three or more specific symptoms (four or more if the mood is only irritable) typically occur: inflated self-esteem or grandiosity; decreased need for sleep; being more talkative than usual or feeling under pressure to keep talking; flight of ideas, or subjective experience that thoughts are racing; distractibility; increase in goal-directed activity or psychomotor agitation; and excessive involvement in pleasurable activities that have a high potential for painful consequences. Psychotic symptoms develop in approximately 25% of manic episodes and typically consist of grandiose delusions, hallucinations of deities, or paranoia born of a delusional sense of importance.

A hypomanic episode, which is less severe than mania, is a distinct period of elevated, expansive or irritable mood lasting for at least 4 days, during which time three or more symptoms of a manic

episode are experienced (four if the mood is only irritable). The changes represent an unequivocal change in functioning, which is observable by others, but is not severe enough to cause marked impairment in functioning or to necessitate hospitalization, and there are no psychotic features present.

A mixed episode is a period of at least 1 week during which the above criteria for both a major depressive episode and a manic episode are experienced. Few patients have episodes that meet the full criteria for a mixed state, but dysphoric manias, in which a depressed and/or anxious mood coexists with manic symptoms, are frequent in patients with bipolar disorder.

For all four of the above mood episodes, the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) specifies that the symptoms should not be due to the direct physiological effect of a substance (e.g. drug of abuse or medication) or a general medical condition.

Mood Disorders

Major depressive disorder is defined by the lifetime presence of at least one episode of major depression that is not precipitated by a medical illness, a medication, or a substance of abuse and is not better accounted for by bereavement. Dysthymic disorder is a mild form of depression that often has an early age of onset (in childhood, adolescence, or early adult life) and usually lasts for protracted periods (at least 2 years in adults, according to DSM-IV). Patients with dysthymia do not meet full criteria for major depression during the course of their illness. Dysthymia tends to be characterized more by emotional and cognitive symptoms, such as depressed mood, pessimism and poor self-esteem, than by the types of neurovegetative symptoms seen in major depression (i.e. changes in sleep, appetite, and physical activity level).

Bipolar I disorder is defined by the lifetime presence of a manic episode not judged to be caused by a medical illness or ingestion of recreational drugs or medications. Bipolar II disorder is characterized by the presence of major depressive episodes and periods of hypomania. Although hypomanic episodes tend, by definition, not to produce the degree of functional impairment caused by full manias, bipolar II disorder patients may actually have more overall impairment in their lives than many patients with bipolar I disorder, owing to the greater length and treatment resistance of depressive episodes in bipolar II disorder, as well as to the tendency of patients with bipolar II disorder to develop rapid cycling, a condition characterized by rapid progression from one mood episode to the next with little or no period of normal mood between episodes.

Cyclothymia, like dysthymia, is a chronic condition characterized by the presence of mood symptoms insufficient to meet the criteria for a major affective disorder. In the case of cyclothymia, these symptoms take the form of a repeated alternation of subsyndromal hypomanic and depressive symptoms. It appears that the presence of cyclothymia is a risk factor for the later development of both bipolar I and II disorders, although some patients never experience a full mania or major depression.

Affective disorders are distinguished from other psychiatric conditions not so much by specific symptoms as by the fact that alterations in mood and/or a loss in the ability to find pleasure in life are considered to be the primary derangements in the disease course of the individual. Beyond this central focus, however, patients with affective disorders can evince symptoms seen in a number of other psychiatric conditions. In addition, comorbidity is the rule rather than the exception in psychiatry. Other psychiatric conditions that are highly comorbid with affective disorders include anxiety disorders (generalized anxiety disorder, social phobia, panic disorder, and obsessive–compulsive disorder) and various alcohol and drug abuse and dependence problems.

ETIOLOGY OF AFFECTIVE DISORDERS

Genetics and Biological Factors

Affective disorders, especially bipolar disorder because of its greater degree of familiality (stronger evidence for a genetic basis), have been the subject of much research into their genetics and heredity. Despite methodological and interpretive limitations, several reproducible findings have emerged.

The risk of bipolar disorder in first-degree relatives of patients with bipolar disorder ranges between 3% and 8%, compared with a 1–1.5% rate in the general population. The risk of depressive disorders among first-degree relatives of patients with depression is two to three times that of the general population. If one parent has an affective disorder, a child's risk of an affective disorder is between 10% and 25%; if both parents are affected, the risk roughly doubles. Having more affected family members confers increased risk, especially when family members have bipolar disorder.

In addition to genetic factors it is becoming increasingly clear that, as a group, people with

affective disorders differ physiologically from well-matched controls without histories of depression or mania. Evidence suggests that patients with affective disorders have consistent changes in brain structure and functioning. These changes include decreased volume in prefrontal and temporal cortex, as well as in the basal ganglia. Consistent with these structural changes, many patients with major depression demonstrate decreased functioning in these same areas when they are studied by modern imaging techniques. Postmortem studies suggest that changes in brain volume and function may reflect cell loss and/or atrophy as well as loss of functional connections (synapses) between nerve cells in these brain areas. Major depression is associated with changes in sleep architecture. Some of these changes remit when affective symptoms resolve, but others remain, and are even found in unaffected family members, suggesting that such sleep abnormalities may be a risk factor for the development of affective disorders.

Psychological and Social Factors

Major depression frequently develops in a psychological context of anxiety and/or neurosis, as well as in individuals with a long-term tendency toward excessive social inhibition. Many patients with bipolar disorders, especially bipolar II disorder, demonstrate premorbid psychological traits of moodiness, impulsivity, and acting-out behavior. The likelihood that a person will develop an affective disorder is also influenced by a number of environmental factors, many of which are psychosocial in nature. For example, it is known that childhood conditions such as the death of a parent, or exposure to neglect or to physical, sexual or emotional trauma, pose a significant risk for the development of affective disorders later in life. Although traumatic events early in life appear to be especially potent in fostering later depression, probably as a result – at least in part – of negatively influencing postnatal brain development, actual or perceived stress at any time in the life cycle is strongly associated with the development of depression.

Investigations into psychological and environmental contributions to the affective disorders tend to be empirical in nature, using biological and ethological approaches in an attempt to map out pathways through which psychological and environmental factors influence mood. However, many of these research interests have been anticipated by the more theoretically driven approaches to the issue that dominated the field of psychiatry until well into the last half of the twentieth century. Many such theories derive from psychoanalytic perspectives and tend to privilege early life experiences. Other schools of thought have advanced behavioral and cognitive factors as primary causes of affective disorders. Fewer psychological theories have tried to explain the experience of mania, and genetic vulnerability has been more clearly implicated. Nonetheless, psychological models have been proposed for manic reactions. For example, some theorists have described mania as a stance defensive against an underlying depression (for example, self-deprecation and excessive guilt of depression become replaced by grandiosity and elevated self-esteem characteristic of hypomania or mania). Key figures in the formulation of these models include Karl Abraham and Melanie Klein.

ONSET AND COURSE OF AFFECTIVE DISORDERS

Affective disorders are highly prevalent illnesses that significantly impair functioning, interpersonal relationships, and quality of life. In the USA, lifetime prevalence rates are 17.1% for major depressive episode, 6.4% for dysthymia, and 1.6% for manic episode. Epidemiological studies reveal that affective disorders are more prevalent among individuals under the age of 45 years (the average age of onset is 20–40 years). Women suffer from unipolar depressive disorders about twice as often as men. Certain points in the human life cycle confer increased risk for the development of depression: these include puberty, as well as childbirth in women and the passage through middle age in men (after middle age, rates of depression are equal between the genders). Menopause may be a risk factor for mood disturbance in certain women, but does not pose anything like the threat of the postpartum period, a time in which 20% of new mothers will develop a major depression. Rates of bipolar disorder do not appear to be affected by gender. The prevalence of affective disorders does not vary significantly by race or ethnicity.

It is increasingly recognized that both unipolar depressive disorder and bipolar disorder are frequently recurrent illnesses that lead to increased functional impairment with the passage of time and the accumulation of episodes. On average, people diagnosed with unipolar major depression in youth or early adulthood can expect five or six episodes over their life span, compared with an average of eight to nine major lifetime mood episodes in people with bipolar disorder. Twenty-five percent of patients with unipolar major depression

demonstrate a chronic course. Similarly, 5% of patients with bipolar I disorder remain chronically manic, often providing a diagnostic conundrum to clinicians used to assigning a diagnosis of schizophrenia to anyone with a chronic psychotic illness. One-third of patients with unipolar depression will have only a single episode. These patients tend to be older at the time of onset and are less likely to have a history of affective disorders in their families.

Affective disorders underlie 50–70% of all cases of suicide, and individuals with serious depression (i.e. requiring hospitalization) have a 15% suicide rate. Rates of suicide in bipolar disorder are probably higher, approximately 20–25%.

TREATMENT

Pharmacologic and Somatic Treatments

Pharmacologic and somatic treatments for depression compare favorably with the pharmacologic treatment of other chronic medical disorders in terms of efficacy. A broad spectrum of effective antidepressant strategies are available, from electroconvulsive therapy through a wide array of antidepressant medications. In addition, psychotherapy and medications have a synergistic effect when used in combination.

The modern era of psychopharmacologic treatment was initiated in the mid-twentieth century with the discovery that lithium, monoamine oxidase inhibitors, and tricyclic antidepressants effectively treated affective disorders. Monoamine oxidase inhibitors (MAOIs) block the enzyme that metabolizes biogenic amines, increasing the availability of these neurotransmitters. Though especially efficacious for atypical depression, the use of MAOIs is greatly limited by their adverse effects, by their potential to induce possibly lethal hypertensive episodes in combination with foods that contain tyramine, and by a propensity to induce a frequently fatal condition known as 'serotonin syndrome' when taken in combination with medications that affect serotonin functioning. Tricyclic antidepressants (TCAs) are thought to work by blocking the reuptake of noradrenaline (norepinephrine) and serotonin into presynaptic nerve cells. However, in addition to these therapeutic actions at reuptake transporter sites, TCAs block other receptors leading to a host of unwanted side effects, including blurred vision, dry mouth, tachycardia, constipation, urinary retention, cognitive dysfunction, postural hypotension, dizziness, sedation, weight gain, and sexual effects. Of even more concern is that fact that TCAs are highly lethal in overdose as a result of direct effects on cardiac conduction.

As suggested by their name, selective serotonin reuptake inhibitors (SSRIs) work by blockade of the serotonin reuptake pump. Unlike the MAOIs or TCAs, these newer agents were specifically designed to diminish or abolish activity at other receptors known to mediate many side effects of the older drugs. As a result, SSRIs are associated with a decreased side-effect burden and significantly enhanced safety in overdose. However, these agents are not without their own limitations, including a high rate of sexual dysfunction, and a tendency, as a class, to block the metabolism of other medications, leading to potentially problematic interactions with other drugs. Antidepressants developed since the arrival of the first SSRIs show a trend toward reversing the specificity of action that was the goal in SSRI development. Examples of newer medications that use a combined action strategy include venlafaxine, which works by blocking the reuptake of both serotonin and noradrenaline, and mirtazapine, which blocks presynaptic noradrenaline autoreceptors and postsynaptic serotonin receptors.

Finally, although typically reserved for patients who have failed to respond to other treatments, electroconvulsive therapy (ECT) remains a highly effective therapy for depression. It is especially effective in melancholic and/or psychotic forms of depression and for patients whose illness has catatonic features. Nonetheless, ECT has long been hampered by the striking short-term memory loss associated with the treatment, as well as by the risks of undergoing anesthesia and the general difficulties inherent in implementing this typically hospital-based procedure.

Because bipolar disorder is a recurrent, severely impairing psychiatric disorder, the search for efficacious pharmacological treatments continues to be at the forefront of psychiatric research. Lithium is a naturally occurring salt that was found to have antimanic properties in 1949. In the experience of many experts, lithium remains the 'gold standard' for treatment of both the manic and depressive phases of bipolar disorder. In addition to its acute effects in curtailing mania and depression, lithium when taken chronically is known to protect against the advent of future mood episodes. Lithium treatment also decreases the lifetime risk of suicide in people with affective disorders, a finding that has been difficult to replicate with other pharmacological agents.

Several anticonvulsant medications have attracted attention as treatments for bipolar disorder. The use of valproic acid for the treatment of acute mania is supported by data suggesting that (like lithium) it is effective in protecting patients from future mood episodes. Valproic acid appears to be more effective than lithium in treating dysphoric manias and may give better results in patients who have a disease course characterized by manias that follow depressions, rather than the other way around. Lamotrigine may be effective for bipolar depression, with a minimal risk of the induction of mania or hypomania that accompanies the use of traditional antidepressants. Carbamazepine was the first anticonvulsant used in the treatment of bipolar disorder, but its use has largely been eclipsed by valproic acid, which has a more tolerable side-effect profile in many patients.

In addition to mood stabilizers such as lithium and the anticonvulsants, antipsychotic agents and benzodiazepines have been shown to be effective in the acute treatment of mania, both as additions to mood stabilizers and as single agents. Finally, ECT is an effective treatment in both the manic and depressed phases of bipolar disorder, and is especially effective when patients demonstrate catatonic symptoms.

Psychotherapeutic Treatments

Several forms of psychotherapy are roughly as effective as antidepressant drugs in the treatment of most cases of major depression. Current treatment of bipolar disorders favors the use of pharmacological and somatic interventions, but studies suggest that psychotherapy has a valuable adjunctive role in these conditions. Two commonly employed psychotherapeutic techniques that have received considerable empirical validation are interpersonal therapy and cognitive behavioral therapy.

Interpersonal therapy is descended from a long-held and valuable insight from the psychoanalytic tradition that interpersonal relationships are crucial to the maintenance of a normal mood state (euthymia) for most people, and that major depression is frequently associated with disturbances in the realm of interpersonal relations. The therapist directly explores and works with the patient's interpersonal difficulties, operating under the assumption that these difficulties are frequently causative of depression and that their resolution promotes a return to euthymia. Cognitive behavioral therapy is a highly structured, effective short-term psychotherapy that aims to correct negative thought patterns, specific distorted schemas, and cognitive errors. Unlike older psychoanalytic traditions, cognitive behavioral therapy specifically and directly confronts maladaptive cognitions through a process of gentle challenging, but also through the use of educational components and 'homework' aimed at encouraging the patient to practice more positive behavior in daily life. Interestingly, although these two psychotherapies are based on different – though not mutually exclusive – theoretical underpinnings, most studies suggest they are equally effective in the treatment of depression.

NEURAL CORRELATES AND THEORIES OF AFFECTIVE DISORDERS

No single physiological abnormality has been found to account for affective disorders, but many years of research have established a number of abnormalities that are present in many affectively ill patients. The current biological theories of affective disorders began to emerge in the 1950s coincident with the discovery of antidepressants and mood stabilizers. Based on the suspected mechanisms of action of antidepressants, early theories focused on putative deficiencies in single biogenic amine neurotransmitter systems, especially noradrenaline, and later, serotonin. While these early (and relatively simplistic) proposals have given way to far more complicated heuristic models, it remains true that affective disorders as a whole continue to be characterized by evidence of altered functioning in catecholamine (noradrenaline and dopamine) and indolamine (serotonin) neurotransmitter systems, as well as in other related systems such as the hypothalamic–pituitary–adrenal axis that, together with the sympathetic nervous system, constitutes the mammalian stress response system.

Biogenic Amines

Based on existing technologies, early psychobiological investigations into the role of biogenic amines in the pathogenesis of affective disorders focused on the concentration of these neurotransmitters (or their metabolites) in blood, urine, and cerebrospinal fluid. Taken as a whole these studies suggested a decrease in serotonergic activity in people with unmedicated depression. The relationship between noradrenaline production and depression appears more complex. Early studies reported decreased urinary levels of catecholamine metabolites in depression, and animal models of stress suggest that depleted noradrenaline in selected brain areas might contribute to the

diminished energy, inability to feel pleasure, and decreased libido that frequently accompany depression. However, later research suggested that people with melancholic major depression have a markedly increased release of catecholamines into the cerebrospinal fluid.

Despite the initial attractiveness of these neurotransmitter models, significant evidence has accumulated countering the notion that affective disorders are caused by a simple neurotransmitter deficiency or excess. Current formulations of the role of biogenic amines in depression tend to focus on the potential restorative role that increased levels of these transmitters might have for 'downstream' neural functioning. Chronic alterations in aminergic availability fostered by antidepressant medication may stimulate intracellular second-messenger pathways to favor the production of neurotrophic factors that lead to enhanced functioning of neurons in brain areas believed to be centrally involved in mediating mood abnormalities.

Neuroendocrine Axes and Neuropeptide Systems

The hypothalamic–pituitary–adrenal (HPA) axis serves as the principal mammalian stress response system. Abnormalities of this axis are amongst the most replicable biological findings associated with affective disorders, especially major depression. These abnormalities in major depression include evidence for increased corticotrophin releasing hormone (CRH) production in the central nervous system, a blunted adrenocorticotrophin response to CRH stimulation, enlargement of pituitary and adrenal glands, increased blood levels of cortisol, and decreased tissue sensitivity to glucocorticoids. Evidence for heightened production of CRH in the brain is especially intriguing, given that this neuropeptide serves as a neurotransmitter in limbic brain regions linked to depression, in addition to its role in the hypothalamus as the primary activator of the HPA axis.

Hypothyroidism is frequently associated with a markedly depressed mood. Studies have documented alterations in thyroid axis activity in patients with depression, including increased thyrotrophin releasing hormone (TRH) concentrations in cerebrospinal fluid, altered thyrotrophin response to TRH stimulation, decreased nocturnal plasma thyrotrophin concentrations, and presence of antimicrosomal thyroid or antithyroglobulin antibodies. Similar abnormalities have been associated with bipolar disorder, the course of which is worsened by hypothyroidism.

CONCLUSION

Affective disorders, including unipolar depressive disorder and bipolar disorders, are prevalent psychiatric illnesses, affecting approximately 25% of individuals during the course of a lifetime. They are classified by the presence of discrete or chronic mood episodes characterized by abnormal depression or elevation of mood and mood-related functions below or above the individual's baseline. The causes of affective disorders are multifactorial, with both genetic and biological factors involved, and modified by psychosocial variables. Treatment consists of psychiatric management with pharmacological agents, ECT, and psychotherapy. Contemporary psychiatry and neuroscience are increasingly concerned with the neurobiological correlates of affective disorders, predictors of response to particular therapies, and achieving return to complete euthymia (remission).

Aging and Cognition

Introductory article

Pat Rabbitt, University of Manchester, Manchester, UK

CONTENTS

The study of aging and cognition aims to identify the mental changes that occur in old age and relate them to corresponding neurophysiological processes.

INTRODUCTION

Cognitive aging cannot be equated with passage of calendar time because it is a complex of processes that proceed at different rates in different people and in different parts of the brains and central nervous systems (CNS) of individual persons. A main goal of cognitive gerontology is to identify the mental changes that occur in old age and to relate them to these neurophysiological changes. Demographics, socioeconomic status, and lifestyle are also important because factors such as gender, prolonged education, lengthy marriage to an intelligent spouse, complexity of workplace and social environments, level of income, and personality type all affect longevity and also maintenance of cognitive functioning in old age. Because the influences on cognitive aging are so numerous, and their interactions are so complex, individuals have strikingly different trajectories of aging. Consequently, as a population ages, the widening gap in competence between its most and least able members is more striking and informative than is the average decline in ability.

SENSORY CHANGES AFFECT, AND PREDICT, COGNITIVE ABILITY

Loss of efficiency of the sense organs is among the most obvious and widespread changes with age. Besides curtailing efficiency in obvious ways this increases the effort necessary to resolve degraded visual and auditory information, and this distracting difficulty makes it more difficult to remember, or to make useful associations to, material that has been correctly heard or seen. Losses of visual and auditory acuity, and also of balance, muscle strength, and lung capacity, are good markers for levels of cognitive efficiency in old age, probably because they reflect changes in the brain CNS resulting from cerebrovascular inefficiency and other causes.

Effects of 'Primary' and 'Secondary' Aging

For some investigators, the growing dependence of mental ability on physiological efficiency as old age advances begs the question of the relative extents to which cognitive changes are caused by 'primary' processes of 'normal' or 'usual' aging that may be genetically programmed to occur at different rates in different individuals, or by the 'secondary' effects of lifetime accumulations of pathologies and biological damage. Unsurprisingly there is clear evidence that pathologies that become common in later life, such as late onset diabetes, hypertension, or loss of cardiovascular and respiratory efficiency, can significantly reduce cognitive ability.

However, the boundaries between 'primary' and 'secondary' aging are seldom clear-cut or physiologically meaningful. For example, 'primary' heritable differences in immune system efficiency determine longevity and so also maintenance of cognitive efficiency, by protecting against the 'secondary' effects of pathology. Consequently, the effects of 'primary' aging have been defined by default after pathologies have been identified and taken into account. Alternatively, the relative impacts of primary and secondary effects have been estimated by taking individuals' calendar ages as a rough proxy for the progress of 'primary' aging and using multivariate statistics to estimate the relative amounts of variance in mental abilities between individuals that are associated with differences in their calendar ages and with their

self-reported, or diagnosed, health status. Such analyses typically find that while differences in individuals' calendar ages account for only 15 to 20 percent of variance between them, differences in their self-reported health accounts for 2 percent or less.

These estimates can be misleading because while individuals' cognitive performance sharply declines with the number of different pathologies from which they suffer, people who volunteer for studies of cognition in old age are, typically, unusually fit, active, capable, and highly motivated members of their age groups. The variance associated with pathology is thus largely contributed by a few who, as individuals, have suffered severe losses. Another difficulty is that older people's self-reports of their health and cognitive efficiency must be cautiously interpreted because they cannot make absolute judgments of their status and so tend to compare themselves with their frail coevals. Perhaps for this reason, though the number of different pathologies that individuals report significantly increases with their ages, their subjective ratings of their general health may alter accordingly.

Pathologies that Directly Affect Cognitive Function

Apart from illnesses that indirectly affect mental ability by causing general physiological changes that have knock-on consequences for the central nervous system there are also pathologies, collectively known as 'dementias', that directly affect the brain. On its own the term 'dementia' is a label of convenience for changes in mental competence, much grosser than those observed in 'normal' aging, resulting from a diversity of different causes. For example, 'multi-infarct' dementia is a condition of diffuse brain damage often caused by small, but relatively numerous, cerebrovascular accidents (such as strokes, aneurisms, and minor narrowings and blockages of blood vessels) while others, such as Pick's disease, are more tightly defined in terms of causes and symptoms. The most common of these conditions, accounting for over 60 percent of all cases of dementias, is Alzheimer's disease (AD). This condition involves death of and changes in neurons resulting in the appearance of its main diagnostic criterion: 'senile plaques' and neurofibrillary tangles in brain cortex. Unfortunately these key signs can still only be ascertained on post mortem so that early diagnosis remains difficult. Other brain changes are neurotransmitter abnormalities, decreased brain volume, and, as is increasingly recognized, the incidence of many, and substantial, brain lesions that bring about marked loss of general cognitive ability and problems with memory, language, and general mental ability. Emotional problems such as anxiety, agitation, and depression, and marked personality changes may also occur. Any of these changes may also be encountered in dementias resulting from other causes.

The prevalence of AD sharply increases with age. 'Early onset' AD may occur in the 40s and 50s, the condition becomes more common in the 60s, and, it has been claimed, more than 30 percent of individuals aged 70 and above may be diagnosed as having cognitive changes consistent with a prognosis of AD. Early onset AD, occurring in middle age, progresses relatively rapidly, but when the condition occurs later in life it usually develops more slowly and patients may survive for a decade or longer.

For this article the issue is whether the marked and accelerating increase in incidence of AD with age means that it is the 'natural' and inevitable end state for all who survive long enough, or whether it should be regarded as a distinct pathology unrelated to 'normal' cognitive aging. The evidence is inconclusive. Although there are clearly genetic predisposing factors for AD, and there have been suggestions that viral or prion infection may be a causal or a triggering factor, all of the brain changes seen in AD, including the key diagnostic signs of neurofibrillary tangles and senile plaques, are found, though to a much less marked extent, in most healthy older individuals. In this respect the definition of 'normal' aging can, pragmatically, be treated as those changes in brain and behavior that are observed when a diagnosis of AD and of other dementias has been eliminated. Since, at the moment, this can only confidently be done at post mortem, the distinction is logically useful, but not always practically helpful.

Accounting for the Increased Variability between Individuals in Aging Populations

A main aim of cognitive gerontology is that by understanding the nature of declines in ability we may find means to delay them. It is therefore encouraging that trajectories of change vary markedly between individuals, because we may hope to discover what makes some more fortunate than others. For all mental skills, except those, such as vocabulary, that have been acquired early in life and practiced continuously ever since, plots of average levels of performance for successive age

groups show a steadily accelerating decline after youth (Figure 1(a)). However, these averages are uninformative and might represent either of two, very different, limiting scenarios. One is that individuals' trajectories of change all have the form illustrated in Figure 1(a) but, because they accelerate at very different rates, they increasingly diverge as a population ages (Figure 1(b)). Another is that individuals attain peak performance early in life, and experience little loss until terminal pathology causes abrupt decline (Figure 1(c)). Either of these limiting cases can equally well account for both the form of observed average trajectories of change and the marked variance between individuals that increases as a population ages. Both indicate a degree variability between individual trajectories that encourages hopes for useful interventions.

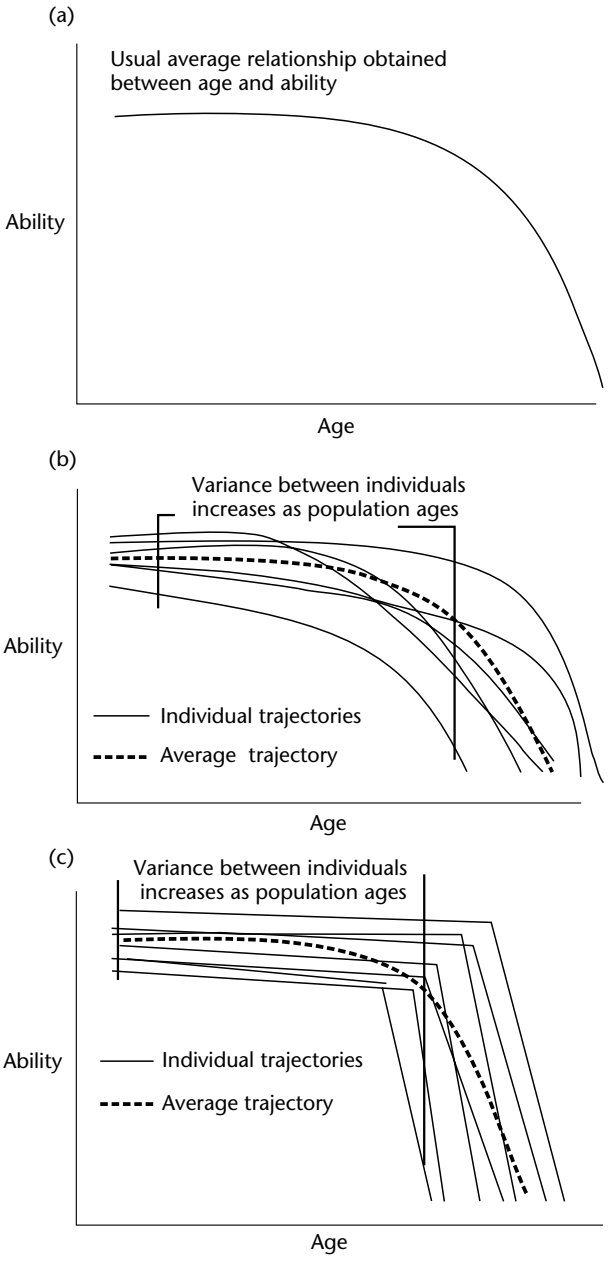

Figure 1. Relationship between age and ability. (a) Average performance levels show steadily accelerating decline after youth; (b) different rates of acceleration lead to increasing divergence in the population; (c) peak performance is maintained until terminal pathology causes abrupt decline.

In practice the best description will depend on the particular population examined. In socioeconomically disadvantaged populations, in which disease or accident sharply and abruptly curtails life expectancy, many individual trajectories of cognitive change will tend to show catastrophic 'terminal drops' rather than continuous declines. In affluent societies in which life expectancy is much longer, and medical interventions postpone death from pathology, gradual declines will become more common. Single cross-sectional comparisons between groups of different ages cannot distinguish true trajectories for individuals from average trajectories for populations. To do this we need longitudinal studies in which the same people are repeatedly assessed over many years.

DO DIFFERENT MENTAL ABILITIES CHANGE AT THE SAME OR AT DIFFERENT RATES?

'Global' Change Models

To relate behavioral to neurophysiological changes we must propose functional models. One limiting case is *global single factor models* which propose that changes in all mental abilities reflect changes in a unique 'master' functional characteristic, most typically 'information processing rate' or 'mental speed' or 'general fluid mental ability'. This would imply that all mental abilities 'age' at similar rates. Another limiting case is *modular aging models*, which are based on evidence that age affects some subsystems in the brain, and so the disparate cognitive abilities that they support, to different extents and at different rates.

If changes in performance on all cognitive tasks directly, and solely, reflect changes in a single, 'master' functional performance characteristic the effects of differences in age should completely disappear when the effects of individual differences in this characteristic have been directly measured and taken into consideration. So, for example, we may test whether age-related declines in 'general fluid intellectual ability' (gf), as assessed by unadjusted

scores on intelligence tests (IT scores), causally determine declines in all other cognitive skills. On nearly all mental tasks individuals' levels of performance correlate negatively with their calendar ages and these correlations are, indeed, abolished or greatly reduced when differences in general mental ability, assessed by unadjusted scores on intelligence tests, are also taken into consideration. Another way to put this is that individual differences in decision speed or IT scores pick up all age-related changes in many simple laboratory tasks.

One explanation might be that IT scores directly reflect some single functional property of the central nervous system that determines levels of performance on all these tasks. A simpler, and more likely, explanation is that intelligence tests predict levels of performance over a very wide range of functionally distinct mental abilities because they include a correspondingly wide range of different problems that, collectively, make demands on all of them.

The same argument cannot dispose of a different theory, that the key performance characteristic on which all mental abilities rely is the maximum rate at which the brain can process information, and that this is directly reflected in the speed with which people can make very simple decisions. It early became apparent that age markedly slows average choice reaction time (CRT) and also that, as tasks become harder, so differences between the average decision times of older and younger groups markedly increase. Subsequent reanalyses of these data suggested that age apparently slows decisions of all kinds, and of all levels of difficulty, by the same proportional amount. That is, on any task, whatever particular demands it makes, decision times for older groups can accurately be estimated by multiplying decision times for younger groups by the same simple constant. This was taken as evidence that 'global slowing of information processing' affects all mental functions, so that changes in information-processing speed are the most sensitive and general indices of cognitive aging. Some authors go much further and suggest that individuals' IT scores, like their performance on all other tasks, directly reflect their maximum information-processing speeds because these, in turn, directly reflect the limiting efficiency of neurophysiological characteristics such as speed of synaptic conduction.

Recent work has questioned both the evidence and the methodological assumptions on which global single factor slowing models are based. It is increasingly recognized that changes in average decision times with age are better described as the consequences of greatly increased moment-to-moment variability in the speed of decisions rather than as the average slowing of all decisions. A direct consequence of this increased moment-to-moment variability is greater average variability from day to day and week to week and that, in both these respects, older people show much greater variability than do the young. When the same individuals are tested on a wide range of tasks, those who show greater moment-to-moment variability on one kind of task are also found to be consistently more variable on others. Findings that age increases variability within individuals at least partly account for findings that, when people are compared on any given occasion, age markedly increases variability between individuals.

There is also evidence that 'global slowing' does not affect all cognitive skills equally. While 'fluid intellectual abilities', indexed by IT scores, decision speed, and rate of learning of novel tasks, all markedly decline with age, language skills, that have become crystallized by practice throughout a lifetime, remain unchanged, or may even slightly improve into the late eighth or even the ninth decade of life. For example, age markedly affects the time taken to respond to simple signals such as lights or tones but has much less effect on speed of decisions about words. Age also does not reduce the speed with which people can carry out highly practised skills such as mental arithmetic. Sustained practice over a lifetime protects skills from age-related decline, and even tasks that have been relatively briefly practiced in the laboratory to the point when they become automatic are then less affected by age.

'Local' or 'Differential' Change Models

Post-mortem and brain imaging studies suggest that age affects frontal cortex more radically and earlier than other parts of the brain in terms of loss of volume, cell loss, reduced cerebral blood flow, and reduction in the concentration, synthesis, and number of receptor sites for dopamine and other neurotransmitters. Consistently, some investigators have found that clinical tests for frontal damage, and laboratory tasks that make demands on functions supported by the frontal and prefrontal cortex, are especially sensitive to age. These functions include the inhibition of unwanted information or of inappropriate responses, the ability rapidly and accurately to generate categories of words, and the ability to switch easily between different criteria for classification of signals. However, there have been inconsistencies of replication

due to problems of measurement, problems of task familiarity, problems of construct validity, and, finally, and probably most basically, much neglected problems of participant selection. On balance, some frontal tasks do seem particularly sensitive to age-related changes, but it is not yet clear whether this is because the incidence of focal brain lesions increases in older populations or because all, or most, people suffer varying degrees of diffuse frontal changes.

MEMORY CHANGES IN OLD AGE

Both older people's subjective complaints and countless laboratory studies confirm that memory efficiency declines in old age and that, in general, the more difficult a memory task is, the greater will be the difference between the average numbers of errors made by young and by elderly adults. This general interaction between age and task difficulty is methodologically inconvenient, because to establish that age affects some functional processes more than others we must show that older people find it especially difficult to cope with a particular *kind* of task demand rather than simply a general increase in task difficulty. Neglect of this point makes brings into question much of the evidence that age affects some particular functional processes in memory, or some 'kinds' of memory, more than it affects others. Consequently, rather than reviewing evidence that age differentially affects speculatively different functional memory processes it may be more helpful to consider the effects of age in terms of the different uses that individuals make of their memories in their everyday lives.

WHAT IS MEMORY USED FOR?

Age changes in efficiency of immediate verbatim memory are slight but consistent, and seem to occur both because age speeds the rates at which memory traces decay and slows the rates at which they can be rehearsed. In everyday life a more common problem is to recover information selectively rather than completely, in some different order from that in which it is presented, or transformed in some way. The ability to meet such demands, particularly in order to schedule decisions and choices, has become known as 'working memory'.

Use of working memory allows people to transcend the limitations of their immediate verbatim recall for novel material ('memory span') by developing and using mnemonics to recode information about items or events. When sufficiently practiced, such recoding techniques seem to allow recall of almost limitless amounts of information but, because old age slows decision speeds, it also makes such recoding less efficient. The extent to which older persons' memories of events are limited by the amounts of information that they can immediately process is illustrated by findings that when older people are asked to recall accounts of actions performed by others, actions they have themselves performed, or actions they have imagined performing, they often correctly recall particular actions but have difficulty remembering whether they have performed, heard about, or imagined them.

Even when they do not deliberately and consciously use mnemonic techniques, people of all ages encode their experiences in terms of their expectations of what is most likely to have occurred. In this sense, video- or tape-recording that passively and unselectively registers information, subject only to failures to register or loss of information, provide poor metaphors for memory which is, rather, a dynamically selective and reconstructive process in which current motivations and lifetime knowledge of the world determine which aspects of new events are attended to, which are ignored, and how previous experience is used to shape interpretation. Because older people can process less information about events in unit time, and lose more of the information that they process, they must increasingly rely on their knowledge of the world to guide economical selection and to reconstruct events from sparse remembered detail. Increased reliance on interpretation and expectation can betray older people when they recreate events that contain unexpected and unfamiliar elements that cannot easily be inferred from context.

This dynamic view of memory highlights the counterintuitive point that humans and other animals typically use their memories to tell them what to do next rather than as archives of past experiences. This use of previously acquired information to anticipate future events and to formulate and execute appropriate plans to cope with them is termed 'prospective memory'. There is evidence that age does impair prospective memory but in everyday life these effects may not be noticeable because most of us, and perhaps especially the elderly, live predictable lives in structured environments that support us by providing contexts that cue us to perform appropriate actions. Such 'environmental support' is especially valuable to the elderly, and may serve them so well that the full

extent of their memory impairment is not apparent until they are deprived of familiar routines and environments.

Once information has been successfully encoded there seems to be no limit on how much of it can be retained, or for how long it remains available. This uncertainty is partly due to the logical difficulty of demonstrating that any information has been permanently lost, rather than having become temporarily inaccessible. Nevertheless, older people's ubiquitous subjective complaints, and many laboratory studies, show that they find it more difficult to access information that they are sure they once knew. For example, when young and older adults are compared on recall of public events that they have both shared, the young do much better. This can be taken to show that the young have forgotten less, but it may also mean that they could encode the events better when they first experienced them so that their memory representations have always been correspondingly more detailed and elaborate.

The complexity of inferences necessary when making such comparisons is illustrated by studies of the relative frequency, and efficiency, with which people of different ages can spontaneously recall events from different times of their lives. Both elderly and young adults recall very recent events more often, and more vividly, than distant events. Apart from losses of information over time a likely explanation is that recent events may be relatively frequently recalled, pondered, and discussed because they tend to have implications for the immediate future. Older people recall relatively fewer events than do the young from intermediate periods of six months or a year previously, but also recall relatively more events from their adolescence and young adult lives than from their middle age. This may partly be because events are better and more elaborately encoded, and so longer remembered, in youth than in middle or in old age, but another factor is that because young adult experiences are often more engaging, and have more long-lasting and memorable consequences than those that occur later in life, they may have since been much more often recalled, reassessed, and discussed. For similar reasons, at whatever age they may occur, vivid experiences during dramatic historical periods, such as wars or marked social change, are better recalled than those in more humdrum epochs. These factors can explain the subjective contrast that older people experience between their vivid recall of remote events and tenuous grasp of the recent past. However, the need for a distinction between older people's subjective impressions of vividness, and the objective completeness and accuracy of their memories, is illustrated when documentation such as school records is available. Older individuals' recall of events in their early lives is often much less reliable than they suppose.

The idea that the accuracy and durability of memories depends on the period of life when they were laid down is supported by recent work showing that individuals who have attained similar standards in university degree examinations forget their hard-won, but seldom used, knowledge more rapidly if they acquired it in early middle age than as young adults.

In contrast to marked age decrements in accuracy of explicit, conscious, recall and recognition of items and events there is evidence that information that is held in memory, but cannot be overtly recalled, can nevertheless influence behavior. For example, people can solve anagrams of words that they have recently learned, but subsequently failed to remember or recognize, more easily than anagrams of words that they have not recently seen, and fail to register as recurring. Loss of conscious, 'explicit' memory, with preservation of unconscious, 'implicit' memory, is found not only in older people but also in patients suffering from amnesias resulting from local damage to the hippocampus and temporal lobes of their brains. This has been taken as evidence that explicit and implicit memories are retained by functionally separate systems that are differentially sensitive both to focal brain damage and to normal aging.

Investigations of the ways in which old age alters mental abilities, particularly memory, have produced extremely detailed descriptions of behavioral changes but, so far, much less information on how these changes relate to changes in the brain and central nervous system. One obvious reason is that our knowledge of relationships between brain and cognition has mainly depended on studies of rare patients with highly localized brain damage and with equally well-defined cognitive impairments. In contrast, old age brings about both diffuse and focal brain changes. Prior to recent advances in brain imaging, diffuse brain changes could not be assessed until death terminated investigations of behavior and post-mortem data became available. Brain imaging now allows detection of global and diffuse, as well as local and specific, brain changes while individuals' cognitive losses can still be investigated. Methodologies for acquisition and interpretation of behavioral data have also greatly improved. It seems likely that the first decade of the twenty-first century will see greater

advances in our understanding of the effects of aging on cognition than have been possible during the entire twentieth century.

Analogical Reasoning, Psychology of

Intermediate article

Dedre Gentner, Northwestern University, Evanston, Illinois, USA

CONTENTS

Analogical reasoning is a kind of reasoning that applies between specific exemplars or cases, in which what is known about one exemplar is used to infer new information about another exemplar. The basic intuition behind analogical reasoning is that when there are substantial parallels across different situations, there are likely to be further parallels.

INTRODUCTION

Analogical thinking is ubiquitous in human cognition. First, analogies are used in explaining new concepts. Domains such as electricity or molecular motion, which cannot directly be perceived, are often taught by analogy to familiar concrete domains such as water flow or billiard-ball collisions. Within cognitive science, mental processes are likened to computer programs (e.g. neural networks; parallel or serial processes), or to searching within a space (e.g. mental distance; close or far associates). Such analogies can then serve as mental models to support reasoning in new domains. Another use of analogy is in making predictions within domains. When the stock market plunged in 2001 after the attack on the World Trade Center, many newswriters made an analogy to the 1929 Wall Street crash, and argued on this basis that the market would be higher after a few years (or that, because key causal conditions are different, the reverse would occur). Analogy is also important in creativity and scientific discovery, as discussed later. Finally, analogy is used in communication and persuasion. For example, environmentalists have compared the earth to Easter Island, where overpopulation and exploitation of the island's once-rich ecology led first to massive loss of species, and then to famine and societal collapse. Such persuasive analogies are meant to invite new inferences: for example, that continued population growth will lead to irreversible ecological decline.

Analogical processing involves several subprocesses. First, given a current topic, *analogical retrieval* is the process of being reminded of a past situation from long-term memory. Once two cases are present in working memory (either because of an analogical retrieval or simply through encountering two cases together), *analogical mapping* can occur. We will begin by discussing the mapping processes.

MAPPING AND USE

History

Important early work on analogical mapping came out of philosophy, notably Hesse's analysis of analogical models in science. Early psychological research on analogy focused on simple four-term analogies of the form a:b::c:d. In the 1970s and 1980s, artificial intelligence researchers introduced a new level of representational complexity and computational specificity. Patrick Winston explored computational algorithms for analogical matching and inference, and Jaime Carbonell modeled the transfer of solution methods from one problem to another. This kind of work inspired psychologists to lay out detailed process models of how analogies are represented and processed. The ensuing period has seen intense computational and psychological research, theory revision, and an expansion of the phenomena studied. The field of analogy continues to be characterized by extremely fruitful interchange between computational models and psychological research. (*See* **Analogy-making, Computational Models of**)

Analogical Mapping

Analogical mapping is the core process in analogy. In a typical instance of analogical mapping, a familiar situation – the *base* or *source* description – is matched with a less familiar situation – the *target* description. The familiar situation suggests ways of viewing the newer situation as well as further inferences about it. Analogical mapping requires *aligning* the two situations – that is, finding the correspondences between the two representations – and *projecting inferences* from the base to the target. Then the reasoner must *evaluate* the analogical match and its inferences. Two further processes that can occur are *re-representation* of one or both analogs to improve the match, and *abstraction* of the structure common to both analogs.

Structure-mapping theory (Gentner, 1983) aims to capture the psychological processes that carry out analogical mapping. According to this theory, the comparison process involves finding an alignment between the base and target representations that reveals common relational structure. On the basis of this alignment, further inferences are projected from base to target. People prefer to find an alignment that is *structurally consistent*: that is, there should be a *one-to-one correspondence* between elements in the base and elements in the target, and the arguments of corresponding predicates must also correspond (*parallel connectivity*). For example, in the analogy below, Timmy in (a) could be put in correspondence with Timmy in (b) (on the basis of a local entity match) or with Fluffy in (b) (on the basis of matching relational roles). People appear to entertain both possibilities during processing, but to settle on one or the other by the end of the process.

(a) Lassie rescued Timmy.
(b) Timmy rescued Fluffy.

Another important early theory was Holyoak's (1985) *pragmatic mapping theory*, which focused on the use of analogy in problem-solving and held that analogical mapping processes are oriented towards attaining goals (such as solutions to problems). According to pragmatic mapping theory, it is goal relevance that determines what is selected in analogy. Holyoak and Thagard (1989) later combined this pragmatic focus with structural factors in their multi-constraint approach to analogy.

Analogical inference projection is a crucial part of the mapping process. Once an alignment is achieved, further inferences can be made by projecting information from the base (or source) domain into the target domain. For example, in the above analogy, suppose we knew more about event (a), such as:

(a) Lassie rescued Timmy because she loves him. She has beatiful brown eyes.
(b) Timmy rescued Fluffy.

In this case, the likely inference in (b) is that Timmy rescued Fluffy because he loves Fluffy. This ability to invite new inferences is central to analogy's role in reasoning. Importantly, analogical inference is rather selective. For example, we are unlikely to make the inference here that Timmy has brown eyes (or that he has four legs, even if we also know this to be true of Lassie).

This illustrates the *selection problem* in theories of analogical inference. If people projected everything known about the base into the target, analogy would be useless in reasoning. Fortunately, people do not do this. Thus a central aim of theories of analogy is to characterize this selection process. At least three factors have been proposed.

Holyoak and his colleagues have emphasized *goal relevance*: the inferences projected are those that fit with the reasoner's current goals in problem-solving.

A second factor, proposed in structure-mapping theory, is relational connectivity – more specifically, *systematicity*: a preference for projecting from matching systems of relations connected by higher-order relations such as *cause*, rather than projecting local matches. In many cases, goal relevance and systematicity will make the same predictions, because problem-solving goals often involve a focus on causal systems.

A third factor in selecting inferences, proposed by Keane, is *adaptability*: the ease with which a possible inference can be modified to fit the target.

There is evidence for all three of these criteria. Spellman and Holyoak (1996) showed that when two possible mappings are available for a given analogy, people will select the mapping whose inferences are relevant to their goals. Evidence for systematicity comes from the finding that when people read analogous passages and make inferences from one to the other, they are more likely to import a fact from the base to the target when it is causally connected to other matching predicates (Clement and Gentner, 1991; Markman, 1997). Finally, Keane (1996) found evidence that the degree of adaptability predicts which inferences are made from an analogy.

There remain many open questions. For example, according to the structure-mapping account, many different higher-order relations can provide inferential selection – including causal relations, deontic

relations such as permission and obligation, and spatial relations such as symmetry and transitive increase. The challenge then is to delineate the set of higher-order relations that can serve this purpose. Another open question is the time course of these constraints. For example, do goals have special priority *during* the analogical mapping process, or do the effects of goals occur through influencing the initial representations of the two analogs (*before* the mapping process) or through selecting among multiple possible interpretations (*after* the mapping process)?

Evaluation

Once the common alignment and the candidate inferences have been discovered, the analogy is evaluated. *Evaluating* an analogy involves at least three kinds of judgment: (1) *structural soundness*: whether the alignment and the projected inferences are structurally consistent; (2) *factual correctness*: whether the projected inferences are false, true, or indeterminate in the target; and (3) *relevance*: whether the analogical inferences are relevant to the current goals. In practice, the relative importance of these factors varies quite a bit. In domains where little is known, or where there is disagreement about the facts – for example, in politics – goal relevance may be more important than factual correctness.

Abstraction

In *analogical abstraction*, the common system that represents the interpretation of an analogy is extracted and stored. This kind of schema abstraction helps to promote transfer to new exemplars. When people are asked to compare two analogous passages, they are better able to later retrieve and use their common structure (given a relationally similar probe) than are people who were given only one of the stories (Gick and Holyoak, 1983). Further studies have shown that actively comparing two analogous passages leads to better subsequent retrieval than reading the two passages separately. These findings are consistent with the claim that analogical alignment promotes the common structure and makes it more available for later use.

Analogy in Real-world Reasoning

Analogy is often used in common-sense reasoning to provide plausible inferences. It must be noted that analogy is not a deductive process. There is no guarantee that the inferences from a given analogy will be true in the target, even if the analogy is carried out perfectly and all of the relevant statements are true in the base. However, the set of implicit constraints described above make analogy a relatively 'tight' form of inductive reasoning. This may be why analogy is heavily used in arenas such as law, where clear reasoning is important but formal principles are often not sufficient to decide issues.

The lack of deductive certainty in analogical reasoning has a positive side. It means that analogy can suggest genuinely new hypotheses, whose truth could not be deduced from current knowledge. One arena in which this kind of analogical inferencing has been extensively studied is scientific reasoning and discovery. Nancy Nersessian has examined the role of analogy and other model-based reasoning processes in the thought processes of Faraday and Maxwell. Paul Thagard has discussed analogy as a contributor to conceptual revolutions in science. Kevin Dunbar has observed scientists in working microbiology laboratories and has found that analogy plays a large role in the discovery process.

Analogy appears to be very important in children's thinking, as Halford, Goswami, and others have argued. Children often use analogies from known domains as a way to fill in gaps in their knowledge of other domains. For example, Inagaki and Hatano (1987) asked five-year-old children hypothetical questions like 'What would happen if a rabbit were continually given more water?' The children often answered by using an analogy to humans: for example, 'I would get sick if I kept drinking water, and I think the rabbit would too.' Interestingly, children's answers tended to be more accurate when they used such analogies than when they did not. Children were most likely to use analogies to humans when the target was somewhat similar to humans, suggesting that for children (as for adults) similar analogs are more likely to be retrieved and are easier to align with the target than dissimilar analogs.

FACTORS THAT INFLUENCE ANALOGICAL MAPPING AND USE

People's fluency in carrying out analogical mappings is influenced by three broad kinds of factors. First are factors internal to the analogical mapping itself, such as *systematicity* – whether the common relational system possesses higher-order connective structure – and *transparency* – the degree to which corresponding elements are similar. The second category includes characteristics of the

reasoner, such as age and expertise. The third includes task factors such as processing load, time pressure, and context.

Transparency and systematicity have been found to be important in analogical problem-solving. The transparency of the mapping between two analogous algebra problems – that is, the similarity between corresponding objects – is a good predictor of people's ability to notice and apply solutions from one problem to the other. For example, Ross (1989) taught people algebra problems and later gave them new problems that followed the same principles. People were better able to map the solution from a prior problem to a current problem when the corresponding objects were highly similar between the two problems: for example, 'How many golf balls per golfer' → 'How many tennis balls per tennis player'. They performed worst in the *cross-mapped* condition, in which similar objects appeared in different roles across the two problems: for example, 'How many golf balls per golfer' → 'How many tennis players per tennis ball'.

The intrinsic factors of transparency and systematicity interact with characteristics of the reasoner, notably age and experience. Gentner and Toupin (1986) gave children a simple story and asked them to re-enact the story with new characters. Both six- and nine-year-olds performed far better when the corresponding characters were highly similar between the two stories than when they were different, and they performed worst when similar characters played different roles across the two stories (the *cross-mapped* condition). Thus both age groups were sensitive to the transparency of the correspondences. In addition, older children (but not younger children) benefited from systematicity – that is, from hearing a summary statement that provided an overarching social or causal moral.

The developmental change found here is an instance of the *relational shift*: a shift from focusing on object matches to focusing on relational matches. Some researchers have suggested that this shift is driven by gains in knowledge (Gentner and Rattermann, 1991), while others propose that it results from a developmental increase in processing capacity (Halford, 1993).

The third class of factors affecting analogical processing concerns task variables such as time pressure, processing load, and immediate context. One generalization that emerges from several studies is that making relational matches requires more time and processing resources than making object–attribute matches. For example, Goldstone and Medin (1994) found that when people are forced to terminate processing early, they are strongly influenced by local attribute matches (such as *A* with *A* in the example below), even in cases where they would choose a relational match (such as *A* with *P*) if given sufficient time:

A above M and *P above A*

Adult performance in mapping tasks is also influenced by immediately preceding experiences. For example, in the *one-shot mapping task* (Markman and Gentner, 1993) subjects are shown a pair of cross-mapped pictures, such as *a robot repairing a car* and *a man repairing a robot*. The experimenter points to the robot in the first picture and the subject indicates which object in the second picture 'goes with' it. Subjects often choose the object match (e.g. the other robot). However, if they have previously rated the similarity of the pair, they are likely to choose the relational correspondence (the repairman). These findings suggest that carrying out a similarity comparison induces a structural alignment.

Kubose, Holyoak, and Hummel used this one-shot mapping task to show that processing load influences analogical processing. The experimenter pointed to the cross-mapped object in the first picture (the robot) and subjects were instructed to point to the relational correspondence (the repairman) in the second picture. Subjects made more object-mapping errors when given an extra processing load, such as having to count backwards. Recent work by Holyoak and his colleagues also suggests that damage to the prefrontal cortex is associated with detriments in analogical tasks, although it is not clear whether this results from specific involvement of the prefrontal cortex in analogical processing or from more general factors such as inhibitory control.

Summary

Research on analogical mapping has revealed a set of basic phenomena that characterize human analogical processing (see Table 1). A striking feature of analogical mapping is the importance of systematic, structurally connected representations. Commonalities that are interconnected into a relational system are considered to be more central to a comparison than are those that are not. Connected systems are easier to map to a new domain than are unconnected sets, leading to better transfer in analogy and problem-solving. Systematicity also governs inferences: inferences are projected from interconnected systems in the base to fill out corresponding structure in the target. Even the

Table 1. Basic phenomena of analogy (adapted from Gentner and Markman, 1995, 1997; see also Hummel and Holyoak, 1997)

1 *Relational similarity*	Analogies involve relational commonalities; object commonalities are optional.
2 *Structural consistency*	Analogical mapping involves one-to-one correspondence and parallel connectivity.
3 *Systematicity*	In interpreting analogy, connected systems of relations are preferred over isolated relations.
4 *Candidate inferences*	Analogical inferences are generated via structural completion.
5 *Alignable differences*	Differences that are connected to the common system are rendered more salient by a comparison.
6 *Interactive mapping*	Analogy interpretation depends on both terms. The same term yields different interpretations in different pairings.
7 *Multiple interpretations*	Analogy allows multiple interpretations of a single comparison.
8 *Cross-mapping*	Analogies are more difficult to process when there are competing object matches.

differences associated with a similarity comparison are influenced by systematicity: the differences that are psychologically salient in a comparison are those that are connected to the common system. In addition, goal relevance may have effects over and above the effects of connected relational structure.

RETRIEVAL OF ANALOGS

So far, we have discussed the processing of an analogy once both analogs are present. When we turn to the issue of what leads people to think of analogies, we see a very different pattern of results. People often fail to retrieve potentially useful analogs, even when there is an excellent structural match, and even when they clearly have retained the material in memory. For example, Gick and Holyoak (1983) gave subjects a thought problem: how to cure an inoperable tumor without using a strong beam of radiation that would kill the surrounding flesh. Only about 10 percent of the participants came up with the ideal solution, which is to converge on the tumor with several weak beams of radiation. If given a prior analogous story in which soldiers converged on a fort, three times as many people (about 30 percent) produced convergence solutions. Yet the majority of participants still failed to think of the convergence solution. Surprisingly, when these people were simply told to think back to the story they had heard, the percentage of convergence solutions again tripled, to 80–90 percent. Thus, the fortress story had been retained in memory, but it was not retrieved by the analogous tumor problem. The implication is clear. Even when a prior experience has been successfully stored in memory, it might not be retrieved when a person encounters a new analogous situation where it would be useful.

When we ask what does facilitate analogical retrieval, one major factor emerges: the similarity between the analogs. As noted earlier, similarity is one of the factors that facilitates analogical mapping; but it has a much larger effect on retrieval. For example, Gentner *et al*. (1993) gave subjects a set of stories to remember and later showed them probe stories that were either surface-similar to their memory item (e.g. similar objects and characters) or structurally similar (i.e. analogous, with similar higher-order causal structure). Surface similarity was the best predictor of whether people would be reminded of the prior stories; people were two to five times more likely to retrieve prior stories with only surface commonalities than with only structural commonalities. However, their judgments of the goodness of the match were completely different. They rated the surface-similar pairs (including their own remindings) as low in inferential value and in similarity, and preferred the structurally similar pairs. A similar dissociation between reminding and use has been found in problem-solving tasks: remindings of prior problems are strongly influenced by surface similarity, even though structural similarity better predicts success in solving current problems (Ross, 1989). This failure to access potentially useful analogs (unless they are highly similar to the target) is an instance of the *inert knowledge* problem in education. One piece of good news is that it appears that domain expertise may improve matters somewhat. For example, Novick (1988) found that people with mathematics training retrieved fewer surface-similar lures in a problem-solving task than did novice mathematicians. Moreover, experts were quicker to reject these false matches than were novices.

One factor that may contribute to experts' success in analogical retrieval is *representational uniformity*: the extent to which the relations in the memory trace are represented similarly to those in the probe. Clement *et al*. (1994) explored the effect of relational predicate similarity on analogical access and mapping between stories. They found that retrieval was more likely when the probe and target

contained synonymous terms (*manifest* similarity) than when they contained loosely similar predicates such as 'munched' and 'consumed' (*latent* similarity). However, unlike retrieval, analogical mapping when both situations were present was relatively unaffected by the latent–manifest distinction. In analogical reminding, with only the current situation in working memory, success depends on the degree of match of the pre-existing representations; whereas during mapping, with both situations present in working memory, there is opportunity for re-representation.

ANALOGICAL LEARNING

Analogical comparison can lead to new learning in at least four ways: analogical abstraction, inference projection, difference detection, and re-representation. The first two we have already discussed. In *analogical abstraction*, the structure common to base and target is noticed and extracted. Sometimes the common system is stored as a separate representation; this is referred to as *schema abstraction* (Gick and Holyoak, 1983). In *inference projection*, a proposition from the base is mapped to the target. If it is retained as part of the target structure, then learning has occurred. In *difference detection*, carrying out a comparison process leads people to notice certain differences – namely, those connected to the common structure. In *re-representation*, two non-identical predicates are aligned and decomposed (or abstracted) to find their commonalities, resulting in a re-representation that contains a common predicate: for example, comparing *chase*(dog, cat) and *follow*(detective, suspect) might result in *pursue* (entity1, entity2). A further kind of knowledge change, hypothesized to take place in scientific discovery, is *restructuring*, in which the target undergoes a radical change in structure.

COMPUTATIONAL MODELS

The interplay between computational models and psychological studies has been extremely productive in analogical research. Current models include Boicho Kokinov's AMBR model, which integrates retrieval and mapping; Keane's IAM model, which utilizes an incremental mapping algorithm; Halford's tensor product model; and the systems of Doug Hofstadter and his colleagues Melanie Mitchell and Robert French, which integrate perceptual processing with analogical matching. (*See* **Analogy-making, Computational Models of**)

Analogical modeling has made great strides, but there are still open questions. At present no model fully captures human analogy processing. Two challenges for analogical models are (1) the *selection problem* discussed above – namely, how to avoid indiscriminate inferencing; and (2) the problem of *representational flexibility* – that is, how to achieve a matching process that does not require absolute identity matches. Falkenhainer *et al.*'s (1989) SME, which uses a local-to-global alignment and inference process over structured symbolic representations, meets the benchmarks in Table 1 and can capture selective matching and inference, as well as schema abstraction. But it is not yet sufficiently flexible in its match process. Another leading model, Hummel and Holyoak's (1997) LISA model, uses a combination of distributed representations of concepts and structured representations of the relational connections (necessary for achieving structural consistency in mapping). It uses a connectionist temporal-binding algorithm and makes its matches in a serial order partly guided by the experimenter. LISA's use of distributed representations allows for flexible matching, and unlike most models of analogy, it attempts to capture working memory limitations. However, it has yet to solve the selectivity problem in inferencing.

THE FUTURE

Of the many research questions that remain, four stand out as particularly interesting and timely. First is the role of analogy in cognitive development: how much of children's rapid learning can be attributed to the processes of comparing and drawing inferences between partially similar situations? Second is tracing the neuropsychology of analogical processes: what areas of the brain are implicated, and what is the course of processing? Third is the exploration of analogy in animal cognition. Comparative research so far indicates that humans excel in analogical ability, yet this ability exists in certain other species as well – for example, in chimpanzees and dolphins. Cross-species comparisons may help us decompose the cognitive components of analogical ability. A final important research frontier is the integration of analogy into larger models of cognition.

Animal Cognition

Introductory article

Valerie A Kuhlmeier, Yale University, New Haven, Connecticut, USA
Sarah T Boysen, Ohio State University, Columbus, Ohio, USA

CONTENTS

The study of how animals learn, behave, and think, often from a comparative perspective, is the crux of animal cognition research. Recent topics explored in this field include understanding of abstract concepts, spatial learning and memory, imitation, representation of social relations, and examining the similarities between nonhuman primates and human children.

INTRODUCTION

The field of animal cognition has emerged since the 1980s as a rich, interdisciplinary area representing animal learning and behavior, comparative psychology, ethology, and behavioral ecology. It is different from the behaviorist tradition in that researchers do not focus primarily on conditioning processes. Interest in animal cognition cuts across numerous academic fields, including psychology, zoology, biology, anthropology, and primatology, among others. In psychology, several topic areas have been particularly important, although they represent only a portion of ongoing studies in animal cognition. In particular, studies of abstract concepts, spatial learning and memory, imitation, representation of social relationships, and developmental comparisons between human children and animals (typically primates) represent a growing literature. These areas encompass research issues and approaches that are currently being studied with different animal species, including (but not limited to) rats, pigeons, primate species such as rhesus monkeys, capuchins, and squirrel monkeys, as well as great apes such as chimpanzees, bonobos, and orangutans.

ABSTRACT CONCEPTS

One of the most basic questions being investigated with animals is whether any species is able to reason abstractly. That is, can an animal understand an abstract concept such as 'same versus different', recognize itself in a mirror (possess a 'concept of self'), or even count using numbers through a process similar to numerical skills shown by young children? Are they able to use their understanding of a concept when presented with new examples? Finally, and most importantly, how might such capacities for abstract thinking and concept formation serve a particular species in the wild when they are confronted with real problem-solving opportunities and/or life-and-death situations?

What is meant by an abstract concept, particularly for an animal, requires careful thought, and has been a contentious issue in animal learning and cognition. If concepts are defined in such a way that only humans can acquire them, as some investigators have proposed, and especially if conceptual understanding can be acquired only if mediated by language, then clearly concepts must be unique to *Homo sapiens*. However, investigators in animal cognition have suggested that an abstract concept should be operationally defined. For example, if an animal is presented with complex stimuli such as photographs of trees and other scenes, learns to respond only to pictures of trees, and subsequently chooses new pictures of trees from among a novel set of photographs, the animal may be said to have an understanding of the 'tree concept'. Similarly, if an animal with training on counting and other number skills is able to correctly assign a number to a novel collection of objects, despite learning to count using only gumdrops, it could be argued that the subject, whether it was a chimpanzee, rat, or pigeon, has a concept of number. In this case, the ability to generalize an understanding of numbers to brand-new counting opportunities would suggest that the animal has

some representation of an abstract concept of number and numerical relationships.

According to the current literature in animal cognition, both types of capacities for abstract concepts have been demonstrated in animal subjects. Such studies include pigeons' abilities to recognize a range of items conceptually, demonstrated by identifying slides depicting trees, people, or even the letter 'a' presented in very different typefaces, when the animals were presented with novel sets of visual stimuli. In the case of number concepts, Sarah Boysen has demonstrated that chimpanzees can assign Arabic numerals to quantities of candies and other collections of objects. More impressively, individual chimpanzees have been shown to invoke spontaneous addition algorithms that enabled them to count different-sized arrays that were hidden in several locations around a test room. The animals were able to report the total number of objects found during their search of the sites when they were given the very first opportunity with this novel task, even though they had no prior training or testing with items separated in both time and space.

In this case, previous associative training with numerals and candy arrays most probably contributed to emergent conceptual skills with numbers and counting which went far beyond the animals' specific training. Thus, this study of rudimentary addition in chimpanzees supported the notion that the subjects had acquired a 'concept of number' and could use it spontaneously with completely novel problems and in a new setting. Such cognitive flexibility and generalizability of skills, above and beyond explicit training, provides evidence for animals' capacities for conceptual understanding.

SPATIAL LEARNING AND MEMORY

As early as the 1930s, an experimental psychologist, Edward Tolman, studied the ability of rats to learn the spatial organization of a maze. As the animals explored the maze, they learned the various turns, blind alleys, and eventually, the location of the goal box. Tolman proposed that, during the course of their exploration, the rats came to represent the spatial configuration of the maze internally as a kind of 'cognitive map'. The term is still used today to refer to a mental representation of territory and the landmarks within it, sites where food has been cached, and a host of other spatially mediated information which may contribute to survival. Since Tolman proposed the idea of a cognitive representation of the external environment within the rat, scientists from numerous disciplines, including comparative psychology, neuroscience, cognitive science, biology, and ethology, have designed experiments to test ideas about such mental representations in a wide range of species, including many types of passerine birds and rodents, nonhuman primates, as well as comparative studies with children and adult humans from differing cultures.

Studies of spatial learning and memory are providing a wealth of clues towards understanding basic mechanisms related to the processing of spatial information. Most animals must be able to learn and remember information about their location within their territory in order to forage for food, seek mates, migrate, select nest or den sites, care for offspring, store food (cache), and avoid predators. For example, hoarding food and relocating it later, sometimes months after the original caching, places exceptional demands on spatial learning and memory. Among the caching birds, several species of jays and nutcrackers store large numbers of nuts and seeds, and are dependent upon finding stored food in order to survive the winter months. During experimental laboratory studies, efforts to control possible odor and visual cues did little to decrease the birds' accuracy in locating cached food. However, displacement of the cached food to a site a short distance away resulted in the birds' inability to locate it. Furthermore, while there have been some suggested alternative explanations for the birds' success, including mere chance encountering of the sites, their ability to locate and retrieve hoarded food has repeatedly been far better than would have been predicted by chance alone. Such findings have been replicated in numerous laboratories, with several different species, with the same results.

Another factor influencing spatial learning and memory is a species' particular social structure and mating system. For example, males and females of a monogamous species (i.e. those in which males and females mate exclusively) live in the same territory together. Consequently, both sexes use similar spatial abilities for getting around their range. On the other hand, in species that are polygynous (i.e. those in which males have access to more than one female), males have additional spatial demands: they must keep track of females' locations within the territory and avoid rival males. These critical behaviors might translate to better spatial processing abilities in polygynous males relative to females of polygynous species and to males and females of monogamous species.

This hypothesis has been explored in studies of sex differences in neural structure and spatial cognition in different rodents, specifically prairie voles, a monogamous species, and meadow voles, which are polygynous. Males and females of these two closely related species were compared on their performance on a series of mazes, in order to test their spatial abilities. As predicted, polygynous males outperformed females and monogamous males. Studies such as these demonstrate how particular spatial abilities may develop in a species and subsequently help to explain observed differences within and between species.

It is likely that the mechanisms and processes that subserve spatial learning and memory in animals will continue to be an active area of research, as a host of critical and intriguing questions remain about how animals acquire and utilize spatial information. For example, new research in animal spatial cognition is examining what types of cues in the environment (e.g. landmarks, configurations of landmarks) animals attend to, learn, and remember in order to effectively navigate and orient. Researchers are even exploring animals' understanding of symbols of their environment, such as maps and scale models. The research continues to be comparative in nature, looking for similarities and differences among animal species and between humans and other animals. Indeed, the study of animal spatial learning and memory promises to have an exciting future in the field of animal cognition.

REPRESENTATION OF SOCIAL RELATIONS

Animals that live in long-lasting social groups interact with the individuals of their group in a complex manner. Required for these interactions are cognitive abilities that may include recognizing others as individuals, remembering which individuals have aided one in the past, and monitoring interactions among the other members of the group. Indeed, some researchers in the 1960s and 1970s proposed that the evolution of general problem-solving abilities was driven by the need for complex cognitive mechanisms for social interactions. But what exactly do animals understand and represent of their social world? Do animals recognize and interact with others in certain ways only because of past experiences with these individuals (i.e. by making associations), or can animals also distinguish classes of relationships and understand concepts such as kinship and dominance (by having mental representations)?

Although the social lives of many animals with long-lasting social groups have been examined (e.g. wolves, lions, elephants, marine mammals, birds), most research in the representation of social relations has focused on primate species. For example, Verena Dasser tested whether Java monkeys can discriminate pairs of animals based on their familial relationship. One monkey subject was trained to choose a photograph of a mother and daughter from the subject's social group and ignore a photograph of an unrelated pair. After training trials using this same mother–daughter pair, the monkey subject was able to correctly choose new photographs of other mother–offspring pairs from the social group. How did the monkey do this? It is possible that the monkey relied on the perceptual similarity between the mother and her offspring to represent the relationship between the members of the pair and solved the task by choosing the pair of animals that looked alike. Results from a recent study by Lisa Parr and Frans deWaal support this possibility. They tested chimpanzees with a similar task; however, their subjects had to match photographs of unfamiliar chimpanzee mothers with their equally unfamiliar offspring, while ignoring a third photograph of an unrelated chimpanzee. The chimpanzees were successful; they correctly selected the photographs of the sons of the sample mothers. Since the subjects had no past experience with the pictured animals, successful matching implied a recognition of physical similarity between individuals.

Dorothy Cheney and Robert Seyfarth have used vocal playback experiments to study how monkeys represent their social world. In one experiment, when an infant vervet monkey's cries were played out of hidden speakers, the other monkeys in the group looked to the direction of the infants' mother. Their behavior indicated that they associate particular infants with the infants' mothers. But can monkeys go beyond simple associations like these and demonstrate the existence of mental representations of their social world?

A second vocal playback experiment with baboons suggested that this might indeed be the case. The experimenters took advantage of natural vocal exchanges between baboons at different levels of the dominance hierarchy. Normally, when a dominant female approaches a subordinate female, the dominant monkey will grunt and the subordinate monkey will fear bark. However, when a subordinate female approaches a dominant female, there is no vocal exchange. The experimental procedure relied on the fact that monkeys tend to look longer at sources of unfamiliar or

strange sounds. The experimenters played sequences of consistent and inconsistent grunt/fear bark exchanges. In the inconsistent exchange, the sound of a subordinate female's grunt was played, followed by a dominant female's fear bark, an unlikely event. However, in the consistent exchange, a subordinate female's grunt was followed by a high-ranking female's fear bark and a higher-ranking female's grunt. This sequence is consistent with natural baboon vocal behavior due to the last part of the sequence; the high-ranking animal's fear bark could have been caused by the higher-ranking female's approach. The baboons looked longer in the direction of the hidden speaker that played the inconsistent sequence, indicating that they recognized the strangeness of the event and had some representation of their dominance hierarchy and the appropriate behavior of the members within it. This understanding of social causation suggests a mental representation of their social environment.

Thus, research has demonstrated that some social animals may interact differentially with the individuals of their group with the aid of associations such as physical similarity and past experience. Furthermore, they might also develop mental representations of the underlying social relations based on these associations. It is possible, then, that the learning of associations between individuals and other individuals, or even associations between individuals and certain behaviors, may help give rise to mental representations such as kinship and dominance status.

IMITATION

Since the time of Darwin, there has been an interest in whether animals can imitate, that is, perform an action after seeing the same action being performed by another animal. Darwin concluded that this ability was one we share with other animals; however, researchers today are not so quick to grant animals this ability. Indeed, many terms other than 'imitation' have been coined to describe behavior that may appear to be truly imitative, but that actually occurs through much simpler cognitive processes. But why the careful attribution of imitation? Many researchers believe true imitation to be a precursor to theory of mind (the ability to attribute mental states to others), and thus involves processes such as self-awareness and perspective-taking. Thus, to grant that a behavior is imitative is to grant the actor the precursors to highly complex cognitive capacities.

For most researchers, demonstrating true imitative behavior typically requires that an animal has a representation of another animal's action and uses the representation to behave in a manner that matches that of the other. Observations of animals doing human-like actions (e.g. a pet opening the back door) are not enough to demonstrate true imitation. Without knowing past training experience, it is difficult to determine how the behavior developed. Also, it may be that an animal is not attending to the actions of another, but attending to the object or location the other animal is acting on. For example, when animal A behaves similarly to nearby animal B (perhaps by digging for food in a certain area), it may be the result of A's attention being drawn to the location of the food, not a direct imitation of B's action. This type of behavior has been called 'stimulus enhancement' or 'local enhancement', and it is often difficult to separate this type of explanation from one implicating true imitation.

One promising paradigm has been the 'two-action task', in which one animal watches the actions (usually a trained, unusual behavior) of another animal and is then placed in a similar situation to examine whether it completes the same actions. For example, Thomas Zentall and his colleagues have trained pigeons and Japanese quail to either step or peck on a lever to receive food. Then, untrained birds were allowed to observe the trained demonstrator as it pecked or stepped on the lever. After the observation period, the untrained observer was placed in the cage with the lever and its behavior was measured. These birds displayed almost 90 percent imitative responses during testing. That is, if they had observed the demonstrator bird step on the lever, they too stepped, but if they observed pecking, they pecked. One criticism that has been raised is that the pecking and stepping behaviors themselves were not necessarily unusual for the birds in natural contexts, and thus, these experiments may not have demonstrated true imitation, but stimulus enhancement to the lever. However, despite this criticism, the results are very suggestive of imitative behavior and point to the value of the two-action experimental design for examining animal imitation.

The study of nonhuman primate imitative ability has consisted of many suggestive anecdotes, but recently, controlled experiments have also been conducted. Many of these have incorporated object manipulation and tool-using, taking advantage of the animals' dexterity and, in some cases, their

natural tool-using abilities. For example, Andrew Whiten and his colleagues developed a two-action task for both chimpanzees and young children. The chimpanzee and human subjects observed an adult human either twist or poke out bolts that secured the opening of a box containing a desired fruit. When given access to the box, all subjects used the action demonstrated, suggesting imitation. However, the chimpanzees exhibited fewer instances of imitation than the oldest children tested (four years old). Indeed, the children seemed to imitate the fine motor details of the demonstrator more closely than the chimpanzees.

Similar observations have been made by Michael Tomasello and his colleagues. In their study, chimpanzees tended to achieve the same goal as a demonstrator (e.g. use a rake to attain food), but the techniques the chimpanzees used differed slightly from those of the demonstrators. Tetsuro Matsuzawa and Masako Myowa-Yamakoshi have interpreted these results and results from their own similar experiments to suggest that apes may have difficulty in transforming the demonstrator's motions into their own matching motor acts. That is, in these imitation experiments, the apes may be less sensitive to the demonstrator's body movements than to his or her underlying goals and the objects used to attain them.

In summary, new methodologies have brought us closer to understanding the extent of animals' imitative capacities. The results so far are highly suggestive of true imitative behavior, yet many skeptics are still not convinced. The two-action task has proven to be an effective method of testing, although experimenters will have to address concerns that performance is due to stimulus enhancement and not true imitation. Furthermore, the creative studies with nonhuman primates, especially those simultaneously testing young human children, are valuable and should be explored further to determine possible species differences and similarities.

COMPARISONS BETWEEN NONHUMAN PRIMATES AND HUMAN CHILDREN

Animal cognition research is often comparative, and very often the comparisons are made between humans, specifically infants and children, and nonhuman primates. These specific comparisons are often made to examine the cognitive capacities that can exist in the absence of language, to examine the possibility of innate modules for certain cognitive or perceptual processes, and to chart the evolution of our cognitive capacities and examine conditions that may have supported their development. Research in animal cognition and human cognitive development has often delved into the same questions, yet direct comparisons on a given topic have sometimes been hard to make owing to different experimental procedures. Of late, however, there has been an increase in experimental studies that directly compare children and nonhuman primates by using very similar methodologies. Some of these studies have been discussed above, including the imitation studies by Andrew Whiten and his colleagues. Two more examples, studies of numerical ability and scale model comprehension, will be mentioned here.

Karen Wynn has used the 'violation of expectation' procedure to examine the numerical abilities of infants. This procedure relies on the fact that infants tend to look longer at events that are unexpected, or involve some sort of violation. In one study, infants watched as an object was placed on a stage. A screen was then raised to hide the object. The infants then saw a second object being placed behind the screen. Now, the screen was lowered, revealing one of two outcomes: one object (the unexpected outcome) or two objects (the expected outcome). Infants looked longer at the unexpected outcome of one object. In fact, in subsequent studies, they looked longer at a $1 + 1 = 3$ event than at $1 + 1 = 2$. This effect was also seen for simple subtraction events, and together, the studies suggest that infants have some understanding of number estimation and quantity. Using similar experimental procedures, Marc Hauser and his colleagues have examined wild rhesus monkeys' numerical abilities. The experiment was unchanged from Wynn's except that large eggplants were used as the items to be counted. The monkeys responded to the events in a manner similar to the infants, looking longer at operations that yielded unexpected numbers of eggplants. Thus, the use of identical experimental procedures has demonstrated that infants and rhesus monkeys seem to have similar numerical estimation abilities.

How and when humans come to understand the correspondence between a physical representation of space, such as a map or a model, and its real-world referent has also been the focus of much research in developmental psychology. Judy DeLoache has approached this question in her studies exploring children's ability to understand the representational nature of a scale model. She and her colleagues have found that after witnessing a

miniature item being hidden in a scale model of a room, three-year-old children can locate a full-size item hidden in the analogous location in the real room. However, slightly younger children, 2.5-year-olds, have difficulty with the task. Their difficulty with the task implies the lack of 'representational insight', or knowledge that the model and room are related as symbol and referent. DeLoache and her colleagues have suggested that many factors can contribute to the development of this understanding, including the perceptual similarity between the model and the room, experience with other symbol systems, instruction on the nature of the model–referent relationship, and the ability to form a 'dual representation' (i.e. understanding the model as an object unto itself as well as a symbol for something else).

Until recently, it was not known if a nonhuman species could understand a physical representation of space such as a scale model and use it as a source of information regarding the environment. Valerie Kuhlmeier and Sarah Boysen found that chimpanzees were able to solve a scale model task that was similar to DeLoache's procedure. After watching an experimenter hide a miniature bottle of juice within a scale model of an outdoor enclosure, three chimpanzees readily found the real juice bottle that was hidden in the analogous location in the actual enclosure. That is, they went to the correct site and retrieved the bottle immediately upon entering the enclosure. These chimpanzees performed similarly to the three-year-old children in DeLoache's task. However, the performance of the other four chimpanzees tested was poor, or at best, varied. These four chimpanzees often relied on a search strategy that consisted of searching the hiding site in the front left corner of the enclosure, and continuing to search each site successively as they circled the room clockwise. The search strategy that was observed with these chimpanzees has not been reported in studies by DeLoache and suggests that, although some chimpanzees solve the task in a manner similar to young children, there may be other factors that influence some chimpanzees' performance. These factors will no doubt be the focus of future study.

Thus, these studies of numerical ability and scale model comprehension illustrate how similar test procedures can be used to examine the similarities and differences between nonhuman primates and human children. They demonstrate that the dialogue between those who study cognitive development and those who study animal cognition is increasing, with many researchers flexibly moving back and forth from one to the other during their careers.

CONCLUSION

The study of animal cognition is a growing one, with increasing dialogue among researchers in different academic fields. The topics discussed above represent only a subset of research in animal cognition but provide evidence for flexible and complex cognitive abilities in nonhuman animals. Future research of these topics, and all areas of animal cognition, is necessary to further examine the manner in which animals learn, behave, and think.

Animal Language

Introductory article

Duane M Rumbaugh, Georgia State University, Atlanta, Georgia, USA
Michael J Beran, Georgia State University, Atlanta, Georgia, USA

CONTENTS

Animal language references the field in which animals' capabilities for various dimensions and functions of language are researched. Language is here defined as a neurobehavioral system that provides for the construction and use of symbols to enable the conveyance and receipt of information and novel ideas between individuals. The meanings of symbols in this system are basically defined and modulated through social interactions.

INTRODUCTION

Although fascinated for centuries by the prospect of 'talking with animals', humans have only recently begun studying language as a part of the behavioral repertoire of nonhuman animals. Although there are abundant data indicating that many animal species have evolved various forms of both simple and complex communication systems (such as the vocalizations of vervet monkeys), language, as it is defined and promoted by humans, has been a more difficult phenomenon to demonstrate when studying nonhuman animals. Songs of the whales and birds, dances of the honeybee, vocalizations of monkeys, and other such forms of communication all fall short of the requirements of a formal language system in that they lack some or all of the formal components of language as it is defined. For example, the meaning of the dance of the honeybee is disrupted with landmark orientation changes. Also, monkeys give alarm calls to individuals already aware of the danger, and bird songs are predominantly ritualized and do not frequently change to meet new circumstances. However, some experimental attempts to demonstrate that nonhuman animals can learn and use language systems have been successful.

SYNTAX USE AND COMPREHENSION

There are two primary structural components to a language system: its semantics and its syntax. Syntax refers to the rules and guidelines governing how linguistic units (typically words) can be combined and the order in which those units must be used to convey the meaning of the speaker. Syntax is therefore highly tied to productive use of a language. Semantics refers to the word meanings of a language, and is intricately tied to comprehension of a language. Animal language studies have focused on both of these aspects of language.

APES

Numerous experimental investigations of language have been conducted with great apes. In these projects, the focus has shifted across time. Initial attempts were aimed at teaching apes to speak. Later, attempts were made to teach apes the formal syntactic structure of a language. Then, the focus shifted to comprehension of symbol systems. Most recently, apes' acquisition of language has occurred most robustly when infant apes are provided with a linguistic environment in which to mature, and the apes can observe and integrate themselves into this language-rich surrounding. In these attempts, the focus is on the environment and its role in both comprehension and production of language by apes.

It was discovered very early on that apes had a limited ability for producing speech sounds. This handicap would have to be overcome through the use of 'artificial' symbol systems. These systems included sign language, plastic tokens used on magnetic boards, and embossed geometric symbols called lexigrams. The sign language studies were among the first conducted, and they were conducted in four separate research projects. The Gardners worked with the chimpanzee Washoe, Terrace worked with the chimpanzee Nim, Patterson worked with the gorilla Koko, and Miles worked with the orangutan Chantek. In these projects, the apes were taught to make signs, and they

were exposed to human caretakers' use of sign as well. Although initial reports indicated that the apes quickly learned to use and respond to others' use of the signs, doubt was cast on the projects by Terrace himself. Terrace concluded that the apes were simply imitating the sign use of the humans around them, and that there was not an originality or appropriateness (nor any indication of syntax) in the sign language of the apes.

Premack worked with a chimpanzee, Sarah, using plastic tokens that the chimpanzee responded to, based on the 'questions' posed to her. Sarah showed a great affinity for properly answering the questions posed to her using this system, but she rarely used the tokens to communicate her intentions or desires. Her use of the tokens was in response to posed questions only. Thus, although Sarah demonstrated comprehension of the 'linguistic' problems, she did not develop language in the sense of operating in a two-way, give-and-take communicative context.

Rumbaugh worked with the chimpanzee Lana through use of a computerized system. The lexigram keyboard responded to the requests made by Lana, provided those requests were in the proper grammatical order. Lana learned to string together lexigrams into stock sentences that produced desired outcomes. On her own, she learned to finish sentences correctly when those sentences were started by others.

Despite these novel approaches to studying language acquisition in apes, concerns and criticisms remained that, although the apes were learning what was expected of them, they did not have a true language. Rather, claims were made that apes such as Lana learned only to chain sequences of lexigrams appropriately without understanding the meanings of the symbols that were used. To address these concerns, future projects centered on the issues of intentional communication, reference, and semantics, and syntax became of secondary concern. Receptive competence became the important capacity to demonstrate.

Savage-Rumbaugh made several important findings when she began work with two chimpanzees, Sherman and Austin. These chimpanzees were taught not only to use lexigrams (which were no longer linked solely to a computer system but were used in the everyday interactions between humans and apes) but also to comprehend each other's (and human caretakers') use of those symbols. Sherman and Austin displayed a sense of symbolic thought through the novelty of their lexigram use as well as the use of other symbols (such as labels to containers and food items). The two chimpanzees made statements about their future actions, they requested items from each other, and they responded to each other's requests appropriately. Both chimpanzees also learned not only to categorize real-world items into functional categories, but also to categorize the lexigrams for those items as well. Lexigrams were categorized as either foods or tools on the very first trial in the same manner in which the real-world objects represented by those lexigrams were categorized. In other words, the lexigrams had meanings for these apes, and the lexigrams functioned as symbols for these apes.

Fortuitously, the next finding in ape-language research occurred as a result of the failure of an adult female bonobo (*Pan paniscus*, a species closely related to the chimpanzee) to replicate the findings with Sherman and Austin. After repeatedly trying to teach this bonobo to use the lexigram symbols, the attempts were interrupted so that she could be bred with another bonobo. During this time, it was discovered that her son, who had never been instructed in the use of lexigrams but who had constantly been in the area while his mother was instructed, had acquired not only comprehension of some of the symbols, but also comprehension of spoken English. This bonobo, Kanzi, responded appropriately to novel spoken requests of humans as well as to their lexigram use. This finding, of spontaneous language acquisition that occurs when young apes are raised in a language-rich environment in which there is structure in the use of lexigrams and spoken English, has since been replicated with two additional bonobos and a chimpanzee. Additionally, research with bonobos has demonstrated a much greater complexity in both language comprehension and production than had previously been demonstrated in any other study of nonhuman animals. The bonobo Kanzi responded appropriately to sentences in which word order was of vital importance in correct interpretation of the speaker's meaning. Additionally, Kanzi and other bonobos raised in a similar language-enriched environment displayed comprehension of far more spoken English than lexigrams; this comprehension is the result of their living in a linguistically rich environment in which information is available, provided that the apes can glean it from both the context of an interaction and the words spoken by humans in that context.

These findings provided clear evidence that both comprehension (of spoken English and lexigrams) and productive use (of lexigrams) was a part of the cognitive competence of these animals when raised in a structured, language-rich environment in

which language learning was latent (i.e. not taught through discrete trials training). This environment is much like that in which human children are raised, and it is almost certainly this environmental context which provides the necessary stimulation for language to develop in humans and apes.

In ape-language studies, those focused on sign language have been primarily concerned with the extent to which apes could learn the meanings of different signs (the semantic aspects of sign language). Washoe, Nim, and Chantek learned the names of numerous items as well as actions and locations. The work of Premack and Rumbaugh, however, was more focused on the grammatical requirements of language. Lana learned not only to construct grammatically correct sequences of lexigrams that followed the grammar of her language (called 'Yerkish'), but she also finished sentences started by experimenters by retaining the necessary grammar needed for the sentence to be correct. However, if the provided sentence fragment was already grammatically incorrect (as produced by the experimenter), Lana would erase it and start from scratch with a correct sequence. Thus, the emphasis was on Lana's productive language skills.

As the emphasis shifted to the productive and receptive skills demonstrated with lexigrams by the chimpanzees Sherman and Austin, elements of receptive language were more evident. However, a focus on the syntactic understanding of these chimpanzees was absent. In contrast, it became clear with later research that at least one bonobo, Kanzi, responded appropriately to spoken requests dependent not just on the words within that request, but also on the order in which the words were produced. Kanzi, therefore, could respond appropriately to sentences such as 'Pour the Coke in the lemonade' and 'Pour the lemonade in the Coke'. Additionally, Kanzi responded appropriately to sentences with embedded phrases. For example, when presented with the sentence 'Kanzi, get the ball that is outdoors', Kanzi would walk past another ball indoors to retrieve the ball that was outdoors. Kanzi demonstrated syntactic understanding of word-order rules for spoken English, and he responded appropriately based on the referential and relational aspects of spoken sentences.

DOLPHINS

Dolphins also made good candidates for language acquisition research because of their complex use of vocal communication (in the form of whistles) as well as their large brain size. Research with dolphins by Herman has focused on comprehension rather than production. In one experimental paradigm, the dolphin Akeakamai (Ake) was taught to respond to gestural signals produced by humans using their arms and hands (another paradigm used by Herman involved an acoustic language with acoustic signals). Each signal representing an object, an action or a modifier (such as 'left' or 'right') could be combined with other signals so that the dolphin's comprehension could be measured through its response. Initially, the question was whether the dolphins could respond appropriately to requests either asking for an action to be done to a single object or asking that the dolphin perform an action with two objects. Later, semantic categories could be combined according to syntactic rules in such a way that three-, four-, and five-word relational sequences could be directed to the dolphin. The dolphins organized their responses in such a way as to take into account both the syntactical aspect of the sentence and the meanings of all symbols within that sentence. For example, syntactic understanding was demonstrated through correct responding to sentences containing the same words but different word order (such as LEFT HOOP PIPE FETCH, which asked the dolphin to take the pipe to the hoop on her left, versus HOOP LEFT PIPE FETCH which asked the dolphin to take the pipe on her left to the hoop). Semantic understanding was demonstrated through selection of the correct items.

In addition to responding to the requests of humans who were present, the dolphins responded appropriately to video displays of this gestural language even when the clarity of the image was degraded, and to anomalous gestural signals in which the semantic rules and syntactic constraints of the language were violated. These abilities indicate that the dolphins have a referential understanding of the signs used in their language. As with apes, dolphins utilize mental representations when responding to language-mediated tasks. Comprehending degraded images without training suggests that the dolphins have a network of semantic and gestural representations in memory. The dolphins recognized degraded images by comparing those images to a set of representational exemplars in memory rather than through simple stimulus generalization. The degree of generalization in responding to even highly degraded gestures indicates that the dolphins represent the gestures in memory.

The research with dolphins, as well as research by Schusterman with sea lions, has focused heavily

on syntactic aspects of language comprehension as well as semantic understanding of word meaning. As noted, the dolphins respond appropriately not only to the meaning of individual gestures and signals, but also to the relation of those gestures and signals to each other within a sentence. Syntactic understanding was shown through responses to semantic contrasts in reversible sentences, to syntactically anomalous sentences, to structurally novel sentences, to sentences with word modification within the sentence (where one word modified the meaning of another), to interrogative and imperative sentence form contrasts, and to sentences that contained variations in the placement of modifiers.

SUMMARY

We have provided a working definition appropriate in defining the aspects of communication that differentiate language from nonlanguage. This definition allows us to investigate language competence in nonhuman animals. Such a definition is needed to establish the comparative and evolutionary bases of fully elaborated human language. Although humans clearly do more with their language capacities (especially in the area of verbal speaking) than do any other animals, comparative language acquisition research is vital to understanding the basic mechanism of language. Animal competencies for certain dimensions of human language clearly reflect comprehension and use of meanings accrued by symbols.

Animal Learning

Introductory article

Armando Machado, University of Minho, Braga, Portugal
Francisco J Silva, University of Redlands, Redlands, California, USA

CONTENTS

The field of animal learning studies the behavioral mechanisms and processes that animals use to adapt to changes in their environment. Its emphasis is on environment–behavior interactions.

INTRODUCTION

Learning refers to a heterogeneous set of processes that evolved in animals to accommodate changes in their environments. These processes can produce relatively permanent changes in behavior and are brought into play by some form of interaction between the animal and its surroundings. For instance, a moving nematode (a tiny roundworm) that stops momentarily or reverses its motion when it experiences a vibration will cease doing so if the vibration occurs repeatedly. Foraging bees perform an intricate dance, the orientation and speed of which change with the direction and distance of the food source from the hive, such that other bees also can locate the food site. Hungry domestic cats mew in the presence of their owner, who will then give them food. In all of these examples, the organism's behavior is showing the effects of particular interactions between itself and its environment. Classifying distinct types of interactions, identifying their elements, quantifying their static and dynamic properties, and describing how their cumulative effects are expressed is the goal of people who study learning. Before classifying interactions between organisms and their environments, it is important to place the process of learning within an evolutionary context – that is, to understand why learning evolved.

EVOLUTION AND LEARNING

It is widely assumed that learning evolved in specific contexts, such as gathering food, eluding predators, capturing prey, attracting mates and avoiding poisons. Despite this variety in contexts, countless experiments indicate that the same principles of learning hold across many different species, tasks and behaviors. How can we reconcile the assumption that learning evolved in specific contexts with the fact that it occurs similarly in many contexts? The answer is, by conceiving of learning processes as mixtures in varying proportions of both context-specific and general mechanisms. For example, taste aversion learning occurs when animals avoid gustatory and olfactory cues associated with foods that made them ill, even when the flavor is separated from the illness by many hours. That animals can learn which cues predict biologically significant events is commonplace; that animals can learn to avoid cues separated by many hours from a biologically significant event typically happens only when flavor is the predictive cue and illness is the significant event.

To clarify further the relationship between context-specific and general features of learning, consider the following analogy. A house built for living near the Arctic Circle will differ considerably from one built for living in south Florida: the former requires thick insulation, double-paned windows and a furnace; the latter needs mildew-resistant insulation, shaded glass and air conditioning. Despite these differences, there are general features common to both houses, such as the presence of windows, doors, rooms, walls and a roof, and a general function for both houses, such as sheltering and protecting its inhabitants from weather and predators. Because the function of a house is similar in both regions, there is some commonality to the solutions.

The presence of general features in learning is illustrated by the fact that animals from widely separated taxa respond to environmental stimuli in similar ways. For example, they ignore repetitive harmless stimuli, a process called habituation; they

detect correlations among biologically important events, a process called Pavlovian conditioning; and they learn causal relations between their behavior and its consequences, a process called operant conditioning.

Central to these processes is temporal integration, for only by tracking and integrating events across time can animals determine whether an event is repeating, whether it occurs before, during or after other events, or whether it is a reliable consequence of responding or not responding. It should come as no surprise, then, that temporal variables are often critical determinants of learning.

HABITUATION: ADAPTING TO REPETITIVE, HARMLESS EVENTS

When a harmless stimulus occurs repeatedly and there are no other events associated with it, there might be an advantage to ignoring the stimulus. For example, imagine a land snail on a small wooden platform that vibrates briefly while the animal moves. Typically, this stimulus (the vibration) elicits a protective response, contracting the antennas. If these vibrations are repeated, say every 30 s, then the contractions decline. Eventually, the vibrations are ignored in the sense that the antennae are not contracted and the snail keeps moving. This waning of a response to repeated presentations of a stimulus is termed habituation.

To interpret habituation we can appeal to the concept of response threshold, which is defined roughly as the minimum stimulus intensity required to elicit a reflexive response. As the stimulus is repeated, the threshold increases, which makes it more difficult to produce a response. Eventually the threshold is greater than the current stimulus intensity and the response fails to occur.

Properties of Habituation

Habituation is present in virtually every animal species, from single-celled animals such as the ciliate *Vorticella* to humans. It has even been observed in individual motor neurons. This widespread phenomenon deserves attention for two related reasons. First, it introduces some of the key variables and functional relations that psychologists have identified in most learning processes. Second, habituation reveals the amazing complexity of even the simplest of learning processes.

Recovery from habituation

In the example above, if the platform ceases to vibrate after habituation has occurred, then with the passage of time since the last vibration, the snail's antennae are increasingly likely to contract when the platform again vibrates. In other words, habituation seems to 'wear off' when the stimulus that produced it is not presented. This recovery of the response corresponds with a return of the threshold to its initial value.

Stimulus intensity

If the vibration of the platform is sufficiently intense, then the snail may withdraw into its shell. This response might also habituate if the strong stimulus is repeated. Typically, however, the courses of habituation and recovery from habituation are slower for strong than for weak stimuli. When the stimulus is more intense, the rise of the threshold takes longer to surpass the stimulus intensity, and the fall of the threshold in the absence of the stimulus takes longer to return to its initial, baseline value.

Time between stimulus presentations

All else being equal, stimuli closer in time produce faster habituation than stimuli farther apart. This finding is consistent with the threshold account of habituation: longer intervals give the threshold more time to decrease, which partly offsets the effect of the stimulus presentations. Interestingly, high rates of stimulation may also lead to faster recovery from habituation. This result, unlike the preceding ones, does not follow from the view that changes in threshold are responsible for habituation, unless the rate at which the threshold returns to its baseline value depends on the rate of stimulation.

Relearning effect

Imagine the following experiment. After we record the course of habituation on day 1, we stop the vibrations and let recovery occur. On day 2 we vibrate the platform again and record the new course of habituation. Typically, the rate of habituation is faster during the second day. The importance of this finding is that the difference in the rates of habituation shows that the animal's internal state on day 2 is different from its state on day 1 despite the similarity in its initial responses. Again, a simple change in the response threshold cannot accommodate this finding.

Stimulus generalization and stimulus specificity

The contraction of the antennas ceases not only in the presence of the original vibration, but also in the presence of similar stimuli (stimulus generalization). However, it is readily elicited by different

stimuli such as a blast of air (stimulus specificity). These properties are two sides of the same coin; generalization focuses on the fact that habituation to one stimulus extends to some of the other stimuli that can also elicit the response; specificity focuses on the fact that habituation to one stimulus does not extend to all stimuli that can elicit the response. Careful empirical work is needed to identify the stimulus properties (e.g. intensity, duration, rate) along which generalization proceeds.

Functions of Habituation

As noted above, habituation has been observed in almost every animal species. Why is it so prevalent – and why do the properties of habituation hold true across many different species, responses and *a fortiori* physiological mechanisms? Probably, habituation occurs because it is sometimes safe and economical to ignore a repetitive stimulus. An animal that continued to respond to every stimulus impinging on its receptors would be overwhelmed by stimulation and incapable of acting appropriately. However, the animal would pay a high price if the effects of habituation were permanent, for what was once a harmless vibration caused by the running of a distant animal might now be caused by an approaching predator. In the same vein, assuming stronger stimuli are potentially more harmful than weaker stimuli, it makes sense that they should be ignored less quickly than weaker stimuli. Classifying incoming stimuli as 'The same!' 'The same!' 'The same!' also seems safer when the stimuli are close in time.

PAVLOVIAN CONDITIONING: LEARNING ABOUT CORRELATIONS

Food and water, predators and prey, mates and offspring, and escape routes and shelter, are some of the primary determiners of survival and reproduction. As such, it is reasonable to attribute great evolutionary advantage to animals capable of anticipating them. For all animals, specific sounds, sights or odor trails, places or times of occurrence, or more complex sequences and configurations of stimuli might be reliably correlated with biologically important events. If an animal could learn the correlational texture of its world (i.e. the relationships among events), then it would have the advantage of responding one way when a stimulus predicts an important event and in another way when a stimulus does not.

The correlations that an animal can learn depend on the animal and the types of stimuli and events in its environment. In terms of the animal, there might be reliable cues that it cannot detect simply because it has not evolved the required biological machinery (e.g. sensory receptors). In terms of the environment, a stimulus might be detectable but its frequency of occurrence or its reliability as a cue might be too low to support the evolution of an ability to fully exploit it; the cost would outweigh the benefit, as it were. Learning about the cueing function of a stimulus is therefore constrained both by the animal's physiology and the specific arrangements of events in the animal's world.

Constraints notwithstanding, how does an animal learn the correlation between a neutral and a biologically important stimulus? The pioneering work on this question was conducted by Ivan Petrovich Pavlov (1849–1936), the famous Russian physiologist and 1904 Nobel prizewinner. In good scientific fashion, Pavlov reduced the problem to its bare essentials: a tone reliably preceded a bit of meat powder delivered to the mouth of a hungry dog. Of interest was the animal's behavior during the tone. Initially, when the tone was presented the dog pricked up its ears and looked in the direction of the source of the tone, but, critically, it did not salivate. After a few pairings of the tone and food, the orienting response elicited by the tone ceased (habituation had set in) and a new response during the tone began to occur – salivation. Because, 'food in the mouth' elicited copious salivation without any previous training, Pavlov called it the unconditional stimulus (US) and 'salivation in the presence of food' the unconditional response (UR). As the quantity and quality of salivation to the tone depended on the prior predictive history of the tone, Pavlov called the salivation to the tone a conditional response (CR) and the tone a conditional stimulus (CS). The study of how behavior changes when two or more stimuli are paired, as in the preceding example, is known as Pavlovian or classical conditioning.

With this and similar laboratory preparations, Pavlov and many subsequent researchers have tried to understand how animals learn the cueing function of stimuli. Some of their experiments showed the following results, many of which resemble those obtained in studies of habituation.

Extinction

If, after the tone elicits salivation reliably, it is presented without the food, then the dog will eventually stop salivating during the tone. That is, when the CS no longer predicts the US, the CR weakens and may eventually disappear. Through acquisition

and extinction processes, animals adjust to changes in the pattern of events in their environment.

Spontaneous Recovery

If the experimenter allows the dog to rest for, say, 24 h after the extinction training, and then presents the tone again, the animal that had stopped salivating to the tone may again salivate to it; that is, the CR spontaneously recovers. The passage of time undoes some of the effects of extinction. Why spontaneous recovery of the CR happens is still poorly understood.

Stimulus Generalization

Having learned to salivate to a specific tone, the dog also will salivate to similar tones. That is, a CR will be elicited by the original stimulus as well as similar stimuli; however, the more different these other stimuli are from the original CS, the weaker the CR they elicit. Because no stimulus ever recurs in precisely the same way (e.g. the rustling of the leaves announcing a lion is different in different situations), it is advantageous to extend newly acquired responses to similar stimuli.

Stimulus Discrimination

When Pavlov alternated two tones during training and paired one but not the other with food, his dogs eventually salivated only to the tone paired with food. That is, if one stimulus (CS+) is paired with a US, but another stimulus (CS−) is not, then the CR will occur only or mainly in the presence of the CS+. Stimulus discrimination helps ensure that a response occurs in particular environments, rather than indiscriminately across situations and time.

Contingency Effects

Assume that during the original training the food only follows the tone on 50 percent of the trials. On the remaining 50 percent the tone occurs alone. Under this circumstance, the amount of salivation to the tone during training is smaller than when the food always followed the tone. Similarly, if food also occurs occasionally in the absence of the tone, the CR is weaker than when food only follows the tone. In the extreme, if food occurs more often in the absence of the tone than in its presence, the tone will actively suppress salivation instead of eliciting it. In summary, the results of many experiments show that animals are sensitive to the direction (positive or negative) and the strength of the correlation, or contingency, between the CS and the US.

The effect of contingency shows that temporal contiguity between the tone and food is insufficient to ensure that the tone will become a CS. Much depends on what else the animal has been experiencing, both during the presence and the absence of the tone. That is, the animal seems to integrate events that are temporally extended, and to behave according to the actual correlation value between the tone and the food. Both temporal and probability relations between the CS and US, or contiguity and contingency, are important in Pavlovian conditioning.

In fact, the process is even more complex than stated above. Consider an experiment in which a tone is paired with food until it elicits salivation reliably. Next, the tone is presented along with a light, and this compound stimulus is followed with food. Will the light elicit salivation when it is presented alone and without the food? Because food always occurs after the light and never in its absence, the light is maximally (and positively) correlated with food. Moreover, because the food closely follows the light, the two stimuli also are temporally contiguous. Hence, one might predict a strong association between the light and food and, therefore, salivation to the light. However, routinely little or no salivation to the light is found. Control experiments indicate that because the tone already predicted the food at the end of the first part of the experiment, it somehow blocked the association 'light–food'. We could say that the light provided no new information about the food beyond that already provided by the tone and, hence, the light did not help the animal anticipate the US any better than the tone. The important point is that such blocking highlights the fact that an animal's prior experiences can modulate the effects of contiguity and contingency.

Relevance of Pavlovian Conditioning

Since Pavlov's pioneering work, the study of Pavlovian conditioning has revealed many other complex relations among the CR and temporal variables, the sequential arrangements of the various stimuli, the context in which conditioning occurs, and the animal species and the particular response system under consideration. Pavlovian conditioning is fundamental to understanding drug addictions, phobias and a variety of sexual responses in humans and other animals. Its domain of study also has become increasingly quantitative. Real-time, dynamic models of the learning process

have started to replace verbal accounts. However, much remains unknown about the process through which stimuli that are insignificant when considered in isolation become significant when they signal biologically important events.

OPERANT CONDITIONING: LEARNING ABOUT CAUSATION AND CONTROL

The preceding discussion focused on how an animal's behavior is changed by repeated presentations of single stimuli (habituation) or by relationships among stimuli (Pavlovian conditioning). In both of these situations, behavior changes as a result of the stimuli that precede it. However, it is also the case that things happen after a response. For example, a young male cowbird sings one of its song variants and elicits a subtle wing flick from a female. An adult male cowbird sings a variant that stimulates a precopulatory display in a female and a vigorous attack from a dominant male. However, if the same adult cowbird sings a less stimulating song, then it avoids being chased by the dominant male. Operant or instrumental learning results when an animal's behavior causes a stimulus change, which in turn changes the animal's subsequent behavior: the young cowbird is more likely to sing the variant that caused the positive female reaction; the adult cowbird is less likely to sing the song that caused the attack and more likely to sing the one that avoided it. This capacity to change behavior because of its consequences enables animals to learn about control and to exploit the causal texture of their social and physical worlds.

In the examples above, the operant response produced different types of consequences. Psychologists classify these consequences by means of their effect on behavior. Consequences of an action that increase the likelihood of that action recurring are termed 'reinforcers' – positive reinforcers if the consequence is the occurrence of a stimulus (e.g. the wing flick display from the female), and negative reinforcers if the consequence is the cessation or avoidance of a stimulus (e.g. the threat and attack avoided by the adult cowbird when it sang the less stimulating song). Consequences of an action that decrease the probability of that action recurring are 'punishers' (e.g. the attack suffered by the low-ranking cowbird when it sang its most stimulating song). By modifying its behavior to produce reinforcers and eliminate or avoid punishers, an animal shapes its world while its behavior is shaped by its world. This closed feedback system is the hallmark of operant conditioning.

The laboratory study of operant conditioning began with the work of Edward L. Thorndike (1874–1949), who showed that cats placed in a puzzle box (a wooden cage with a door that could be operated by the animal) become quicker at escaping with repeated successes. Later, B. F. Skinner (1904–1990) studied how behavior is shaped by its consequences, and how new response forms emerge when variations in behavior have different consequences. To conduct his experiments, Skinner invented the operant chamber, a box with a lever that hungry rats could press to receive food dispensed into a tray. The operant chamber soon became the microscope of learning psychologists.

What sort of consequences function as reinforcers or punishers? An agreed-upon theory that predicts which stimuli reinforce or punish behavior, the circumstances in which they do so, and why they do so, has eluded experimental psychologists. However, researchers have identified several factors that influence the behavioral effects of reinforcers and punishers.

Contiguity and Contingency

As in Pavlovian conditioning, contiguity and contingency are important. Other things being equal, long intervals between a response and a consequence weaken the strengthening effect of the latter; the more immediately a consequence follows a response, the more likely it is that the response will be affected by the consequence. However, short intervals may have weak effects if the correlation between the response and the consequence is low. This can occur in two ways – when a response is followed by the consequence too infrequently, or when a reinforcer occurs independently of the response that normally produces it. An adult, subordinate cowbird might continue to sing its most stimulating song if that song rarely produces aggression from other males; a young cowbird might spend less time singing if the positive female display occurred in the absence of the song.

Extinction

The behavioral changes brought about with operant conditioning are reversible. When the environment changes and a response that used to be followed by a positive outcome is no longer followed by it, the probability of that response occurring declines. That is, the animal ceases emitting behavior that is no longer functional. However, extinction may be rapid or slow. On some occasions, the animal quickly changes its behavior,

whereas on other occasions it perseveres for long periods of time. Whether extinction is rapid or slow depends largely on whether every instance of a particular response was reinforced (rapid) or only occasionally reinforced (slow).

Schedules of Reinforcement

In the natural environment, it is rare that every instance of a particular response is followed by a consequence. To understand the effects of intermittent reinforcement psychologists have studied different rules specifying when a response will produce a consequence. Two examples of these rules, collectively known as schedules of reinforcement, are ratio and interval schedules. In ratio schedules the reinforcer depends solely on the occurrence of behavior (e.g. a rat receives food each time it completes five lever presses); in interval schedules the reinforcer depends on the occurrence of behavior and the passage of time (e.g. a rat receives food following the first lever press after 15 s since the previous occurrence of food). Because there are no restrictions to when the rat can press the lever, the experimenter can study how the rate of a response changes across time as a function of how it produces a consequence.

Typically, ratio schedules support higher rates of responding than comparable interval schedules. Why? Because the two types of schedule induce different feedback functions, that is, different relations between response rate and reinforcement rate. As an illustration, consider a ratio schedule in which five responses produce one reinforcer. In this schedule, how often reinforcers occur depends exclusively on how rapidly the animal responds; reinforcement rate will always equal one-fifth of the response rate. In contrast, consider an interval schedule in which a response is reinforced if it occurs at least 15 s since the previous reinforcer. In this schedule, a response rate of four responses per minute matches the reinforcement rate. Slower response rates produce proportional changes in reinforcer rates, but faster response rates do not. That is, reinforcement rate ceases to vary with response rate. Differences in the feedback function explain why ratio schedules typically produce higher rates of responding than interval schedules.

Choice

Just as simple processes combine to produce complex phenomena such as weather, geological formations and evolution, so too do basic processes of learning combine to produce more complex behavior. Choice among options is an example that illustrates how reinforcement rates interact to affect behavior.

In the simplest situation, an animal faces two response keys, each of which delivers a reinforcer according to a schedule of reinforcement. For example, a pigeon might peck one key and receive a morsel of food with probability p, or peck another key and receive food with probability q. Another example might consist of a rat that presses one lever that delivers reinforcers with rate r, or another lever that delivers them with rate s. Studies such as these with pigeons, rats, rhesus monkeys and humans, among other species, have yielded a robust empirical finding known as the matching law. The law states that the proportion of choices on one alternative equals the proportion of reinforcers obtained from that alternative. In symbols:

$$x/(x+y) = R_x/(R_x + R_y) \quad (1)$$

where x and y are the total numbers of choices of each alternative, and R_x and R_y are the corresponding total numbers of obtained reinforcers.

Much less understood is how basic behavioral processes combine to yield the matching law. Some researchers propose that the equality is the outcome of the cumulative strengthening effect of individual reinforcers on the two response alternatives. Others suggest that the law results from the animal's sensitivity to global rates of reinforcement and its ability to maximize these rates under constraint. Still others suggest that matching derives from the tracking of the intervals between successive reinforcers on the two alternatives. In these three hypotheses we see, once again, the difficulty of determining the timescale of the learning process. Equally poorly understood is the acquisition of preference and how it relates to the various parameters of the choice situations (e.g. how the values of p and q, or r and s, in the examples above, determine how fast the animal comes to prefer the best alternative).

Stimulus Control

Because no response occurs in a vacuum, a response–consequence relation is always context-specific. In the laboratory, if a pigeon is reinforced for pecking a green key but not a red one, then the bird will restrict its pecking to the green key. This differential responding occurs because the two stimuli are correlated with different response–consequence relations: but, as with habituation and Pavlovian conditioning, the extent that stimuli different from the ones used in training control

operant behavior depends on a variety of factors. For example, the amount of pecking in the presence of stimuli similar to the green key (e.g. a blue key) and stimuli similar to the red key (e.g. an orange key) depends on how much training the pigeon received with the original stimuli. More extensive stimulus discrimination training promotes discrimination, whereas less training promotes stimulus generalization. Also, reinforcing behavior differentially in the presence of different stimuli produces sharper discriminations (less generalization) than reinforcing a response in the presence of a single stimulus.

Moreover, when two or more stimulus elements signal that a response is likely to be reinforced, some form of stimulus competition may ensue. Consider the following experiment: a pigeon is trained to peck a green key with a black horizontal line, but not to peck a red key with a vertical line. The degree of stimulus discrimination and generalization is then tested by recording the amount of pecking at a white key during presentations of the line in various degrees of orientation. During the test, the pigeon pecked all line orientations similarly (i.e. stimulus generalization). However, when tested with keys of different colours but without the line, the pigeon pecked most at the green key and least at the red one (i.e. stimulus discrimination). This example shows that, for reasons that are poorly understood, some features of a stimulus may overshadow others. For the bird in this example, color overshadowed line orientation; but the reverse could have happened. A similar effect occurs in Pavlovian conditioning.

Timing

Temporal variables play a fundamental role in habituation and in Pavlovian and operant conditioning. Time may also be more directly involved in learning, as when animals learn to act according to the temporal attributes of a stimulus. For example, rats, pigeons, monkeys and other vertebrates can learn to behave in one manner after a 2 s stimulus and in another manner after an 8 s stimulus. When a reinforcer such as food is available periodically, say every 30 s (an example of an interval reinforcement schedule), animals learn to pause immediately after food and then, after about 15 s, respond at an increasingly faster rate until reinforcement. The study of the temporal regulation of behavior is one of the most developed areas in the study of animal learning.

A major empirical finding that has emerged from these studies is the scalar property of temporal discrimination, which states that all temporal judgments are relative. Hence, how a rat behaves at 10 s when reinforcement occurs every 30 s is similar to the way it behaves at 20 s when reinforcement occurs every 60 s. As another example, assume that a rat is trained to press a lever on the left after a 2 s signal and a lever on the right after an 8 s signal. Empirical tests show that the rat will be indifferent (i.e. it is just as likely to press the left as the right lever) when presented with a 4 s signal, because 2 is to 4 as 4 is to 8. However, if the two training stimuli were 4 s and 16 s long, then the rat would be indifferent when presented with an 8 s signal. The scalar property derives its name from the fact that when the intervals of a temporal discrimination change, the animal's performance is scaled (stretched or shrunk) by the same factor. Why the scalar property holds remains a matter of controversy.

Avoidance Learning

Although operant and Pavlovian conditioning seem clearly distinguishable, components of each are often present in the procedures of the other. In this sense, it is perhaps better to conceive of operant and Pavlovian conditioning as analogous to elemental hydrogen and oxygen. These two elements are rare in nature, but their combination in the form of water is common. Similarly, most learned behavior is a mixture in varying proportions of operant and Pavlovian conditioning.

The clearest examples of operant–Pavlovian interaction can be seen in situations where animals have to avoid aversive outcomes. A gopher that sees a hawk overhead will not wait to see what the bird will do; upon sensing the hawk, the gopher will retreat to its burrow. In the laboratory, a dog will jump over a hurdle during a tone if this response prevents the delivery of shock. In these and similar circumstances, the sight of the hawk or the sound of the tone predict an aversive outcome (being attacked or shocked) unless a certain response occurs (retreating to a burrow or jumping a hurdle). The relation between the signal and the aversive event is a Pavlovian CS–US relation; but because responding during the CS allows the animal to avoid the aversive event, this response is negatively reinforced (an operant response–consequence relation).

Relevance of Operant Conditioning

Since Thorndike's and Skinner's early work, the study of operant conditioning has been extended

in many different directions. Neuroscientists, pharmacologists and clinical psychologists, for example, have used the techniques and conceptual tools of operant conditioning to understand the functioning of the nervous system, the behavioral effects of drugs, and the intricacies of behavioral disorders such as depression. Artificial intelligence researchers also have borrowed ideas from the domain of operant conditioning to design systems that learn through the consequences of their actions. The study of operant conditioning also has become more quantitative. As in Pavlovian conditioning, real-time, dynamic models of the operant process have started to replace purely verbal accounts. However, much remains unknown. For example, although it is reasonable to assume that a consequence with survival value (or which is closely associated with a stimulus that has survival value) will have a strong effect on the response that produced it, research has yet to yield a general theory of reinforcement and punishment.

CONCLUSION

The processes reviewed above represent only a fraction of the most basic categories of the taxonomy of learning. Much else has been done, but still more remains to be investigated. Despite a century of research, three central questions of learning theory remain largely unanswered. First, how does an animal's evolutionary history constrain the sorts of things that it can learn? Second, how are processes that occur on different timescales integrated? Third, why are seemingly simple processes so complexly organized? These questions are likely to set the research agenda of learning psychologists for the next decades.

Animal Navigation and Cognitive Maps

Intermediate article

Bruno Poucet, National Centre for Scientific Research, Marseille, France

CONTENTS

Many species have impressive spatial navigation capabilities which seem to rely on the existence of representations, or cognitive maps, of the spatial environment.

INTRODUCTION

One of the most challenging questions for contemporary neuroscience is to understand the mechanisms by which the brain processes, encodes and stores information. In this respect, our understanding of memory has considerably improved in recent decades. Such progress is largely due to the use of animal models which allow us not only to tackle the problem of memory from a comparative perspective, but also to raise empirical issues that cannot be addressed in humans.

Spatial memory is a popular model of memory. One reason is that spatial memory is ubiquitous: almost every action takes place in space and requires some form of spatial memory. Another reason is that it can easily be studied in animals that often have outstanding spatial capabilities. Consider, for instance, the memory capabilities of rats that solve the radial arm maze task (Olton, 1979). In this task, the animal has to gather food at the end of the eight arms of a radial maze (Figure 1). As arms depleted of food are not rebaited, the rat learns to avoid locations that have already been visited. Once the animal is trained, a delay can be inserted between the fourth and fifth choices: the rat is blocked at the central choice point of the apparatus and required to wait for some time before completing the trial. Even with delays lasting up to 30 min, the rat is still able to perform the last four choices without returning to arms visited before the delay. This ability implies that it has stored the memory of the locations of depleted arms and uses this memory to visit the remaining baited arms. The current interpretation of such performance is that the rat's choice is based on a cognitive map; that is, a representation of the food locations relative to the configuration of visual cues within the testing environment.

COGNITIVE MAPS AND PLACE NAVIGATION

Historically, the concept of spatial cognitive maps is important because it suggests that animals do not

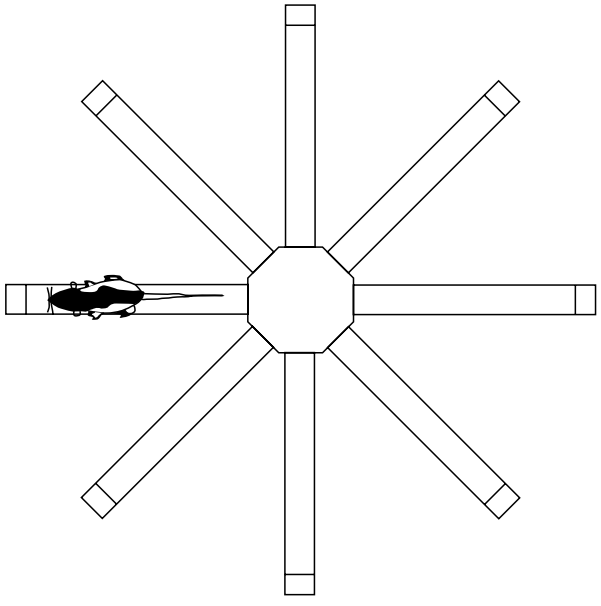

Figure 1. Overhead view of the radial arm maze. Food is located in small containers at the end of each arm and cannot be seen by the rat until it has reached the container. The task for the animal is to visit each arm without returning to an arm previously visited during the trial.

merely base their actions on specific stimulus–response associations (as strongly advocated by the early behaviorist theory in the twentieth century), but also internally reorganize acquired spatial information so as to form cognitive representations of the environment (Tolman, 1948). An important property of such representations is that they allow a reaction to stimuli that are not immediately present, since the relationship of such stimuli to those actually perceived is maintained in a cognitive representation. In other words, animals are aware of the properties of the environment beyond their field of perception. Thus, cognitive maps confer greater flexibility and efficacy to behavior. These properties depart considerably from the rigidity in behavior that results from the gradual acquisition of fixed relationships between stimuli and responses. (*See* **Tolman, Edward C.**)

A prototypical illustration of the behavioral flexibility afforded by cognitive maps is provided by the ability of rats to navigate efficiently in the water maze task (Morris, 1984). In this spatial task, the rat must find a safe platform in a pool filled with water (Figure 2). As the start position is changed from trial to trial and the platform is not visible, the animal cannot apply rigid solutions to the problem. Instead, it must rely on the visual cues located outside the swimming pool so as to infer the platform location. The rat quickly learns to swim directly towards the platform from all starting positions. More importantly, it shows immediate transfer when novel start points are used. Thus, the animal's knowledge of the platform location is independent of its current location.

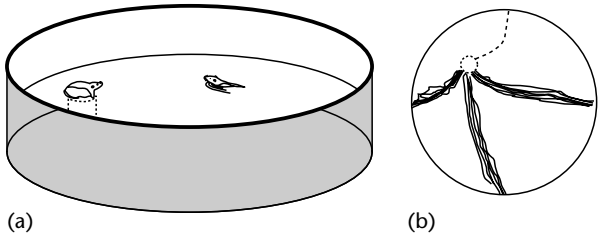

Figure 2. The water maze. (a) The pool is filled with water made opaque by the addition of powdered milk, preventing the rat from seeing the platform which lies under water level. Only distal visuospatial cues can be used to locate the goal platform. After 10 days of training, the rat performs direct trajectories. (b) Superimposed trajectories for the last six trials from the three start points used for training (black lines) and the almost direct path used by the rat when started from a start position never experienced before (dotted line).

ALLOCENTRIC CODING AND PLANNING

The rat's performance in the radial maze and water maze navigation tasks provide nice illustrations of two major functions of spatial cognitive maps. Namely, such maps are useful to memorize the positions of potential goals and to perform place navigation. These capabilities rely on an allocentric coding process, which allows the organism to memorize a location in relation to the spatial layout of surrounding landmarks, independently of its own current position.

The allocentric coding of spatial locations stands in contrast to an 'egocentric' (self-centred) coding process. This process allows an animal to memorize a location in relation to its own position. The goal location is stored in egocentric coordinates as a vector that specifies the distance and head-referred direction of the goal from the animal's current location. The egocentric coding process requires a path integration mechanism which updates the memory of the goal location as the animal moves. Although egocentric coding has the major advantage that the information to be stored is limited to two values (distance and direction of the goal relative to current position), its major drawback is that the computation of these parameters is subject to cumulative error. If the cumulative error is great enough, the animal may miss its target. Although the egocentric coding process is unreliable, its precision can be improved if the path integration information can be recalibrated from visual or other sensory information available from the environment. It is not clear, for rats or humans, if any reliance is placed on path integration except when external sensory information is missing or inadequate.

Place navigation in the water maze cannot be accounted for by an egocentric coding process, because the experimental design precludes the use of route information. So, how can we explain this performance? One possibility is that the rat takes a 'snapshot' of the cue configuration when it is on the goal platform. It could return to the platform by moving in a direction that reduces discrepancies between its current views of environmental landmarks and the views of the same landmarks from the goal. However, analyses of paths suggest that the rat does not behave in this way. The straightness of swimming paths when the rat is started from different locations in the water maze indicates that it is not just continually adjusting its current position in reference to a memorized snapshot taken at the goal; such a solution, which relies on

step by step movements, would result in more erratic movements. Rather, right from the start of its movement, the rat seems to have some knowledge of the distance and direction of its final destination, and sets its course immediately to reach the goal as soon as possible.

This ability to generate a plan requires a stored representation of the spatial relationship between the goal and rat's current position relative to the environment. This representation makes behavior relatively independent from immediately available sensory information, thus allowing adaptive changes in trajectories when the circumstances so require. Rats, cats, dogs as well as many other species are able to take short cuts when a new, less circuitous, path is made available, or to make detours around obstacles in their way to a target. For example, if a previously available path is suddenly blocked, the animal quickly reorganizes its trajectory to select the next most appropriate path leading to the goal. This ability shows that place navigation directed at a specific goal location takes into account the overall connectivity of space. (*See* **Navigation**; **Spatial Cognition, Models of**; **Animal Learning**)

EXPLORATION AND COGNITIVE MAPS

Anyone who watches a rat in a novel environment immediately notices the exploratory responses displayed by the animal. Exploratory behavior is vigorous and is presumably necessary to acquaint the animal with its new environment. As familiarization goes on, exploratory activity decreases, to stabilize at a low asymptotic level. This habituation process suggests that the animal comes to know various aspects of its environment. If the animal is deprived of the opportunity to explore its environment, it is unable to successfully solve spatial problems. Thus, exploration is required for the emergence of place navigation, presumably because cognitive maps are built during this phase through active collection of information about the spatial environment. Eventually, the map comes to match the real environment as closely as possible, therefore providing the animal with spatial invariants which allow it to perform efficient place navigation. Knowing the layout of its current space, the animal is also in a position to detect any changes that might occur. To do so, it performs routine patrolling to check the stability of the environment and to update the contents of the map if a change has been detected.

Thus, exploration may lead either to a new representation or to the updating of a former spatial representation. An illustration of the updating process is provided by studies which show that subtle changes in an otherwise familiar environment induce strong re-exploration. If such changes only involve the spatial arrangement of environmental components, it becomes possible to study the way the animal encoded the initial arrangement.

INFORMATION CONTENT OF SPATIAL COGNITIVE MAPS

Recognizing that animals are able to use representations of their spatial environment does not say much about the nature of such representations. In fact, there is some evidence that these representations might not encompass all aspects of the environment.

Configural Cues and Geometry

Based on the re-exploration technique, it can be demonstrated that changing the spatial configuration of small objects in a previously explored arena induces a renewal of exploratory activity generally aimed at the displaced objects (Thinus-Blanc *et al*., 1987). Further analyses of exploratory responses as a function of the object arrangement show that although the animal keeps a record of the spatial situation, this record is possibly specific to certain classes of spatial relationships. In general, changes that induce the strongest responses are those that affect either the overall geometrical arrangement of the object set, or the topological relationships among the objects. The configuration seems to be privileged over the absolute position of objects.

This conclusion is in agreement with the observation that performance in both the radial maze and the water maze tasks relies on configural cues rather than on individual landmarks. It also agrees with the notion that spatial geometry is an important piece of information contained in the map. In one study, rats were placed in a rectangular chamber and were required to visit the four corners of the chamber. Each corner contained a different amount of food and was associated with a distinctive visual insert. Two opposite corners had the most bait while the remaining two opposite corners had the least bait. After the animals mastered the task (i.e. visited each corner according to a decreasing order from the most baited to the least baited arm), a number of probe tests were conducted based on transformations of the initial distribution of the inserts. These tests revealed that the rats' patterns of visits to the food locations were

remarkably insensitive to the modification brought to the spatial arrangement of the inserts. Rather, the animals were using the rectangular shape of the experimental chamber as a means to locate the various food sources (Gallistel, 1990). Thus, rats ignore obvious landmarks and attend to landscape features instead in reorienting themselves in symmetric environments. Although they are aware of the landmarks, they simply do not appear to use them for certain purposes. The rules governing when landmarks or landscapes are used in behavior remain to be fully explicated. Current thinking suggests that local landmarks are not used to determine directions in space, nor to define a spatial framework within which such directions can be nested. Rather, landscape features are seemingly used for these purposes.

Distal Landmarks

Landscape features cannot be considered to be the sole markers of the spatial arrangement. In fact, distal landmarks provide another major source of information on which spatial navigation can rely. In general, animals will preferentially use such distal information when it is available, to the detriment of local cues. Distal information also predominates when it conflicts with movement-related information such as that provided by path integration mechanisms. While path integration-based homing behavior in hamsters is barely altered by the manipulation of local cues, it can be easily altered by manipulating distal information. To understand why distal cues are so effective in controlling place navigation, it is necessary to realize that only distal cues maintain their reciprocal relationships with respect to the animal during its motion. Thus the perceived reciprocal relationships between distal cues are minimally affected by an animal's movements. In contrast, the perceived reciprocal relationships between local cues are subject to strong changes during movements. Since a cognitive map contains absolute topographical information rather than information about egocentric locations relative to the animal, it becomes evident that distal cues provide a more reliable source of information for localization since they retain relatively stable relationships as the animal moves about the environment.

Path Information

Since the primary function of spatial cognitive maps is to allow efficient navigation in space, a question that arises is whether animals are aware of the structural properties of space, so that their knowledge is based on a representation of possible paths (and therefore not limited to the start and the goal). Studies in cats which had to choose between several paths all leading to the same goal location provide an unambiguous answer to this question. The paths differed in several ways, such as their length or angular deviation (i.e. how much the start of a path deviated from the goal direction). Cats displayed preferences for particular paths primarily on the basis of length (with short paths being preferred over long paths), and secondarily on the basis of their angular deviation (with paths whose starting direction was closer to the goal direction being preferred over less direct paths). Thus, spatial knowledge is not limited to representation of the start and goal, but extends to more indirect relationships provided by the rest of the environment. There appears to be an encoding of properties of the structure of the environment. The validity of the hierarchy of properties depends, however, on the goal location being hidden. If the goal is visible, the animals' choices appear to be constrained by the perceived direction of the goal from the start point. The visible goal seems to act as an anchor, shifting control over behavior from spatially based information to sensory guidance. The animals no longer make optimal choices about path length, but instead tend to take the path that most closely approximates the direction from the start to the goal.

Metrics and Topology

Evidence indicates that rats possess a representation of the geometry of their environment. The representation, however, seems not to be complete, as certain spatial relationships are better handled than others. Also, the representation is not homogeneous: animals process certain locations in a more detailed way during exploration. This is not surprising, because space is not homogeneous. It is more surprising, however, that the topological relationships among such locations (e.g. whether they are in the same vicinity) often have stronger control over spatial behavior than do metric relationships (e.g. their absolute distance in Euclidean space). It is therefore possible that spatial representations can be both topological, therefore affording relatively unstructured information about the connectivity within space (for example, place A is directly connected to place B but not to place C), and metric (for example, place A is a certain distance and direction from place B), affording more detailed information about specific relationships

among places (Poucet, 1993). The advantage of this dual format is that topological information is more rapidly acquired than metric information because metric encoding would largely rely on motion-related signals provided by repeated movements between places. However, direct empirical support for a dissociation between topological and metric encoding of spatial information is still awaited.

NEUROBIOLOGY OF SPATIAL COGNITION

Since rats remember various aspects of their spatial environment, it seems natural to look for the brain processes that underlie this ability. One locus that has received much attention in the recent years is the hippocampal formation, a structure lying below the cortex in mammals. Although other parts of the brain are known to participate in spatial behavior, the role of the hippocampus has been demonstrated on many occasions with lesion experiments. Thus, removal of the hippocampus induces dramatic and permanent deficits in a wide variety of spatial abilities. Rats with such lesions are impaired in the water maze navigation task and have an impaired spatial memory in the radial maze. Their spatial patterns of exploration are also strongly altered following hippocampal damage, and they fail to detect spatial changes in a familiar environment.

Spatial Signals in the Rat Brain

The critical evidence for the spatial function of the hippocampal formation is the existence of cells that carry a spatial signal. Such cells can be classified as 'place cells' and 'head direction cells'. (*See* **Hippocampus**)

Place cells

Place cells were first identified in the hippocampus of rats. With appropriate methods, it is possible to record the firing of a single hippocampal neuron while tracking the position of a rat as it moves freely inside a circular arena. It is then possible to display the spatial firing of the neuron by plotting a map of the number of action potentials fired by the neuron per time unit and in each location in the environment. The activity of many pyramidal cells in the dorsal hippocampus is strongly correlated with the rat's position (O'Keefe, 1976). A given place cell is virtually silent except when the animal is in a region called the firing field (Figure 3). Each place cell has its own specific firing location. Place cell discharge is often independent of the direction faced by the rat and varies only with location.

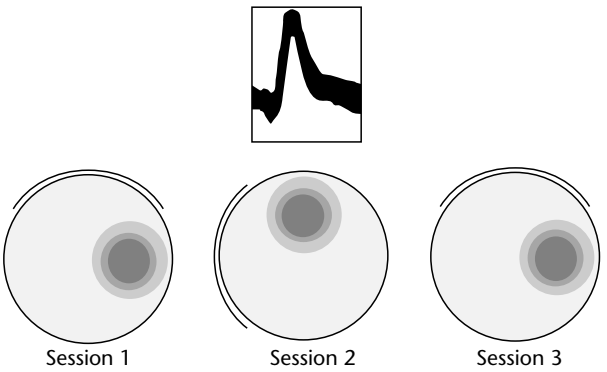

Figure 3. Firing rate maps of a hippocampal place cell during a cue rotation experiment. The cell activity is characterized by the production of action potentials whose waveforms (shown in the inset) are its signature. The cell was recorded for three successive sessions during which the rat freely moved in a cylindrical apparatus one meter in diameter (the outer circle). The firing field of the cell is shown as a set of smaller concentric circles. Darker shading indicates increasing activity of the place cell. The only available visual cue was a white cue card attached to the inner wall of the cylinder (shown as an arc). When the cue card was rotated 90° counterclockwise from the first to the second recording session, the cell firing field also rotated 90°. When the cue card was returned to its original location, the firing field also returned to its initial position. This shows that the cue card has control over the position of the field.

Two properties of place cells are important. First, when rats are placed in new surroundings, place cells become progressively active while the rat is at a given location and, once established, the locations of their firing fields are stationary for weeks and months. Second, place cell firing fields are controlled by environmental visual cues. For example, a rotation of these cues induces a corresponding rotation of firing field. Additional experiments show, however, that this control is more complex than a mere sensory triggering. Thus, if the landmark is removed, place cells usually display firing fields remarkably similar to those observed when the cue is present. This property suggests that these cells encode information about locations in the environment rather than information about sensory views of the environment (Muller, 1996). (*See* **Navigation and Homing, Neural Basis of**; **Place Cells**)

Head direction cells

Head direction cells are primarily found in the postsubiculum. However, cells with similar properties have been found in other brain areas such as the anterior and lateral dorsal nuclei of the thalamus as well as in specific cortical areas. All these

regions have extensive connections with the hippocampus. The firing pattern of head direction cells depends only on the heading of the animal, independently of its location. Each head direction cell has its own specific preferred firing direction. Both head direction cells and place cells share many properties, including being under the control of visual and idiothetic (motor-related) inputs. As for place cells, the activity of head direction cells is maintained when the environmental cues are removed. Their activity is therefore not simply visually triggered. Also, head direction cells do not function independently of each other. Changes in activity of a given cell are accompanied by corresponding changes in activity of other cells, which suggests that they are part of a tightly connected functional neural network. This network includes place cells since their firing fields react in the same manner to environmental manipulations as head direction cells. Thus, the two types of cells have access to the same information, and appear to form a tightly connected functional neural network whose function is to provide the animal with information about both its location and its heading. Their cooperative function is understood to allow the rat to navigate efficiently in the current environment.

Spatial Signals in the Primate Brain

Interestingly, cells that carry somewhat similar spatial signals have been found in the hippocampus of nonhuman primates, suggesting a comparable function in higher species. In addition, evidence based on functional neuroimaging of brain activity during navigation in familiar yet complex virtual-reality environments suggests that the human hippocampus also has a special role in spatial navigation. Activation of the right hippocampus is strongly associated with knowing accurately where places are located and navigating between them (Maguire *et al*., 1998). In addition, specific regions of the hippocampus are found to be enlarged in London taxi drivers, who need to make extensive use of their navigation abilities. This finding bears a direct relation to animal studies and supports the hypothesis that the role of the hippocampal formation in spatial memory should be extended to other mammalian species including humans.

Contribution of the Cerebral Cortex

Clear-cut spatial deficits are found after specific cortical lesions. Rats with parietal cortical lesions are impaired in maze learning, place navigation, spatial working memory and response to spatial novelty, while having no gross visual impairment. However, the magnitude of these deficits is usually smaller than that produced by hippocampal damage. Thus, although the involvement of the parietal cortex in spatial processing is undoubted, its specific contribution is not yet understood. The situation is complicated because other cortical areas are important in spatial processing, as shown by lesion and electrophysiological studies. For example, damage to the posterior cingulate cortex produces a severe spatial deficit in place navigation, even though spatial memory does not seem to be affected. Lesions of the medial frontal cortex result in spatial navigation impairments, although animals are not impaired in their response to spatial novelty. Rather, their deficit is best explained as caused by impaired working memory, which would preclude them from appropriately planning their trajectories. Further work will be necessary, however, to understand how these different cortical areas interact with the hippocampal formation to provide the organism with a spatial representation useful for navigation.

CONCLUSION

Although the navigation capabilities of mammals are impressive, they are not unique since they are found in many other species as well. Consider, for instance, the food-storing birds. During autumn, they can store seeds in hundreds of locations scattered throughout their home range, and yet retrieve them several months after the storing episode. Similarly, the homing ability of pigeons is a well-described behavioral system that allows birds to orient efficiently within huge territories. Even phylogenetically lower species such as bees have outstanding spatial navigation abilities. Do all these organisms rely on a cognitive map to find their way in their environment ? Answering this question would first require that cognitive maps are unambiguously defined. While the literature is replete with the concept, there is still uncertainty about what it means exactly. In fact, while there is little doubt that many species are able to construct internal models of their environment, the spatial extent of such representations is still a questionable issue. For example, are animals able to represent remote portions of space and to use new routes when there is no overlap in the perception of the landmarks available at the origin and goal of the trajectory? So far, this ability seems to be specific to humans. However, uncovering the

premises of such an ability in nonhuman animals is likely to help us understand how our brain creates complex representations of the world.

Antisocial Personality and Psychopathy

Introductory article

Peter R Finn, Indiana University, Bloomington, Indiana, USA

CONTENTS

Antisocial personality is a mental disorder that begins in childhood and continues into adulthood, and involves the persistent violation of the rights of others and social norms in general. Deficits in emotional, motivational, and cognitive processes contribute to the development of the disorder.

INTRODUCTION

Antisocial personality is a personality disorder that affects about 3% of men and 1% of women. Personality disorders are mental disorders that reflect fundamental problems in the early development of personality, resulting in enduring psychological and behavioral problems that begin in childhood or adolescence and continue into adulthood. Antisocial personality is characterized by a range of symptoms that involve difficulties controlling impulses, forming caring interpersonal attachments, learning from experience, and experiencing guilt or remorse. The specific symptoms of antisocial personality disorder include deceitfulness, stealing, destroying property, aggression, impulsivity, engaging in unlawful and other rule-breaking behavior, consistent irresponsibility, and a disregard for others. Conduct disorder is the childhood precursor to adult antisocial personality.

Although antisocial personality is defined as a specific disorder, there are different subtypes, such as primary and secondary psychopathy (or sociopathy). In primary psychopathy antisocial behavior is associated with a deficit in the capacity to experience negative emotions such as fear, anxiety, and guilt, and a superficial and manipulative manner of relating to others. Secondary psychopathy involves high levels of impulsivity and negative affect (guilt and anxiety) combined with a pattern of chronic antisocial behavior. Regardless of the variations in the pattern of symptoms, antisocial individuals demonstrate a failure to inhibit behavior that violates others, transgresses social norms, or increases the risk for generally negative consequences to self or others. Research indicates that emotional, motivational, and cognitive deficits all contribute to the inhibitory problems experienced by those with antisocial personality.

EMOTIONAL PROCESSES

The Role of Emotion in Self-control and Socialization

Because people generally want to avoid experiences that result in fear, anxiety, guilt, or shame, these emotional experiences play an important role in facilitating self-control and socialization. For instance, experiencing anticipatory anxiety when one considers engaging in a specific behavior that might lead to a negative outcome should bolster self-control and lead to an inhibition of that behavior. Also, a common method of socialization involves using the threat of punishment to manipulate fear and anxiety as a means of encouraging or enforcing conformity.

Emotion also has an important role in regulating interpersonal behavior through the experience of sympathy and empathy. The process of experiencing, or sharing, the negative emotion of another contributes to a sense of identification with that person. Since identification involves incorporating aspects of the other into one's own self construct, people are unlikely to do harm to someone with whom they identify because they would be symbolically doing harm to themselves in the process.

Deficits in the ability to experience fear, anticipatory anxiety, or negative emotions in general would compromise the processes that contribute to self-control, socialization, and the regulation of interpersonal behavior.

Emotional Deficits in Psychopathy

A key feature of primary psychopathy is a lack of fear and arousal. Research on the skin conductance response (SCR), a physiological measure of arousal, indicates that people with primary psychopathic disorder have a deficit in the ability to experience anxiety as a response to threatening stimuli. The SCR reflects changes in the level of electrical conductivity of the skin on the palm of the hand resulting from activity of the sweat glands, which are influenced solely by the sympathetic nervous system. In studies where SCRs are classically conditioned to stimuli that signal aversive events, such as electric shock, people with primary psychopathic disorder consistently show smaller SCRs when compared with those with secondary psychopathy and normal volunteers. Research also shows that they have smaller anticipatory SCRs when waiting for a noxious stimulus to be administered (Figure 1).

Another hallmark of primary psychopathy is a deficit in caring, loving, and showing empathy for others. People with this disorder show a peculiar pattern of emotional detachment, in which they can correctly label the emotions of another with words, but do not experience the emotion. Such people show blunted physiological responses to pictures of mutilated accident victims but can correctly describe the pictures as depicting unpleasant scenes.

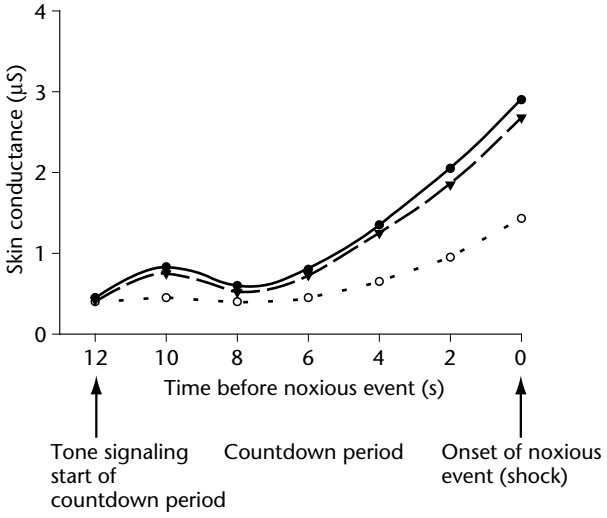

Figure 1. The typical pattern of anticipatory skin conductance while anticipating a noxious stimulus in people with primary psychopathy (open circles), secondary psychopathy (triangles), and normal controls (solid circles).

This same pattern of emotional detachment has been observed in patients who developed psychopathic traits after sustaining damage to the frontal lobes of the cortex of their brain.

IMPULSIVITY

Impulsivity is associated with a wide range of problems, including antisocial personality, substance abuse, suicide, overeating, gambling, and aggressive behavior. Rather than indicating a single trait, impulsivity refers to a range of characteristics that include preferences for immediate versus delayed gratification, acting without thinking, acting quickly, paying more attention to the present than the future, having poor inhibitory control, and being overresponsive to reward. These characteristics promote behavior that often leads to unforeseen negative consequences to self and others, and behavior that disregards the rights, feelings, and safety of others in the service of immediate gratification for self. Both primary and secondary psychopathy are associated with impulsivity, but impulsive behavior is associated with different qualities and probable causes in the two subtypes of antisocial personality. In secondary psychopathy, impulsivity is often associated with negative emotions, cognitive deficits (lack of planning and future orientation), and poor inhibitory control. Impulsive behavior in primary psychopathy is probably due more to a lack of concern about negative outcomes and a greater interest in obtaining immediate gratification of impulses.

Laboratory studies indicate that when given the opportunity to choose between an immediate smaller monetary reward or a larger, but delayed, reward, individuals with antisocial or impulsive traits display a greater preference for the immediate reward and tend to discount the value of future rewards. Other studies indicate that impulsive personality traits and an inability to tolerate delay of gratification are associated with lower levels of brain serotonin, a neurochemical found in areas of the brain associated with emotion and basic motivational functions.

MOTIVATIONAL PROCESSES

Antisocial personality is associated with abnormalities in the motivational processes underlying approach and avoidance behavior. In this broad theoretical perspective, antisocial personality is the result of strong approach tendencies that override the inhibitory influences that affect avoidance

behavior. For example, excessively strong desires for wealth, power, dominance, or sexual gratification (i.e. strong approach motivations) may override the normal inhibitory effects that social sanctions (e.g. arrest, humiliation, rejection) have on attempts to unlawfully gain these rewards. On the other hand, antisocial personality could also result from an insensitivity to punishment that results in weak inhibitory influences. In this scenario, individuals commit antisocial acts because they do not care about – or do not pay attention to – the possibility that their behavior may be punished. Research suggests that both perspectives are true: some with antisocial personality are less sensitive to punishment (weak avoidance), some are more sensitive to reward (strong approach), and still others have deficiencies in processing and attending to information about the potential for reward and punishment.

Response to Reward

The majority of studies of motivational deficits in antisocial personality use go/no go tasks where the person is required to learn when to make a response (go trial) and when to inhibit a response (no go trial). The studies manipulate the rewards and punishments for responses and nonresponses on each type of trial. Typically 'go' responses result in rewards (winning money) and 'no go' responses (failures to inhibit) result in punishment (losing money). In these types of laboratory studies antisocial individuals consistently show deficits in the ability to learn to inhibit their response on no go trials, termed a passive avoidance learning deficit. Figure 2 illustrates the typical pattern of passive avoidance deficits in antisocial personality. Additional research indicates that these passive avoidance learning deficits are only apparent when the antisocial person is trying to obtain a reward, and when the reward stimuli are more salient (i.e. approach behavior is the dominant response). Other research indicates that antisocial individuals are more sensitive to rewards in general. Overall, these studies indicate that when actively seeking out rewards, those with antisocial personality have difficulty inhibiting their behavior to avoid negative consequences. In other words, they are less able to develop an optimum strategy for behavior that maximizes positive outcomes while minimizing negative consequences.

Response to Punishment

Studies that use aversive consequences, such as electric shock as punishments, indicate that people

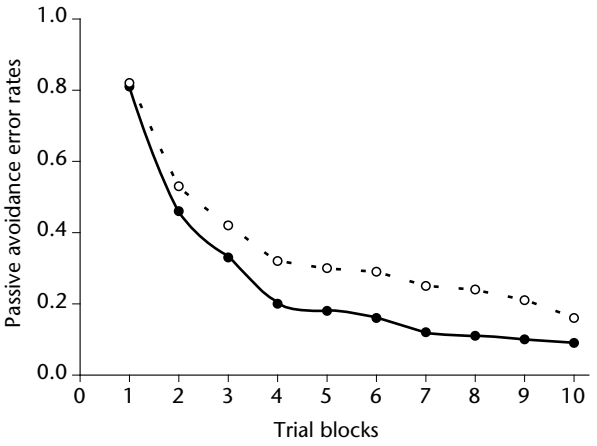

Figure 2. The typical pattern of passive avoidance learning for people with antisocial personality (open circles) and normal participants (solid circles) in a go/no go task where passive avoidance errors (responses on no go trials) result in losing money (e.g. 20 cents) and correct responses on go trials win the same amount of money. The learning curves reflect gradual reductions in the error rates within blocks of four no go trials.

with primary psychopathic disorder are uniquely insensitive to punishment. Although few studies use noxious stimuli as punishments, these studies indicate that such people show substantial deficits in their ability to learn to avoid electric shocks. Rather than being associated with increased response to reward, insensitivity to noxious punishments is associated with a fearless, low harm-avoidant temperament.

COGNITIVE PROCESSES

Cognitive processes such as reflection, planning, and problem-solving have a central role in self-regulation and are important in the motivational deficits and impulsive traits of those with antisocial personality. When abilities to reflect, plan, or solve the problems of strategizing for behavior are deficient, the immediate situation tends to control a person's behavior. In such situations, people tend to act according to their strongest feelings, impulses, and concerns, and fail to consider the effect of their behavior on others or the future. These types of cognitive deficits are associated with the disruptive, socially deviant, and aggressive behavior of many with antisocial personality.

Abnormal, or underdeveloped, frontal cortical lobes are thought to contribute to the cognitive deficits observed in those with antisocial personality. Those with damage to the dorsolateral and orbital areas of the prefrontal portion of the frontal

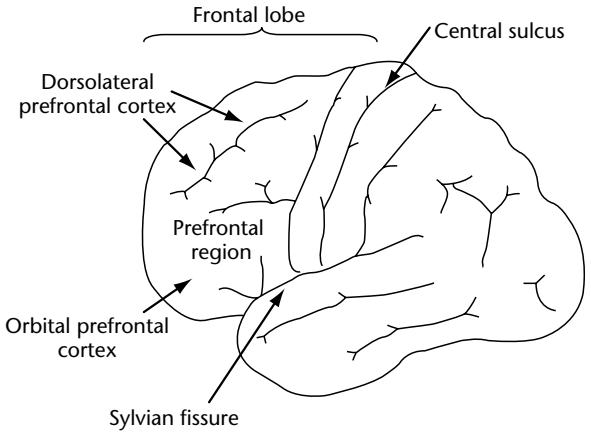

Figure 3. Lateral view of the human brain illustrating the location of specific regions in the frontal lobe of the left hemisphere. The frontal lobe is bounded by the central sulcus and the sylvian fissure.

lobes (Figure 3), display both the antisocial behavior and cognitive deficits observed in antisocial personality. In fact, those with antisocial personality show evidence of cognitive deficits on the neuropsychological tests that were developed to measure the deficits resulting from frontal brain damage. Brain scanning studies also indicate that people with chronic antisocial behavior show evidence of abnormal frontal lobes.

Cognitive Deficits in Antisocial Personality

Deficits in verbal ability and executive cognitive functions are the most commonly reported cognitive abnormalities associated with conduct disorder and antisocial personality. Executive cognitive functions refer to the cognitive abilities involved in the planning and execution of effective goal-oriented behavior. Executive functions include abstract reasoning, planning, associative learning, problem-solving, attentional processes, self-monitoring, set-shifting, and working memory. Deficits in verbal ability and executive functions are associated with a greater severity in antisocial symptoms and poor outcomes in children with a history of antisocial behavior.

Verbal ability

Verbal and language deficits associated with antisocial traits include low levels of fluency (ease of finding words to label experience or concepts), limited vocabulary, poor language expressive skills, problems in understanding and following verbal instructions, reading problems, and poor concept formation.

Executive functions

Antisocial persons perform most poorly on laboratory tests of executive function that tap: (a) the ability to learn arbitrary stimulus–response associations and rules for behavior; (b) the ability to change behavior to adapt to changes in the rules for appropriate behavior (i.e. response set-shifting); and (c) the ability to plan behavior in complex tasks that require the development of strategies for effective performance. In addition, on complex decision-making tasks that tap these executive processes and manipulate rewards and punishments, both antisocial personality and damage to the orbital prefrontal cortex are associated with decisions that favor a larger immediate reward even when it leads to long-term losses. This disadvantageous decision-making style reflects a preference for immediate gratification and a lack of consideration for long-term consequences.

CONCLUSION

Antisocial personality is a disorder associated with a range of symptoms and apparent causes. The factors that contribute to the development of antisocial personality are deficits in the capacity to experience fear and anxiety, preferences for immediate versus long-term rewards, increased sensitivity to reward, deficits in the capacity to inhibit previously rewarded behavior that leads to long-term negative consequences, and cognitive deficits that compromise the ability to reflectively learn and develop effective strategies for goal-directed behavior.

Anxiety Disorders

Introductory article

Patrick A Palmieri, University of Illinois at Urbana-Champaign, Champaign, Illinois, USA
Wendy Heller, University of Illinois at Urbana-Champaign, Champaign, Illinois, USA

CONTENTS

Anxiety is an emotional state generally characterized by fear and worry. When anxiety levels become excessively high owing to a combination of biological, psychological and social influences, one or more anxiety disorders may be diagnosed.

INTRODUCTION

Anxiety is one of the most important topics in abnormal psychology. It is an emotional state that all of us experience at some point in our lives. For some individuals anxiety reaches excessive levels, resulting in significant impairment of functioning in several areas of life – occupational, academic and social. Depending on the specific symptoms shown, such psychopathology would probably be diagnosed as one or more of the anxiety disorders listed in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV). These psychological disorders are described primarily by maladaptive levels of anxiety and associated emotional responses such as fear, panic and worry. Several effective treatment options that alleviate the human suffering due to these conditions are available. These interventions are designed to target the biological, psychological or social aspects of the anxiety disorders. (*See* **Emotion**)

What is Anxiety?

Imagine you are walking across a stage to a podium where you will soon deliver a keynote address to a large audience of respected members of your community. How do you feel? What is going through your mind? In such a situation, most of us would experience one or more of the following: a sense of uneasiness, upset stomach, sweating, trembling, worry about the audience's reaction to your speech, rapid heartbeat, and other similar phenomena. These are all examples of symptoms of anxiety.

Anxiety *per se* is not a bad thing. It is an adaptive response: a low or even moderate level of anxiety would serve to motivate you to prepare for your speech. In evolutionary terms, an appropriate fear response to a threatening situation enhances the likelihood of taking an action that would promote survival. When anxiety levels become excessively high, however, they become maladaptive, often leading to persistent problems in various areas of life. For example, individuals who are deathly afraid of flying (a common phobia) may encounter difficulties in pursuing their career. (*See* **Evolutionary Psychology: Theoretical Foundations**)

Related Constructs

Any discussion of the nature of anxiety must address the related but distinct concepts of fear, panic, worry, obsessions and compulsions. Anxiety can be described in terms of categorical disorders, as defined by the DSM-IV. It can also be described in terms of symptom dimensions such as worry. Worry (anxious apprehension) is a future-oriented emotional response. It involves cognitive activity that is best described as uncontrollable negative thoughts about future potentially threatening events. Obsessions are repetitive, intrusive, anxiety-provoking thoughts. Whereas worry is typically brought on by everyday difficulties, obsessions come more 'out of the blue'. Compulsions are repetitive behaviors engaged in to reduce or avoid anxiety caused by obsessions. Fear (anxious arousal), which involves physiological hyperarousal, is an emotion experienced in the face of immediate danger that serves to prepare the individual to react adaptively to threatening situations. Panic, on the other hand, is essentially a fear response that can happen at an inappropriate time – that is, when no real danger is present. All of these constructs are combined in various ways in the anxiety disorders.

The phenomenon of anxiety is also closely linked to depression. In fact, there is some debate about whether they are distinct constructs, partly because of their high rate of co-occurrence. David Watson and Lee Anna Clark's tripartite model of anxiety and depression posits that negative affect – a general distress dimension – is a component of both anxiety and depression. This general distress may be responsible for the high comorbidity and also may signify a common etiology. Their model also proposes unique aspects of depression (low positive affect) and anxiety (physiological hyperarousal). Jack Nitschke and colleagues have found that negative affect is distinct from anxious arousal and anxious apprehension, both of which, according to their research, were robust factors in their own right. Thus, although depression and anxiety are commonly found together, it appears that each has separable components. (*See* **Depression**)

CLASSES OF ANXIETY DISORDER

History of Anxiety Classification

Sigmund Freud and his followers provided some of the earliest clinical descriptions of anxiety. Because they believed the underlying causes of pathological anxiety were similar, they did not place much value on differentiating types of anxiety. This conceptualization of anxiety persisted through the first two editions of the DSM, in which all forms of anxiety were lumped into one category called 'neuroses'. Over time, however, this method of classification was discontinued, because the psychoanalytic principles on which it was based fell from favor.

The DSM-III marked a major change in the classification of psychopathology. This classification system was based on clinically descriptive symptoms of abnormal psychology, rather than on unproved theories of their etiology. Thus, the category of neuroses was eliminated, and several new categories were formed based on clinical features. Several of these categories were contained under the newly created class of anxiety disorders. Further differentiation of the anxiety disorders is found in the fourth edition of the DSM. Its class of anxiety disorders contains several related but distinguishable psychological disorders.

Specific Phobia

Specific phobia involves a persistent and excessive fear elicited by the presence or anticipation of a particular object or situation. This is the most common anxiety disorder, occurring in approximately 9 percent of the adult population in any given year. Some common phobic objects or situations are spiders, snakes, flying and heights. This diagnosis requires that the individual actively avoid the stimulus, and if avoidance is not possible, that exposure to the object or situation evoke an immediate fear response. Importantly, the fear must be irrational. Fear of truly dangerous situations is adaptive, and therefore not abnormal. The fear and avoidance also must be of sufficient severity to disrupt performance in important areas of the person's life, such as at work or in personal relationships.

Social Phobia

Social phobia involves the fear and avoidance of social situations, such as speaking in public or attending a party. It is similar to specific phobia, but often involves performance (e.g. speaking in front of a group) and the fear of being evaluated negatively, causing embarrassment or humiliation.

Agoraphobia

Another form of phobic anxiety is agoraphobia, a fear of public spaces. Commonly feared situations of the agoraphobic individual are being in a crowded supermarket or theater, or traveling on public transport. The main source of fear is the feeling that one will be unable to escape the situation. People suffering from agoraphobia feel increasingly uncomfortable the farther they are from a safe place, such as home. In its most severe form, the individual might be unable to leave the house.

Panic Disorder

Panic disorder is defined primarily by the presence of recurrent and unexpected panic attacks. A panic attack is an overwhelming experience of fear that develops suddenly 'out of the blue', reaches peak intensity quickly, and is described mostly in terms of physical or somatic symptoms such as rapid heart rate, sweating, dizziness, nausea, trembling, chest pain or discomfort, or chills or hot flashes. Cognitive symptoms also may be present, such as thinking that one is dying or losing one's mind. A misinterpretation of somatic experiences may be largely responsible for panic attacks. For example, a rapid heart rate may be misinterpreted as an impending heart attack (even immediately following aerobic exercise, such as running up

a flight of stairs), and this conclusion can trigger a panic attack. To meet the criteria for panic disorder, panic attacks must be followed by a significant period during which there is worry about the effects of a panic attack or the possibility of future panic attacks, or a change in behavior (e.g. avoidance) designed to prevent future attacks. Often, panic attacks are experienced in settings like those feared in agoraphobia. Because of this, there are two types of panic disorder: with agoraphobia and without agoraphobia.

Obsessive–Compulsive Disorder

Obsessive–compulsive disorder involves the presence of obsessions or compulsions (but usually both) that the individual recognizes as being excessive. The obsessions cause significant levels of distress and anxiety. Two common obsessional themes are contamination (e.g. disease, germs) and loved ones being involved in an automobile accident. Compulsions are repeated behaviors designed to reduce or avoid the anxiety caused by obsessions. One common compulsion is excessive hand-washing; in its most severe form, the individual washes so much that the hands start to bleed. Another common compulsion is excessive checking: for example, an individual might get out of bed dozens of times before falling asleep to check repeatedly that the front door is locked. An individual suffering from this disorder cannot stop engaging in these repetitive behaviors, even though attempts are made to resist them.

Generalized Anxiety Disorder

Generalized anxiety disorder is mainly characterized by excessive worry that is difficult to control and that precipitates impairment in one or more areas of life, such as personal, academic or occupational functioning. The worry must be related to numerous concerns and be present consistently for at least 6 months. In addition, the concerns should not be related solely to events associated with other anxiety disorders, such as having one's performance evaluated negatively, worrying about panic attacks, or fearing embarrassment in a social situation.

Posttraumatic Stress Disorder

Epidemiological studies have shown that most people experience or witness at least one traumatic event in their lifetime. A trauma is a stressful situation involving actual or threatened death or serious injury, or a threat to the physical integrity of self or others; it also must evoke in the individual a sense of intense fear, helplessness, or horror. Examples of such traumatic events are combat experiences, sexual assault and serious motor vehicle accidents. Sometimes such experiences result in a wide variety of physical and psychological symptoms. Posttraumatic stress disorder (PTSD) is diagnosed when those symptoms include, but are not necessarily limited to, reexperiencing or reliving the trauma (flashbacks, nightmares), persistent avoidance of stimuli associated with the trauma (avoiding people, places or activities that evoke memories of the trauma) and increased arousal (difficulty falling or staying asleep, exaggerated startle response). Once the symptoms appear, they must be present for at least 1 month. Interestingly, the symptoms do not always appear immediately after the traumatic experience; instead, onset may be delayed for months or even years. (*See* **Post-traumatic Stress Disorder**)

Acute Stress Disorder

Acute stress disorder is similar to PTSD but with two important differences. First, there is the additional symptom requirement of dissociation during or following the trauma. Dissociative symptoms include such experiences as being unable to recall important aspects of a trauma (dissociative amnesia), feeling detached from or an outside observer of one's own body (depersonalization), perceiving the external world as unreal or dreamlike (derealization), experiencing a reduction in awareness of surroundings, and having a sense of emotional detachment or numbing. Second, symptoms must start within 4 weeks of the traumatic event and must last no longer than 4 weeks. If they persist, then the diagnosis would be converted to PTSD.

ETIOLOGY OF ANXIETY

Anxiety is a complex biopsychosocial phenomenon and thus has no single type of causative factor. In some cases anxiety disorders originate in some stressful life event or series of events that is experienced by the individual as unpredictable or uncontrollable. These events can include social situations that involve fear or perceived physical or emotional threat. The presence of such events interacts with psychological and biological factors to lead to the development and maintenance of anxiety disorders.

Psychological Factors

An abundance of evidence indicates that phobias can develop through classical conditioning, a learning mechanism described by Ivan Pavlov. This is the process in which a previously neutral stimulus, when paired with an unconditioned stimulus (US) that evokes fear (unconditioned response, UR), can acquire the ability (conditioned stimulus, CS) to elicit the fear response (conditioned response, CR) even in the absence of the US. Martin Seligman proposed the idea of preparedness, which states that we are biologically prepared to learn certain CS–US associations very easily, sometimes with only one pairing, because there is evolutionary advantage in doing so. For example, relevant to specific phobias, humans seem hard-wired to develop a conditioned fear response to snakes. (*See* **Conditioning**)

Conditioning also appears to be critical for the development and maintenance of PTSD. Consider the example of a soldier in a fear-evoking combat situation. When stimuli such as loud sounds of machine-gun fire are repeatedly paired with the fear of being in combat, similar loud noises become able to elicit the fear response in noncombat contexts (classical conditioning). This fear is then maintained through operant conditioning, a learning theory introduced by B. F. Skinner, that states that behavior is a function of its consequences (i.e. the frequency of a behavior increases if it is reinforced and decreases if it is punished). Avoidance of fear-evoking situations reduces one's anxiety level. This decrease in anxiety reinforces, or makes more likely, the avoidance behavior, thereby maintaining the post-traumatic stress response. (*See* **Reward, Brain Mechanisms of**)

Information-processing models of anxiety identify cognitive biases as potential etiological and maintenance factors of anxiety disorders. A wealth of research using a variety of cognitive tasks shows that anxious individuals exhibit a selective attention towards threatening stimuli. This attentional bias may result in certain stimuli becoming more salient, thereby affecting the individual's assessment of the level of threat. An increase in perceived threat leads to heightened anxiety which, in turn, can further increase the salience of the stimuli and the anxiety level, in a self-perpetuating cycle. David Clark uses such a cognitive approach to model the etiology of panic disorder. An individual's heart might skip a beat, which might elicit an anxiety response (including the typical physiological symptom of increased heart rate), thereby making the heartbeat more salient, leading to the misinterpretation that a heart attack is imminent. This cycle may continue until it ultimately induces a panic attack. (*See* **Information Processing**; **Selective Attention**)

Genetic Factors

Several twin and family behavioral genetics studies have helped elucidate the role of genes in the development of anxiety disorders. In one such study Russell Noyes found that relatives of patients with panic disorder had higher levels of panic disorder than the general population, suggesting the possibility that a predisposition to this disorder is inherited. Relatives did not have elevated rates of generalized anxiety disorder, however, suggesting that these disorders have some unique etiological factors. A family study of obsessive–compulsive disorder conducted by Donald Black and colleagues suggested that what is inherited is a general predisposition toward developing any anxiety disorder, rather than a specific predisposition for developing OCD. (*See* **Behavior, Genetic Influences on**)

Because family behavioral genetic studies are confounded by shared environment, twin studies are needed to provide converging evidence of the role of genes in anxiety disorders. A large twin study of several anxiety disorders conducted by Kenneth Kendler and colleagues revealed that concordance rates were higher for monozygotic (MZ) or identical twins than for dizygotic (DZ) or fraternal twins but were not exceptionally high, suggesting both moderate genetic and environmental etiological influences. In a separate twin study, William True and colleagues found that concordance rates for experiencing traumatic events and for developing PTSD were higher for MZ than for DZ twins. This genetic effect may be acting through psychological characteristics known to increase risk for trauma and PTSD, such as antisocial personality. In addition to genetic factors, there are other biological factors that may contribute to the etiology of anxiety disorders.

TREATMENT OF ANXIETY

Given the magnitude of anxiety problems as evidenced by epidemiological studies, it is fortunate that several methods of effective treatment exist. These treatments are designed to intervene by affecting the psychological and biological mechanisms responsible for causing and maintaining anxiety. Depending on the nature of the anxiety disorder and possible comorbid conditions, the

optimal treatment might be psychotherapy, pharmacotherapy, or a combination of the two.

Psychotherapy

Behavioral and cognitive-behavioral interventions involving exposure to feared and avoided objects or situations enjoy the strongest empirical support among psychotherapeutic treatments, despite their seemingly counterproductive nature. Joseph Wolpe developed a specific exposure technique called 'systematic desensitization'. In this intervention the first step is to teach relaxation techniques. Then the patient and therapist collaboratively construct a hierarchy of the patient's fears, arranged from least to most anxiety-provoking. Next, the patient imagines the least provoking situation while maintaining the relaxation response. Exposure is repeated or maintained until the imagined situation no longer evokes the fear response. This sequence is repeated with each step up the hierarchy. Empirical evidence indicates that this strategy is very effective in treating phobias, and the treatment gains are maintained after treatment is terminated. In the treatment of obsessive–compulsive disorder, the exposure component is combined with response prevention. Patients are exposed to anxiety-provoking thoughts (their obsessions) and prevented from engaging in the compulsive behavior typically used to reduce their anxiety. This prevention component is necessary for maintaining exposure to the anxiety-provoking situation. (*See* **Imagery**)

Cognitive therapy is another common approach to treating anxiety disorders and is often used in conjunction with the behavioral technique of exposure. The therapist helps the patient identify illogical thoughts (e.g. exaggerated estimates of the likelihood of various negative outcomes of a situation) that may be connected to the anxiety response. For instance, a patient with social phobia might believe the likelihood of a social interaction going poorly is 90 percent. It is possible that this is an overestimate of the actual probability. Having the patient record the outcomes of a number of interactions can be a useful way of gathering evidence to convince the patient that the estimate is exaggerated. Hopefully, the ensuing reduction in the probability estimate will help decrease the fear associated with the situation. Edna Foa and Barbara Olasav Rothbaum have developed an effective cognitive-behavioral treatment for patients with PTSD following rape. It includes, among other things, imaginal exposure to the traumatic event, cognitive restructuring and relaxation training. Another example of an effective cognitive-behavioral intervention is David Barlow's approach to the treatment of panic disorder. In addition to relaxation and exposure it includes a cognitive component to address faulty logic such as jumping to conclusions, overgeneralizing, all-or-none thinking and grossly exaggerating 'worst case' scenarios.

Antianxiety Medications

The benzodiazepines are a commonly prescribed class of medication for alleviating anxiety symptoms. Examples of these tranquilizers are diazepam and alprazolam. They work by binding to receptor sites in the brain for the neurotransmitter γ-aminobutyric acid (GABA) and inhibiting the activity of GABA neurons. They seem to reduce many somatic symptoms of anxiety but are less effective at reducing cognitive symptoms such as worry. There is some empirical evidence for the effectiveness of these drugs for treating social phobia, panic disorder and (ironically) generalized anxiety disorder. On the other hand, they do not seem to provide much relief for individuals suffering from other phobias and obsessive–compulsive disorder. (*See* **Psychoactive Drugs**)

Although there is moderate success for this drug treatment, there are several disadvantages. Common side effects include motor and cognitive impairments. In addition, it is common for gains to be lost once the medication is discontinued. Perhaps most importantly, though, there is a risk of addiction. This risk is highest for individuals who have a history of abusing alcohol and other substances. Unfortunately, such histories are common among people with anxiety disorders, who often self-medicate themselves with these substances to alleviate their anxiety symptoms.

Given the high comorbidity of anxiety and depression it is perhaps not surprising that antidepressant medications show some effectiveness in treating anxiety disorders. This improvement might be due to the alleviation of depressive symptoms, but there also seem to be more direct effects on some anxiety symptoms, which suggests there are some shared etiological factors for depression and anxiety. Traditional (tricyclic) antidepressants such as imipramine and clomipramine can be effective in treating panic disorders and obsessive–compulsive disorder, respectively. However, selective serotonin reuptake inhibitors (SSRIs), a newer class of antidepressants including such drugs as fluoxetine and paroxetine, have shown effectiveness in treating several anxiety disorders and have a more manageable side-effect profile.

ANIMAL MODELS OF ANXIETY

Animal research is an important subset of anxiety research. Such research enables us to investigate questions that are not researchable with humans for ethical reasons. In doing so, much of this work provides a valuable complement to our understanding of the nature of anxiety. (*See* **Neuropsychological Disorders, Animal Models of**)

Controllability and Unpredictability

Early research on experimental neuroses provides a good example of the benefits of animal research. When exposed to inescapable stressful situations or tasks, animals exhibit behavior that resembles anxious behavior in humans. Results of animal experiments show that uncontrollable and unpredictable stressful events reliably elicit animal behavior analogous to intense and persistent fear and physiological arousal in humans. Cognitive theories of anxiety used these findings in stressing the importance of the relation between anxiety and perception of control. Anxiety is less likely to be shown by individuals who feel in control of events than it is by individuals who feel helpless.

Observational Learning, Preparedness and Phobias

Michael Cook and Susan Mineka have conducted animal research on observational learning and preparedness in the development of phobias. Rhesus monkeys raised in their natural habitat are frightened of snakes. Those raised in captivity do not exhibit this fear response when initially exposed to a toy snake. After they observe a monkey, in real life or on videotape, act fearfully in the presence of a snake, however, they do react to the snake with fear. Interestingly, similar results were not found in monkeys observing a model reacting with fear to stimuli not evolutionarily associated with fear. Thus, this animal model of phobic response is consistent with Seligman's idea of preparedness in humans. (*See* **Social Learning in Animals**)

NEURAL BASES OF ANXIETY

Increasing attention is being paid to the neurobiological aspects of the anxiety disorders. Some especially useful research findings deal with particular brain structures, patterns of brain activity associated with anxiety, and the effects of psychological trauma on brain physiology. (*See* **Emotion, Neural Basis of**)

The Amygdala

An abundance of neurobiological research on emotion has focused on the amygdala, a subcortical brain structure involved in processing emotion-related information. Joseph LeDoux and Michael Davis have conducted extensive research on the role of the amygdala within the neural circuitry underlying fear conditioning. This brain structure is thought to be responsible for attaching emotional meaning to incoming sensory stimuli and triggering anxiety responses. Indeed, damage to the amygdala results in a loss of the fear response. (*See* **Amygdala**)

Patterns of Brain Activity Associated with Anxiety

Neuropsychological studies have provided discrepant results regarding the patterns of hemispheric brain activity associated with anxiety. Some suggest there is more right hemisphere activity, others that there is more left hemisphere activity. As it turns out, the studies implicating the left hemisphere tended to include participants characterized primarily by excessive worry, or anxious apprehension. On the other hand, studies implicating the right hemisphere tended to include individuals with more somatic symptoms, or anxious arousal. In a direct test of the patterns of brain activity associated with these proposed subtypes of anxiety, Wendy Heller and colleagues showed that they were distinguishable. These results highlight the need for studies to distinguish between different types of anxiety and depression, since they often occur together, if we hope to identify the precise neurobiological patterns associated with each anxiety disorder. (*See* **Electroencephalography (EEG)**; **Brain Asymmetry**)

Effects of Psychological Trauma on the Brain

The experience of psychological trauma can have profound biological consequences, some of which may be related to the etiology and maintenance of PTSD. Research in this area is growing rapidly with the more widespread availability of technologies for measuring the structure and function of specific brain regions. (*See* **Neuroimaging**; **Neuropsychological Development**; **Neurotransmitters**)

One response to trauma involves an increase in the production of noradrenaline (norepinephrine). It is believed that elevated levels of this neurotransmitter are partly responsible for the emergence of

the hyperarousal symptoms associated with PTSD. In addition, the dysregulation of this neurotransmitter system may elicit a normal stress response that is more intense and more easily triggered. This may be one mechanism by which traumatic events increase the likelihood of future traumatic events leading to full-blown PTSD. There may be a cumulative effect of traumatic experiences.

A complementary response to trauma involves the release of cortisol, a stress hormone that serves as the parasympathetic counterpart to the sympathetic activity of noradrenaline. Whereas noradrenaline serves to mobilize the body's resources in stressful situations, cortisol is released to moderate that response. Cortisol levels are reliably elevated shortly after a stressful event, reflecting the shutting off of the stress response. However, if the trauma is repeated or long-term, such as extended combat or chronic child sexual abuse, cortisol levels are paradoxically low. This may be due to a sensitization of the stress response system, resulting in lower levels of cortisol being needed to shut off the stress response. (*See* **Stress and Cognitive Function, Neuroendocrinology of**)

The hippocampus is a brain structure important for memory. It contains many cortisol receptor sites, and it appears that it may be damaged by elevated levels of cortisol (prior to sensitization) in response to trauma. In fact, some trauma studies show significantly smaller hippocampal volumes in trauma victims with PTSD than in trauma victims without PTSD. This finding is interesting, because one of the symptoms of PTSD is a memory deficit for details of the traumatic event. Owing to the correlational and retrospective nature of these studies, though, it is not yet known whether a small hippocampus is a risk factor for developing PTSD in response to a traumatic experience, or whether the volume reduction is a direct result of experiencing (and possibly reexperiencing) traumatic events. (*See* **Hippocampus**; **Amnesia**; **Hormones, Learning and Memory**; **Memory Distortions and Forgetting**)

CONCLUSION

The anxiety disorders are among the most commonly diagnosed psychological disorders, affecting millions of individuals and their families. Research on humans and nonhumans has provided a great deal of information about the biological, psychological and social factors responsible for the escalationof anxiety from adaptive to maladaptive levels. Several effective psychological and pharmacological treatments have been developed to help ease the human suffering associated with anxiety and its disorders. Further elucidation of the etiology of anxiety will pave the way for even more effective treatments.

CONTENTS

Attention deficit hyperactivity disorder is a childhood syndrome characterized by developmentally inappropriate inattention, impulsivity, and hyperactivity which produces impairment at home and school. Long-term outcome is poor, but treatment with stimulant medication and behavior modification is effective. Investigations of the disorder and its treatments suggest a dopamine deficit exists that may be corrected by stimulant medication.

INTRODUCTION

The combination of inattentive, hyperactive, and impulsive behavior in children has been recognized as a syndrome since the start of the twentieth century, dating back to Still's description in 1902 of children with 'marked inability to concentrate and sustain attention' and impaired 'inhibitory volition'. The term now used as a label for this syndrome, attention deficit hyperactivity disorder (ADHD), is defined in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), published by the American Psychiatric Association. The DSM-IV definition lists 18 behaviors as grounds for diagnosis (Table 1), which fall into two domains: inattention, and hyperactivity/impulsivity. These are behaviors of normal childhood when they occur infrequently or at a low intensity, so they represent symptoms of a psychiatric disorder only when they are developmentally inappropriate, severe, and produce significant impairment in multiple settings. For a diagnosis of ADHD–combined type, both symptom domains must be present and contribute to impairment. Partial syndromes (ADHD–inattentive type or ADHD–hyperactive/impulsive type) are diagnosed if symptoms in only one domain are present, and comorbid conditions (such as anxiety and depression) are diagnosed if they are also present. Based on these criteria, about 3–5% of the population of children in American elementary schools are diagnosed and treated for ADHD.

The identification of a specific cognitive deficit unique to ADHD has been elusive. Some researchers have suggested that deficiencies of children with ADHD are due to their inability to control their behavior, rather than a structural deficit of attention. Others have concluded that there is no attentional deficit in ADHD, but instead that the core deficit is in behavioral inhibition. However, ADHD children do clearly have abnormal performance on several tasks such as the Stroop color-word naming task, the Matching Familar Figures test of comparison of almost identical complex figures, the Tower of Hanoi test of planning and stacking colored rings to match a pattern, and the Trails B test of search for characters on a page in the face of distraction.

Advances in the field of cognitive neuroscience led to new concepts of attention linked to specific brain circuitry. For example, Posner and Raichle's neuroanatomical network theory of attention is based on the concepts of alerting (supressing background neural noise by inhibiting ongoing or

Table 1. Alignment of symptom domains, cognitive processes and neural networks

Symptom domain	*Cognitive process*	*Neural network*
Inattentive – Alerting	Sustained attention	Alerting
difficulty sustaining attention	vigilance level/decrement	cortical: right frontal
fails to finish	persistence	midbrain: locus ceruleus
avoids sustained effort	performance	thalamic:?
Inattentive – Orienting	Selective attention	Orienting
distracted by stimuli	visual cueing	cortical: parietal
does not seem to listen	auditory cueing	thalamic: pulvinar
fails to give close attention	visual search	other:?
Inattentive – Memory	Memory/planning	Executive control
has difficulty organizing tasks	planning	cortical: prefrontal
loses things	memory for objects	striatal: basal ganglia
is forgetful	memory for time	other:?
Impulsivity – Executive control	Cognitive regulation	Executive control
blurts out answers	conflict resolution	cortical: anterior cingulate
interrupts or intrudes	behavioral inhibition	striatal: nucleus accumbens
cannot wait	delay aversion	other:?
Hyperactivity – Fine motor	Motor/vocal control	Fine motor control
fidgets	fine motor control	cortical: left frontal
cannot play quietly	nonverbal control	striatal: cerebellar vermis
talks excessively	verbal	other:?
Hyperactivity – Gross motor	Activation level	Gross motor control
leaves seat	gross motor control	cortical: right frontal
runs about and climbs	novelty seeking	striatal: caudate
always on the go	arousal level	other:?

irrevevant activity or mental effort to establish a state of vigilance), orienting (mobilizing specific neural resources toward a source of sensory stimulation), and executive control (coordinating multiple specialized neural processes by detecting targets, starting and stopping mental operations, and resolving conflict among responses), each with a well-defined neural circuitry (anterior cingulated, prefrontal cortex and basal ganglia). This cognitive neuroscience approach can be used to constrain the definition of attention, and it offers modern terminology for describing its components. The application of three levels of analysis (behavioral, cognitive, and neural) may provide some new insights about the cognitive component of this disorder. Each symptom can be classified based on its relationship to alerting, orienting, and executive control (see Table 1). The nine symptoms of inattention listed in Table 1 logically split into three groups when aligned with the three concepts of attention and the underlying neural networks. The three symptoms of impulsivity are behavioral manifestations of deficits in self-regulation, which align with the executive control network, and the six symptoms of hyperactivity fall into two groups based on deficits in fine motor and gross motor control.

ONSET AND COURSE

The DSM-IV diagnostic criteria specify the onset of symptoms by the age of 7 years, but in most cases the symptoms of ADHD are present much earlier. Impairment tends to increase during the elementary-school years in response to the cognitive and behavioral demands of the classroom setting, and this is when most diagnoses are made. At this age, more boys than girls are recognized and treated for ADHD (reported male to female ratios range from 3:1 to 9:1), but this may be due to referral biases related to disruptive behaviors (aggression, opposition, and defiance) that often coexist in boys. In most cases, ADHD symptoms decline with age, especially for the domain of hyperactivity and impulsivity. When symptoms no longer produce impairment, the diagnostic label changes to ADHD–residual type. In about one-third of the cases, the full criteria are still met in adulthood, and in another third symptoms are present but at a subthreshold level.

The subjective nature of the assessment process raises legitimate questions about the validity of the diagnosis of ADHD, but evidence for validity has accumulated from follow-up studies showing that a childhood diagnosis of ADHD is associated with

extremely poor outcome in many areas, including juvenile delinquency. Children identified by the ADHD diagnosis have a serious disorder that demands recognition and deserves treatment.

TREATMENT

Since the 1930s ADHD has been treated with stimulant drugs. The first of these was amphetamine, but over the years this has been superseded by methylphenidate. Immediate-release formulations of these drugs are short-acting and must be given two or three times a day. Newer sustained-release formulations based on 'osmotic pump' and 'coated bead' delivery systems have been developed that have long duration of action and avoid the mid-day dose at school (which is often associated with embarrassment). The stimulant medications are effective in reducing the symptoms of ADHD (about 80% of children with this diagnosis show clinically meaningful benefits) and are safe (despite some common side effects such as decreased appetite and sleep). With the immediate-release formulations, the therapeutic effects emerge within 1–2 h after each oral dose, but then dissipate within 3–6 h. The sustained-release formulations have a duration of action of 8–12 h. These stimulant medications exert a profound cognitive effect, characterized by focused attention to tasks (even those with low intrinsic interest) and maintenance of attention over time (even in the face of repetitive or boring tasks). The behavioral effects are also profound: inappropriately high levels of activity and inattention in the classroom setting are reduced and compliance with typical requests and rules is increased dramatically. Stimulants do not produce a paradoxical response in ADHD children: normal children and adults respond in the same way on most measures (e.g. by decreasing normal levels of activity and increasing normal levels of attention). It is important to note that in individuals who do not have ADHD there is no impairment in these areas, so the response to stimulants does not alleviate impairment, which is the hallmark of clinical response.

In addition to pharmacotherapy, contingency management programs have been developed based on the general principles of behavior modification (reinforcement, punishment, extinction, and stimulus control). Typically, these interventions use token systems in the home and at school to prompt and shape appropriate target behavior (e.g. getting started, staying on task, interacting appropriately with others, completing work, and shifting activities on schedule) and to extinguish inappropriate behaviors (e.g. getting out of seat, talking without permission).

The most recent information on treatment comes from the Multimodality Treatment of ADHD (MTA) study, a large, six-site randomized clinical trial designed to evaluate the long-term effects of pharmacological and psychosocial interventions. Over 500 children with ADHD aged 7–9 years were recruited from a variety of sources and randomly assigned to a treatment group for a period of 14 months. In this study methylphenidate administered three times a day was more effective than psychosocial treatment (intensive behavioral intervention at home and school), and combinations of these two therapies were little better than medication alone. The success rates defined by a reduction of symptoms to a subthreshold level reflected this also: psychosocial 34%, pharmacological 56%, and combination 68%. This study provides empirical evidence of the long-term effectiveness of these two most common treatments for ADHD.

ETIOLOGY

The most prominent current theory about the cause of ADHD implicates dysfunction of brain dopamine (DA), a neurotransmitter involved in the regulation of motoric, attentional and motivational circuits. One variant of this theory suggests that ADHD is the result of a DA deficit at the neural level, which results in inattentiveness and distractibility at the cognitive level. This theory is supported by the mechanism of action of methylphenidate, which blocks DA transporters, the primary mechanism for removing DA from the synapse. Imaging studies in humans have demonstrated that therapeutic doses of stimulants block more than half of the DA transporters, markedly enhancing DA neurotransmission in the brain. Similar findings have been obtained in animal studies, which have shown that stimulants given at therapeutically relevant dosages increase extracellular DA and activate DA-regulated circuits. In animals, gene 'knockout' studies have suggested that the DA transporter gene (*DAT*) located on chromosome 15 and the DA type 4 receptor gene (*DRD4*) located on chromosome 11 are involved in basic underlying processes of activity and attention that may contribute to ADHD.

What might produce a DA deficit? Acquired and inherited factors have been proposed. One suggestion is that bouts of hypoxia and hypotension during fetal development might selectively damage striatal neurons, which are the main target for DA cells. Inherited factors have also

been implicated by molecular genetic studies of ADHD. Initial investigations focused on two candidate genes involved with DA regulation: the *DAT* and *DRD4* genes. Several research groups have documented association of these two genes with ADHD.

NEURAL CORRELATES OF ADHD

In the early 1990s several teams of investigators used imaging techniques to investigate brain anatomy in groups of children with ADHD compared with children free from this disorder. Abnormalities in size of specific brain regions were observed across multiple studies. Even though groups of children with ADHD were recruited from very different clinical settings by independent research teams, research teams showed a moderate reduction in size (about a 10% decrease compared with a normal group) for measures of frontal lobes and basal ganglia (caudate nucleus and globus pallidus). Functional brain imaging studies have provided converging information implicating basal ganglia and frontal lobe abnormalities in ADHD. Imaging studies based on single photon and positron emission tomography and performed during baseline (resting) conditions documented a reduction in blood flow and metabolism in striatal and frontal brain regions. Studies using [^{18}F]-labeled dopa as a marker of DA synthesis in brain showed significant reductions in prefrontal cortex in people with ADHD when compared with normal controls. Functional magnetic resonance imaging has shown hypoactivity of frontal circuits during activation by cognitive tasks, including blunted activation in the anterior cingulate gyrus, a brain region with a central role in executive attention that has been linked to the behavioral symptoms of inattention and impulsivity in ADHD (see Table 1).

CONCLUSION

The phenomenology of ADHD has been refined over the years, and clinical manuals now agree on the specific symptoms of this disorder. At a cognitive level, abnormalities in neuropsychological performance suggest that children with ADHD are inefficient in information processing, resulting in slow and inaccurate performance. Advances in brain imaging and molecular biology have started to reveal functional and biochemical brain abnormalities associated with ADHD, localized predominantly in dopamine pathways and frontal and striatal circuits modulated by DA. Since these circuits regulate attention, executive function, motivation, response inhibition and motor activity, research on ADHD has focused on how their dysfunction could result in the cognitive deficits and behavioral symptoms of this disorder.

Attention, Models of

Introductory article

Rajesh PN Rao, University of Washington, Seattle, Washington, USA

CONTENTS

Attention is the ability of an organism to select and process only the relevant or 'interesting' parts of its sensory inputs, while discarding other potentially irrelevant parts. Models of attention seek to explain the mechanisms and neuronal substrates underlying this evolutionarily important sensory ability.

INTRODUCTION

Animals are confronted with a vast amount of sensory information in their day-to-day interactions with the natural world. Only a fraction of this information can be processed at any given moment in time owing to the brain's limited processing resources. Fortunately, only a fraction of the total information received is typically relevant to any particular task at hand and to the animal's continued survival. Thus, the fundamental problem faced by an animal's perceptual system is to select and process only the relevant or 'interesting' parts of its sensory inputs, discarding the other potentially irrelevant parts. Attention is nature's solution to this problem. (*See* **Attention**; **Selective Attention**)

Traditionally, attention is defined as the phenomenon by which animals preferentially process parts of their input, shifting their focus of processing from one part of their input to another in a serial fashion. The metaphor that is frequently used, especially in psychology, is that of a spotlight that can be moved to different parts of a scene independent of eye movements. Any information lying outside the spotlight is filtered out. This form of attention is generally referred to as 'covert' attention, to distinguish it from the 'overt' attentional shifts due to eye movements. (*See* **Eye Movements**)

Although the spotlight metaphor is not a computational model of attention, it has proved useful in characterizing various properties of attention. For example, events occurring within a pre-cued 'spotlight' region in the visual field can be detected faster and more accurately than events occurring outside the spotlight region. The spotlight metaphor has also been used to distinguish between two forms of visual search: parallel search, corresponding to a search for an object that differs from neighboring objects by a single feature (e.g. an X among O's), and serial search, where the target differs from neighboring objects by a conjunction of features (e.g. a green X among red X's and green O's). It has been suggested that serial search requires sequential analysis of the scene by an attentional spotlight that 'binds' different features of an object together, while parallel search is the result of 'pop-out' of the target item due to differences in a single feature. Although considerable psychophysical data exist, for instance, on the speed and size of the hypothetical attentional spotlight, neurobiological evidence for such a spotlight has remained inconclusive. The notion of a spotlight has, however, been influential in the formulation of several computational models of attention, some of which are discussed below.

GATING MODELS OF ATTENTION

One of the early quantitative models of attention inspired by the spotlight metaphor is the attention gating model, which characterizes how information is processed within the attentional spotlight. It was originally formulated to explain results from rapid serial visual presentation experiments. In these experiments, participants would fixate on a location on a screen and focus attention on a stream of letters displayed rapidly and sequentially to the left of the fixation point. Upon detection of a specified target letter, the participant shifted attention as quickly as possible to a stream of numerals being displayed to the right of the fixation point, and reported (for example) the four earliest occurring numerals after the target. This paradigm is based

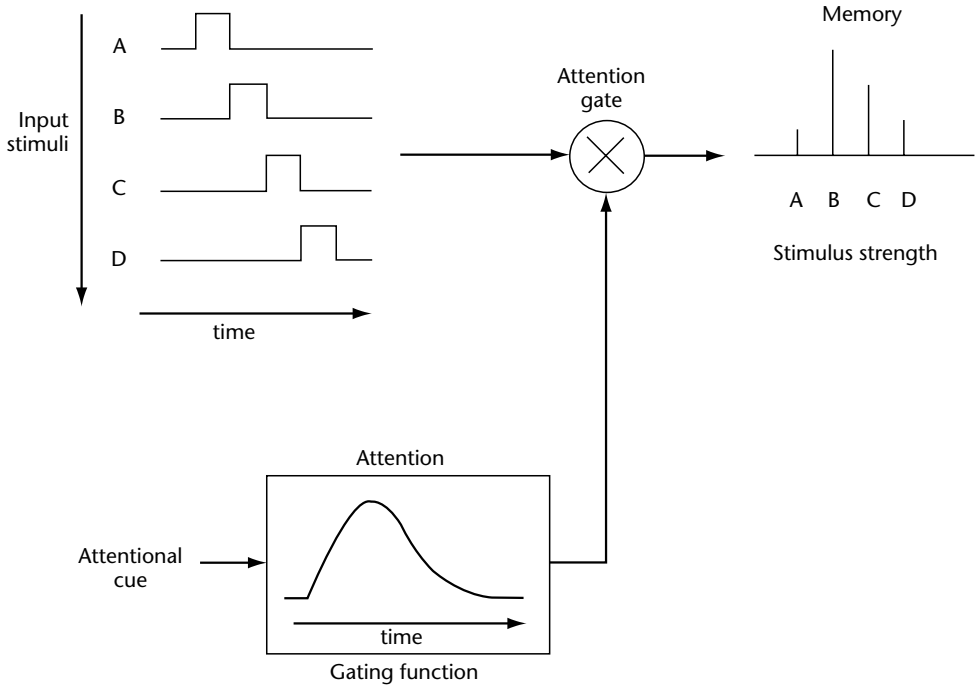

Figure 1. Attention gating model. When an attentional cue is detected, the attention gate is activated with a time course given by the attention gating function (shown within the box). The input stimuli A, B, C and D pass through the attention gate with a strength given by the product of the stimulus with the current value of the gating function. Each input stimulus is stored in memory according to its strength (indicated by the vertical bars on the right). Stimuli from memory are recalled and output as responses in decreasing order of strength.

on the view that the spotlight of attention is first focused on the stream of letters, allowing the target to be detected, and then is moved to the stream of numerals, where the spotlight allows the next four numerals to be registered in short-term memory. Thus, attention acts as a 'gate' into short-term memory, regulating the flow of sensory information into conscious awareness. (*See* **Working Memory, Computational Models of**; **Neural Basis of Memory: Systems Level**; **Working Memory, Neural Basis of**; **Memory Models**; **Working Memory**)

The attention gating model is depicted in Figure 1. In this model, when the attentional cue (for example, the target letter) is detected, the attention 'gate' is opened and the items from the to-be-attended stream of inputs is admitted into memory. To avoid overflow of memory capacity, the gate is automatically closed a short time after opening. This prevents other stimulus items from entering memory. The strength of an item stored in memory depends on the gating function G and the time at which the item occurred with respect to gate opening. The interaction is multiplicative: a stimulus S passes through the attention gate with output strength $G \times S$. The items stored in memory are then reported in decreasing order of strength. The gating function G can be estimated experimentally based on the performance of the subjects and has been shown to be a function with exponential rise and decay (Figure 1).

The attention gating model has been quite successful in quantitatively modeling psychophysical results. However, it is a purely phenomenological model (compare with the description below of Crick's model). For example, the gating model does not address how a spatial region is selected for attentional processing and how information within this region is processed before reaching short-term memory and awareness. These issues have been addressed using saliency maps and dynamic routing circuits respectively.

SALIENCY MAPS

A saliency map is a topographic representation of an input sensory field: each location in a saliency map contains a value that represents how different or salient that location is, compared with other locations in the sensory field. A 'winner takes all' mechanism is then used to select the current most salient location (peak) in the map. Attention is

directed to the selected location by a gating mechanism that allows the stimuli near the selected location to be conveyed to higher processing centers and suppresses stimuli at other locations.

The saliency of a location may be computed based on 'bottom up' and/or 'top down' information. In 'bottom up' calculations the saliency of a location may be defined in terms of the difference between the stimulus at that location and the stimuli in neighboring locations. For example, the presence of an X in a field of O's would cause the location containing the X to attain a higher saliency value than locations containing O's, owing to the large difference in features between the X and the surrounding O's. Thus, 'bottom up' saliency maps provide a computational mechanism for implementing the 'pop-out' inherent in the types of visual search characterized as parallel search. Certain forms of serial search may also be modeled using 'bottom up' saliency maps where saliency is computed based on conjunctions of stimulus features (such as 'red/green' and 'X/O'). In this case, attention is directed sequentially to successively smaller peaks in the saliency map and previously visited locations are suppressed for a short duration, a process known as 'inhibition of return'.

'Top down' saliency maps are based on the differences between sensory stimuli at different locations and a stored prototype target object. The more similar the stimulus at a particular location is to the target object, the higher the saliency value of that location. Such saliency maps provide a mechanism for implementing object-based serial search, where attention is directed sequentially to different objects in a visual scene in the order of their similarity to the prototype target object. This type of search is frequently performed by our visual system, for example when we are looking for a familiar face in a crowd, or for a pen on a cluttered desk. Figure 2 demonstrates how 'top down' saliency maps could be used to perform an object-based serial search during a visual counting task.

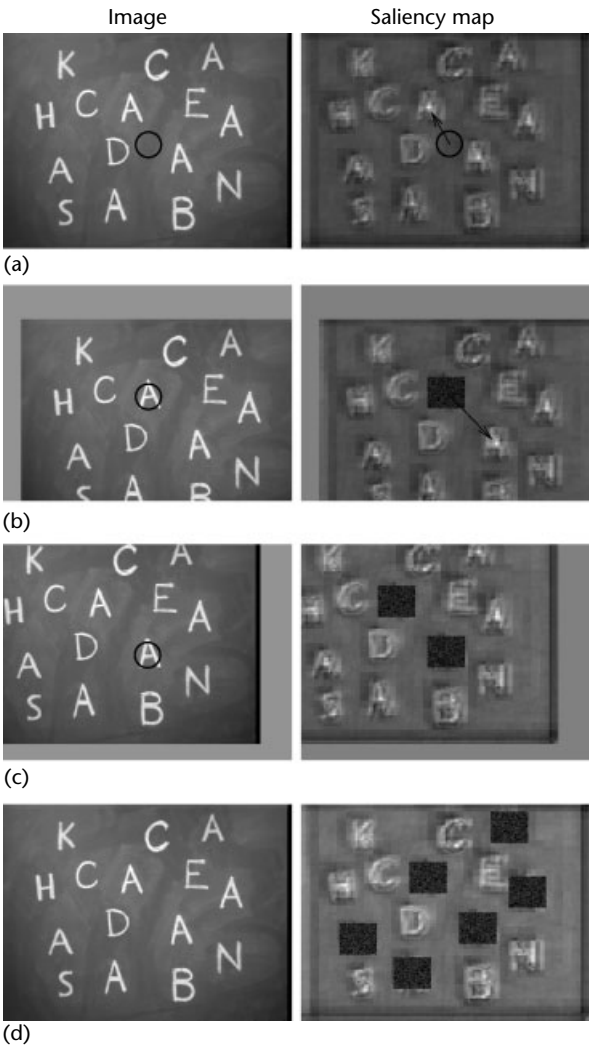

Figure 2. Saliency maps. The use of 'top down' saliency maps in a visual counting task. The goal is to count the number of occurrences of the letter A on a blackboard containing a collection of letters. The image of the board is shown on the left and the corresponding saliency map on the right. Each letter is represented by the vector of outputs of a set of oriented spatial filters modeled after the receptive fields of visual cortical neurons. The brightness at each location in the saliency map indicates the degree of closeness (saliency) of the letter at that location to the letter A, as given by the similarity in their filter-based representations. The brightest spot, indicated by the arrow, is chosen to be the next location to be attended (a). The circle indicates the original focus of attention. (b, c) The result of shifting attention to two different locations containing the letter A. In both cases, once the letter has been attended to and processed, the location containing the letter is inhibited (dark square) to prevent this location from competing again for the focus of attention during the course of the task. This implements the process of 'inhibition of return' during visual search. (d) The final result of counting all six occurrences of the letter A in the input image. Figure adapted from Rao and Ballard (1997).

SHIFTER CIRCUITS AND DYNAMIC ROUTING

Saliency maps offer a solution to the problem of selecting relevant portions of a sensory field for further processing. They do not, however, solve the problem of routing this information to higher centers in a position- and size-invariant way. Shifter circuits were proposed as a computational model for how the brain may accomplish this within the context of visual information processing. These circuits are so named because they allow

information in one location of the visual field to be 'shifted' and fed to a different location in a higher processing module. Such a process leads to the formation of higher-level visual representations that remain stable regardless of actual object position and size at the lowest levels.

The primary components of shifter circuits (also called dynamic routing circuits) are the control neurons, which set the size and position of the attentional window. The control neurons modulate the strength of synaptic connections from the lower level to a higher level such that only the information from the attended region in the lower level is routed to the higher level. The control neurons are driven by a saliency map. Only neurons that correspond to highly salient locations are activated, causing information in only these locations to be routed to higher processing centers.

Position and size invariance is achieved by arranging multiple inputs from a lower level to converge onto a single higher-level unit (Figure 3a). This allows units at higher levels to have access to information from increasingly large areas of the input field. By having the control neurons select appropriate subsets of input connections at each level, one can 'focus attention' on any local region in the input field and route the information in this local region to the same set of processing units at the highest level (Figure 3b). This makes the circuit invariant to the actual position of objects in the input field. Similarly, size invariance can obtained by integrating several lower level inputs into a single higher level output, repeating this strategy at each level until the very highest level (Figure 3c). Once again, the control neurons dictate which inputs are integrated.

As mentioned above, saliency maps control attention in routing circuits. Once a saliency map has been computed, a competitive mechanism is used to activate the control units that correspond to the most salient parts of the input. These control units in turn select the appropriate input connections at each level for routing the selected information to the highest level. The exact equations governing the dynamics of the control neurons can be derived from well-known optimization principles. Information received at the highest level can be fed into an associative memory for recognition. In addition, during the recognition process, the output of the associative memory can be used to readjust the position and scale of the attention window to enhance recognition accuracy. Small-scale dynamic routing circuits of up to three levels have been imulated on desktop computers. Promising results have been obtained for simple pattern recognition tasks such as recognizing letters in binary images, but the performance of routing circuits in more realistic tasks involving natural images has not yet been thoroughly investigated. (*See* **Vision: Object Recognition**)

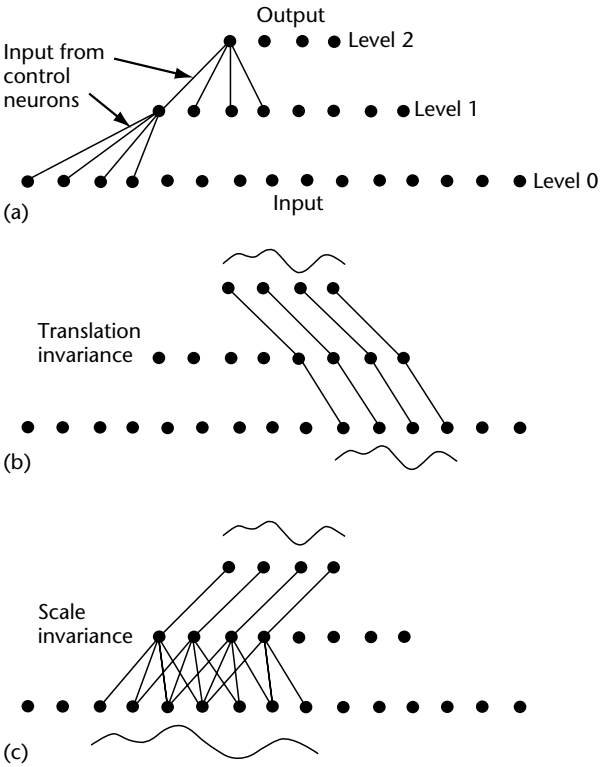

Figure 3. Routing circuits. (a) A dynamic routing circuit with three levels. Each neuron, represented by a black circle, receives inputs from several lower level neurons via dynamically modifiable connections. Only the connections for the leftmost neurons in levels 1 and 2 are shown. The connections for the other neurons are identical except for a rightwards shift. The strength of these connections is determined by the control neurons, which modulate the connections multiplicatively (indicated by the two arrows) and set the position and size of the window of attention. (b) Attention can be focused on a local input region. Information lying within the attended region (depicted as a wavy line) is routed to the output layer by the control neurons. The pattern obtained at the output level is invariant to translations of the pattern at the input level. (c) The window of attention can be enlarged to process large patterns. In this case, the control neurons set the connections for a net convergence from input to output. As a result, the pattern obtained at the output level is invariant to changes in input pattern size.

SPATIAL VERSUS OBJECT-BASED ATTENTION

The models we have considered so far have emphasized how attention may be directed towards

specific spatial locations, and how sensory information from these locations may be routed to higher centers for further processing. Behavioral and single-cell studies have suggested that attention may also select parts of a sensory input based on visual features (such as motion or color) or even whole objects, a phenomenon known as feature-based or object-based attention. (*See* **Visual Attention**; **Selective Attention**)

Evidence for feature- and object-based attention comes from studies showing that participants can reliably track a target object that is superimposed with a distracter object in the same spatial location. For example, if the image of a face is transparently superimposed on the image of a house and the face image is moved back and forth, subjects are able to track the face despite the presence of the image of the house. In addition, brain imaging studies reveal higher neural activity in the face-selective and motion-selective areas of the brain when tracking the face, compared with the case where the house is the target of attention. Other evidence for object-based attention comes from studies involving patients with damage to their right parietal lobe. Many of these patients are unable to attend to the left side of objects, where the definition of an object is dependent on the task at hand. (*See* **Parietal Cortex**)

Computational models of object-based attention are still in their infancy, partly because of the broad range of phenomena that fall into this category. Preliminary attempts at modeling object-based attention have focused on cooperative networks that comprise two complementary subnetworks, one that estimates objects and their features (such as color and shape) and another that estimates object transformations (such as translation, dilation and rotation). In such networks, attention can be focused on a particular object or a particular location by biasing 'top down' signals from higher processing centers or short-term memory. Object-based attention corresponds to keeping the 'top down' signal for the object-estimating network fixed: this causes the transformation network to converge to estimates of the attended object's transformations. Spatial attention corresponds to keeping the 'top down' signal for the transformation network fixed: this causes the object network to converge to the identity of the object in the attended location. The inspiration for such a model comes from neuroanatomical studies showing a rough dichotomy in the mammalian brain between networks specialized for object identification and networks geared towards spatial transformations and action.

NEUROANATOMICAL SUBSTRATE

The spotlight metaphor inspired some of the early attempts at identifying possible neuronal substrates of attention. In 1984, Francis Crick, one of the co-discoverers of the structure of DNA, proposed that the thalamic reticular nucleus (TRN) may have an important role in implementing a spotlight. The thalamus is a nucleus that receives input information from a majority of the senses, including visual, auditory and somatosensory information. This information is conveyed to the neocortex by relay cells in the thalamus. The TRN is a single-layer network of inhibitory neurons strategically located between the thalamus and the cortex. The network receives both ascending inputs from the thalamus as well as descending inputs from the cortex. Its neurons process these inputs and inhibit neighboring neurons as well as corresponding neurons in the thalamus. Thus, the TRN is well suited to regulating the flow of input sensory information from the thalamus to higher cortical centers. In other words, it could implement an attentional spotlight by allowing only selected parts of the sensory inputs to be conveyed to the cortex, inhibiting all other neurons in the thalamus that correspond to other sensory inputs. Despite considerable progress in our knowledge of the TRN and the thalamus, evidence for Crick's spotlight model remains inconclusive. The main stumbling block remains our poor understanding of the feedback loop between the cortex and the thalamus in alert behaving animals, and the role of the TRN in modulating this feedback loop.

Several possibilities exist for biophysically implementing the gating mechanisms that are integral parts of not only the attention gating model, but also other models such as the routing circuit model. The primary requirement here is a mechanism that can inhibit or filter out input channels that are not being attended, allowing only the attended inputs to proceed to the next stage of processing. Presynaptic inhibition (inhibition of an input fiber before it can affect a cell) allows precise gating of inputs to a single neuron, but there is little evidence for its existence in the neocortex. Postsynaptic inhibition (inhibition of a cell after an input has been delivered) can also be used to gate the inputs to a neuron but at coarser level. Various cellular mechanisms have been suggested for this form of gating, most of which are based on particular characteristics of the ionic channels and receptors that are embedded in the membrane of neurons.

The visual cortical areas V1, V2, V4 and inferotemporal cortex (IT) are assumed to be the major

neural substrates of dynamic routing circuits in the visual cortex. These areas are organized in a roughly hierarchical manner, with neurons in each area receiving convergent inputs from up to a thousand neurons in the preceding area. This is consistent with the multiple-level architecture of a routing circuit. The control neurons that direct the flow of information from one level to the next are hypothesized to be located in the pulvinar, a subcortical nucleus of the thalamus. The pulvinar sends and receives connections from each of the areas from V1 to IT, making it a suitable candidate for controlling attentional routing. Neurophysiological and brain imaging studies support the hypothesis that the pulvinar is involved in filtering out unattended stimuli. The competitive interactions between the control neurons are assumed to be mediated by lateral inhibition within the pulvinar and/or through the TRN. Finally, the control neurons in the pulvinar are assumed to be driven by saliency maps, whose neural implementation is discussed below. (*See* **Occipital Cortex**; **Temporal Cortex**)

Several different cortical and subcortical areas have been suggested as possible substrates for implementing saliency maps. The posterior parietal cortex (PP) is one such area. Neurons in PP show either elevated or suppressed activity when attention is directed to a visual target. In addition, damage to PP impairs the ability to disengage attention from a currently attended location. These results are consistent with a saliency map-based interpretation of PP. Another possible neural substrate for a saliency map is the superior colliculus, a subcortical nucleus that plays a major role in targeting eye movements to different parts of a scene. The superior colliculus receives direct input from the retina and can influence activity in higher cortical areas via its connections to the pulvinar. Other possible areas that may encode saliency and/or behavioral relevance of targets include the frontal eye fields and the inferior/lateral divisions of the pulvinar itself. It is currently unclear whether these different areas encode different types of saliency or different types of sensorimotor modalities (such as attentional shifts, or eye or hand movements). (*See* **Parietal Cortex**)

Models that jointly address spatial and object-based attention usually rely on the approximate division of visual processing in the visual cortex into the tasks of 'what' (object identification) and 'where' (motion/spatial reasoning). Object-related processing has traditionally been associated with the so-called 'form' pathway, comprising the hierarchy of areas V1, V2, …, IT in the ventral part of the visual cortex. Spatial reasoning and action-related processing is traditionally ascribed to areas in the dorsal part of the visual cortex, particularly the intraparietal and PP cortex. One model for spatial and object-based attention assumes that the cortical areas in the frontal lobe store task-relevant information and apply either spatial or object-related constraints to the dorsal or ventral networks respectively. A spatial constraint causes the object ('what') networks in the ventral pathway to respond strongly to the objects or features in the input image with that spatial property (such as position or motion). Similarly, an object-based constraint on ventral networks would cause the dorsal networks ('where') to focus upon the spatial properties of the object expressed in the constraint. Such a model, which is based on interactions between dorsal, ventral and frontal areas of the brain, integrates the neuronal and systems-level views of attention. It is, however, hard to validate, given the current difficulty in recording from multiple brain areas simultaneously. (*See* **Temporal Cortex**; **Parietal Cortex**; **Frontal Cortex**)

At the single neuron level, neurophysiological recordings in awake behaving monkeys have provided some important clues to understanding the mechanisms of attention. For example, the response of many neurons in the visual cortical areas V2 and V4 are modulated by attention. In these experiments, a visual stimulus that can activate a recorded neuron is first found and then a second stimulus is placed within the activating region (receptive field) of the neuron. This typically causes the neuron's response to shift significantly from its original response. However, when the monkey is made to focus attention on the original stimulus, the neuron's response becomes almost identical to its original response, as if the attended stimulus appeared all by itself. This provides direct evidence for attention filtering out irrelevant stimuli. A model based on 'biased competition' between two populations of neurons, one representing the attended stimulus and the other representing the distracter stimulus, has been suggested to explain these results. Attention is assumed to increase the strengths of the inputs from the population representing the attended stimulus. Such a model has been shown to account quantitatively for the neurophysiological results. However, the lack of details regarding its neurobiological implementation makes it hard to distinguish this mathematical model from the computationally motivated models discussed above, most of which use biased competition in one form or another to focus attention. (*See* **Attention, Neural Basis of**; **Spatial Attention, Neural Basis of**)

CONCLUSION

Computational models of attention provide useful insights into how the brain selectively processes portions of its inputs based on measures of saliency and task relevance. The process by which parts of a scene are selected and processed without movement of the eyes is often explained by a spotlight metaphor. Saliency maps provide a mechanism for implementing a spotlight by allowing the selection of a single stimulus based on either its 'bottom up' saliency compared with competing stimuli or its 'top down' relevance to the task at hand. Once selected, a stimulus can be routed to higher processing centers and eventually to memory using dynamic routing circuits. These circuits allow information from any portion of the sensory field to be selectively routed from one stage of processing to another in a manner independent of size and position. Once information is routed to memory, attention gating models provide a quantitative characterization of how attended items are transferred to short-term memory. Recent models of attention have stressed global interactions between networks specialized for object identification and spatial reasoning. Such models may provide a unified framework for modeling object-based and spatial attention.

The neural substrates of attention have not yet been completely identified, but the effects of attention on single neurons have been studied in several visual cortical areas, including V2, V4, the frontal eye fields and posterior parietal cortex. The pulvinar nucleus of the thalamus, the thalamic reticular nucleus and the superior colliculus are some of the subcortical nuclei implicated in attentional control. How these different areas interact to produce the emergent phenomenon of attention is currently the subject of both modeling as well as experimental studies.

CONTENTS

Attention is the scientific term primarily used to describe all processes and mechanisms that govern the subjective constraints imposed by the human organism on the flow and interpretation of external and internal information, and on the organization and selection of responses, in the service of goal-directed behavior. In some cases, attention can also be automatically captured by sudden changes in the situation, or by well-trained stimulus–response tendencies.

WHAT IS ATTENTION?

At any single moment in life, humans perceive, attend to, respond to, and make use of only a very small fraction of the information from the outside world that stimulates their sensory systems (vision, audition, touch, motion, balance, etc.), or from the internal information and skills that are stored in their memory and acquired through past experiences. This fraction is described as the focus of their attention. Humans are not passive subjects of their environment. Rather, they actively seek, bias, and attribute significance to outside and inside events. Attention represents this active process. Like any other physical system, humans are limited in the amount and rate at which they can process information and perform tasks. The study of attention is the study of the processes and mechanisms that govern the 'top-down', subjective constraints, that are imposed by the human organism, on the flow and interpretation of information from the outside world, the use of internal information, and the organization and selection of responses in the service of goal-directed behavior. In some cases, it has been shown that attention can be automatically captured by sudden changes in the environment or by well-trained stimulus–response tendencies ('bottom-up' processes). (*See* **Attention, Neural Basis of**; **Visual Attention**)

To illustrate this process, think for example of a person reading a novel in a train, while travelling back home from work. He has to focus attention on the book page and ignore all other visual information, noises of the train, announcements, or passenger conversations. He also has to stabilize the book in his hands and combat interference from train motion, vibration, and acceleration changes. On the book page he needs to focus on one line, ignore all other lines, and progress continuously with reading. Note also that the task of reading calls upon his knowledge of the language, reading ability, and memory of the content of previously read chapters of the book. All are knowledge bases stored in memory. Reading is one of many alternative tasks in which the person can engage himself. He can hum a song, participate in a conversation, or operate a laptop computer. He can also switch from one task to another. Note the difference in the sources of information and responses that have to be attended to or ignored in each of these tasks. Attending to a task is engaging, and limits giving attention to other tasks. The person should be careful to monitor the train route from time to time, so as not to miss his stop.

The above example illustrates many of the phenomena signifying the act of attending. It is also accompanied by distinct subjective experience. Attended information appears vivid and intense, while unattended and ignored information may fade away completely, or appear attenuated and weak.

The study of attention has been a major topic in scientific psychology since its early days. Research has questioned the nature of the underlying processes; the span and limits of attention; the ease and cost of attending to different environmental features and internal events; the ability to control, mobilize, and divide attention; and the linkage

between attention and consciousness. The knowledge and understanding of human attention have greatly benefited from behavioral and neurophysiological studies using animals – in particular, mammals – where direct invasive measurement of brain activity was possible.

ATTENTION AND CONSCIOUSNESS

The relationship between attention and consciousness is of special significance, because early models in psychology equated attention with the content of consciousness. William James, one of the forefathers of scientific psychology, wrote in 1890:

> Every one knows what attention is. It is taking possession by the mind, in a clear and vivid form, of one of what seems several simultaneously possible objects or trains of thoughts. Focalization, concentration of consciousness are of its essence. It implies withdrawing from some things in order to deal effectively with others …

However, we now know that only a very limited portion of the ongoing processing and response activities is admitted to consciousness. Even if triggered by a voluntary, conscious intention, the influences, consequences, and products of this intention on perception, processing, and response, are mostly not admitted to consciousness. The nature of the relationship between conscious and nonconscious products of attention is still a topic of contemporary theoretical debate. It also has an important methodological implication. The study of attention and its influences cannot limit itself to verbal reports of people. Specific research paradigms, employing behavioral and physiological measures, were developed to complement verbal reports and assess the different aspects of attention. Behavioral measures focus on changes in performance speed and accuracy, resulting from a manipulation of attention demands. These measures are complemented by a variety of neurophysiological indices (e.g. heart rate, pupil dilation, brain-evoked potentials), which have been shown to accompany changes in attention requirements. (*See* **Consciousness and Attention**; **Consciousness, Cognitive Theories of**; **Consciousness, Disorders of**)

ASPECTS OF ATTENTION

The study of attention has followed several major task categories: selective attention, divided attention, intensive aspects of attention, and mobilization of attention. They are briefly reviewed below.

Selective Attention

The study of selective attention has addressed two major questions. One is concerned with factors that influence the ease and efficiency of selection. The second examined the consequences of selection for the processing of and response to the selected and the rejected or unattended stimuli. Most of the experiments in selective attention require subjects to perform some kind of a filtering task: that is, subjects are instructed to process, memorize, judge, listen to, or respond only to stimuli that satisfy a specified criterion, for example, 'listen to female and ignore male voices', 'read blue words and ignore red and yellow', 'vocalize and memorize only animal names in a sequence containing animal, plant, and artifact names'. (*See* **Attention, Models of**; **Selective Attention**)

Overall, humans seem to be able to utilize and selectively focus on any group of stimuli that are consistently distinguished by a signifying attribute. Selection is shown to be efficient and easy when the signifying properties are highly distinguishable physical attributes, such as visual location or auditory pitch. In this case there is no long-term memory and little trace of the ignored information. The ease of selection depends on the discriminability of stimuli, with simple physical dimensions easier than semantic dimensions. Indirect behavioral measures indicate that unattended stimuli are also analyzed to a certain level, but in the majority of cases do not reach the level of full semantic analysis.

An interesting aspect of selection is the influence of a preparatory set. Research has shown that when a single stimulus is presented, processing efficiency can derive considerable benefit from advance information on the nature or likelihood of this stimulus. Similarly, performance is impaired when invalid information is presented. These effects are stronger when the number of possible stimuli and their confusability increase. Selective attention is tuned and biased, in anticipation of the forthcoming information.

Divided Attention

In divided attention tasks individuals are asked to attend to or monitor multiple information sources arriving at the same time, or to perform more than one task concurrently. Under such conditions research demonstrated good, parallel, unlimited-capacity monitoring and search capabilities in two major cases. One case is when targets differ from non-targets on a simple, distinct physical feature,

such as color or size. The other case is when targets belong to a very well learned and frequently used symbolic category, and are perceptually easy to distinguish from non-targets (e.g. letters and digits). In all other cases time-sharing and concurrent performance show considerable deficit, compared to single task performance. An interesting phenomenon has been labeled 'attention blink', in which detection of a difficult target impairs performance for a short period thereafter. (*See* **Selective Attention**)

Capacity limitations in dividing attention have been shown to be more severe when targets are defined by complex discriminations (e.g. conjunction of features), rely heavily on working memory (e.g. mental arithmetic), or require coordinated response. The great sensitivity to attention limitations has made divided attention conditions a popular paradigm in the study of mental workload and the cost of mental operations.

Intensive Aspects of Attention

Selection and division of attention do not manifest themselves only in the sources of information and type of events that are attended to or ignored. They also influence the intensity and invested effort in processing and response. This is the intensive dimension of attention. There is ample evidence to show that selection and division do not operate in an all-or-none fashion. Rather, invested effort, which operates like an amplifier or gain factor, influences the response rate and quality of performance on the attended task. Humans can allocate graded levels of effort to the performance of tasks. When fully concentrated on an interesting and demanding task, there is little attention for anything else. When bored by a task, little attention is invested in attending to it; attention is easily distracted, and captured by new events. In divided attention conditions, more than one task is attended to simultaneously, and effort is allocated according to priorities. Think, for example, of the multiple elements comprising the task of driving a car in heavy traffic and the change in the relative importance of each element in different conditions.

Intensity modulations of attention have an autonomous and a voluntary component. The autonomous component is closely linked with the physiological cycles of metabolism, hormones, body temperature, and rest–activity. They jointly influence the arousal, vigilance, and efficiency of the human processing and response system. Research has shown that time of day, and phase in the circadian rhythm, may lead to a change of up to 30 per cent in the efficiency of performance. We are also well aware of the effects of fatigue, exhaustion, jet lag, and sleep deprivation on attention capabilities. The second intensive component is voluntary effort: this represents intensity modulations attributed to the ability of humans to concentrate, focus, and invest graded effort at will. The influence of intensive aspects is of special significance in sustained attention tasks when performers have to attend to a task for extended periods, such as driving for long distances, control room operations, and studying for exams. Such tasks are extremely sensitive to variation in the autonomous component. In addition, it has been shown that the voluntary component can operate at full force for only a limited period, ranging from a few minutes to about half an hour, depending on the demands of the performed task. Tasks performed for extended periods demonstrate an increased number and longer durations of lapses of attention.

Mobilization of Attention versus Modulations of Processing Intensity

An interesting distinction has emerged in the study of attention, between the act of moving attention from one focal point to another, and the act of modulating the intensity of processing once attention has been locked and engaged in a task. Evidence from neurophysiological research on visual attention has shown that these acts are associated with separate brain mechanisms, localized at different brain areas. Corroborating evidence comes from the study of individual differences in attention. It shows that the ability to focus and divide attention, both representing different levels of attention allocation to a task, is distinct from the ability to switch attention between tasks, which represents disengagement, mobilization, and reconfiguration efforts.

THE LIMITS OF ATTENTION

An important topic in the study of attention has been the attempt to identify the limits of attention. How many things can a person do in parallel? How much information can be processed and responded to concurrently? What are the limits on the rate of processing? Theoretical models of attention have advocated two major views of the source of limitations. 'Bottleneck' models associate the limit with the existence of a central, limited-capacity processor that can deal with only one task at a time. This processor constitutes a bottleneck, because a new task cannot access it before processing of the

previous task has been completed. Two variants of this approach have located the bottleneck either early, when only partial or limited analysis of a stimulus has occurred, or late, at the stage of response selection, after stimuli have been fully identified. (*See* **Selective Attention**)

An alternative view of the limitation is proposed by resource models. According to this approach parallel processing is possible, but there is a limited pool of processing and response resources. Resources are allocated to the performance of tasks, performed singly or in parallel, as long as their total demand does not exceed the limit of resources. One variant of this approach is a single general pool of resources which are utilized by all tasks. Another variant advocates a multiple resource view, according to which there are several types of resources which are distinguished by the types of information, processing activities, or response modes that they serve. Performance of tasks is limited only to the extent that jointly performed tasks compete for and exhaust the limits of the same resource.

Proponents of both models conducted extensive experimentation, and brought ample evidence to support their claims. Can both views coexist? A third, and more recent, concept of the limitation of attention proposes to view it as strategic. According to this view there is no mandatory architecture to the flow of task performance, nor a strict universal central limitation and scarcity of processing and response facilities. Rather, given the nature of the task involved, the characteristics of the environment, the specific abilities and skills of an individual, and his motivations and intentions, the best strategic solution to the task's performance is developed. This solution represents the most advantageous combination of all composites at that moment. Once a strategy is developed, it does have its costs and limitations; however, those may change as the conditions are changed, experience accumulates, or utilities vary. The basic idea of the strategic approach is that there are many redundancies in the performance of every task, many degrees of freedom (elasticity) of the human processing system, and a considerable flexibility in using them. Hence, there are many ways in which a single task may be performed, which in turn may change its demand profile. Repeated or very common experiences associated with the performance of some mundane tasks may create the impression of a more 'hard-wired' limitation. However, even this can be changed with extensive training. This view of limitation shifts the focus from the study of the sources of limitation and universal limits, to the study of the degrees of freedom of the human processing system, and the ability of humans to control and efficiently channel their attention capabilities.

ATTENTION AND TRAINING

There is robust evidence to show that experience and practice lead to a dramatic reduction in the attention requirements of tasks. Think, for example, of the differences in the attention requirements of driving, for expert drivers and novice trainees. The difference is attributed to the increased organization of behavior with practice, and the development of well-organized sequences of behavior (schemas) that can operate as one, by a single command. This mode of behavior is labelled 'automatic'. It is contrasted with a 'controlled' mode of operation, which characterizes early stages of responding to new tasks and unexpected events. Controlled processes impose high demands on attention, and in the majority of cases result in less efficient performance.

This relationship between attention demands and training highlights some of the aforementioned functional and phenomenological aspects of attention. First, it underlines the important role of attention during early stages of training, in focusing on relevant information, linking external information with internal knowledge bases, coordinating and synchronizing activities, and developing the overall architecture of a given task. Second, the development of well-organized sequences of processing and response activities that are activated by a single command hints at the possible break between attention and the content of consciousness. It is possible that only the beginning, but not the entirety, of an organized sequence is admitted to consciousness. A related observation is that automated components can capture attention involuntarily and compete with voluntary intents. This finding is easy to interpret, once it is realized that automatic sequences, which are not conscious and only partially controlled, bias the processing and response flow, and attribute significance to events. Finally, training illustrates the way in which attention and performance strategies are linked together, can be developed, and acquire potency. Such strategies may then compete with other tasks, and require considerable effort to change.

The Skill of Attention Control

Intentions and goals are the major drivers of attention. We have seen that humans can focus, divide,

assign priorities, and invest differential efforts in the performance of tasks. However, research has also shown that there are many difficulties and failures in the application and maintenance of attention policies. Can humans be taught to improve the management of their attentional capabilities? The study of this question has shown that there are two major difficulties in the control of attention. One is that people do not have sufficient knowledge of the efficiency of their invested efforts (this is not surprising in view of the limits of consciousness). The second is an execution problem: some attention policies and priority settings are difficult to establish and maintain. Studies that have targeted the development of these components with training have shown that attention control is a skill that can be developed and improved with proper training protocols. Moreover, the skill can be generalized to other situations in which performers face difficult and demanding tasks. Training of attention control was shown to improve the flight performance of trainee pilots, and to help older people to cope with demanding time-sharing tasks.

INDIVIDUAL DIFFERENCES IN ATTENTION

Are there consistent individual differences in attention? Do some people have better attention capabilities than others? The study of these questions showed that there are indeed consistent individual differences in attention, which are generic over and above the specific properties of the tasks that are performed, the modality, and the mode of information and response. Some individuals are better able to deal with high load than others. These studies served for the development of attention ability tests, which were shown to predict performance in flight tasks and the accident-proneness of bus drivers and others. More recent research distinguished between the attention acts of focusing, dividing, and switching between tasks. Consistent individual differences were revealed on all three dimensions. However, focusing and dividing capabilities were shown to be highly correlated, while attention-switching appears to constitute a separate ability. The research has also shown the existence of a general factor of attention control ability, which is common to all acts of attention.

NEUROPHYSIOLOGY OF ATTENTION

Most of our knowledge of the neurophysiology and brain mechanisms of attention in normal-performing humans derives from two classes of measurement techniques. One is the recording from the scalp of the electrical response of large groups of neurons to specific events (event-related brain potentials or ERPs). The second is the measurement of regional cerebral blood flow (positron emission tomography, PET, and functional magnetic resonance imaging, *f*MRI).

Data from ERP and neuroimaging studies together with the behavioral observation of patients with brain damage suggest that several brain areas are involved in attentional processing (Figure 1). The brain systems that have been associated with attention processes can be described as an interconnected network of cortical and subcortical structures which include the prefrontal and posterior parietal lobes, the cingulate gyrus, the basal ganglia, the pulvinar and reticular nuclei of the thalamus, and the midbrain and superior colliculus. These areas have been shown to be sensitive to attention-related manipulations, and control attention through their inputs to perceptual processing areas. ERP studies have also been very useful in identifying the stages of information processing at which attention begins to exert control.

Recent studies have attempted to connect different brain areas to specific aspects of attention. The posterior attentional system, including the parietal cortex, the superior colliculus and the pulvinar, has been shown to be involved in aspects of attention mobilization (directing attention to what has been selected as the focus of attention, engaging and disengaging attention from locations or objects). The two brain hemispheres seem to be involved in different ways in attention control, with the right hemisphere controlling the mobilization of attention to both sides of space and the left hemisphere controlling only the orienting of attention to the right side of space. The anterior attentional system, including the prefrontal cortex and the cingulate gyrus, is responsible for executive control processes. In particular, the prefrontal cortex exerts top-down influence on early sensory processing,

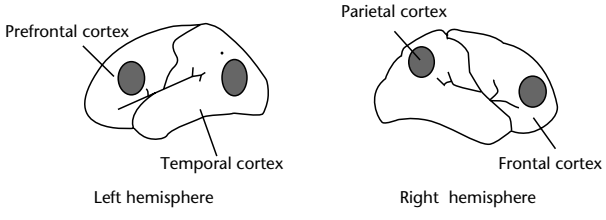

Figure 1. Lateral view of the right and left hemispheres of the human brain. The figure shows the main areas involved in attention control (gray patches).

determining which stimuli entering the perceptual pathway have to be facilitated or suppressed. This area is extensively connected to numerous cortical, limbic, and subcortical areas and seems to play a crucial role not only in attention to external events, but also to the internal mental representations that contribute to working memory, decision-making, and planning. The vigilance system, including the right frontal lobe and the brain stem, is responsible for maintaining readiness during sustained attention and vigilance tasks. (*See* **Attention, Neural Basis of**; **Spatial Attention, Neural Basis of**)

Attention Disorders

As already mentioned, attentional processing seems to involve several brain areas. Research with patients has related deficits in specific aspects of attention to impairment in one or other of these areas. Two major classes of disorder have been documented: impairment in spatial attention, and deficits of attention control. These are briefly described below.

Neglect

Visual neglect is a neurological syndrome that commonly results from lesions of the right cerebral hemisphere, especially from lesions involving the temporoparietal cortex. Although vision is intact, neglect patients are not aware of and fail to report or respond to objects or parts of objects presented controlateral to the lesion (that is, in the left visual field). This disability affects many aspects of their life. For example, patients typically fail to eat the food located on the left side of their plate. They shave or make-up only one half of their face. When asked to copy a picture, they draw only one half of that picture. Patients may no longer recognize the left side of their body as their own. Neglect has been observed in auditory, tactile, and proprioceptive modalities and can also affect mental imagery; for instance, patients may neglect the left side of an imagined mental map. Despite the fact that neglect is considered a disorder of spatial attention, the exact explanation of neglect is still a controversial matter. The combination and severity of symptoms shown by different patients seems to depend mostly on the extent and location of the lesion. (*See* **Consciousness and Attention**; **Attention, Neural Basis of**)

Extinction

This deficit is often associated with unilateral neglect to the extent that some accounts consider it a mild form of neglect. Like neglect, extinction follows unilateral brain damage. Patients suffering from extinction have no difficulty in identifying a single object presented on either side of the visual field, but when two stimuli are presented simultaneously, they do not seem to 'see' the object presented in the visual field controlateral to the lesion.

Balint syndrome

This neurological syndrome is associated with symmetrical lesions to the hemispheres (mostly involving posterior parietal areas or the parietal–occipital junction). It is less common than neglect. It involves three major deficits. First, subjects have difficulties in orienting to visual stimuli or in tracking a moving object. Second, subjects are unable to orient their arm and hand correctly when trying to reach or grasp objects. Third, subjects are able to see only one object at a time (simultagnosia), even when objects overlap. For example, if presented with an apple and a knife and asked to peel the apple, they are unable to follow the instructions because they can see only one of the items. (*See* **Consciousness and Attention**; **Attention, Neural Basis of**)

Frontal lobe syndrome

After lesions of the frontal lobe, patients show disorganized and incoherent behaviour. People suffering from this syndrome, also known as dysexecutive syndrome, are unable to plan actions and to solve problems. They show behavioural rigidity and perseveration, that is they are unable to change their behaviour when required to; increased distractibility accompanied by difficulties in focusing and maintaining concentration; difficulties in inhibiting unwanted behaviours; and difficulty in maintaining goal-directed behaviour. These symptoms seem to be caused by the impairment of areas involved in the top-down control of information processing, such as the prefrontal cortex.

Attention deficit hyperactivity disorder

This disorder appears in childhood; the major features are excessive and impairing levels of activity, inattention, and impulsiveness. The diagnosis is often reached because of the difficulties shown by these children at school. In general, the inattention symptoms include difficulties in remaining seated when required to (for example, at the dinner table or in the classroom); inability to follow instructions; inability to concentrate and focus attention on details; easy distractibility by external stimuli; inability to interrupt an action once initiated; and difficulty in organizing tasks and activity. Some

current accounts of ADHD suggest the possibility that children with ADHD may be impaired in executive control processes. (*See* **Attention Deficit Hyperactivity Disorder**)

Attitudes

Introductory article

George Y Bizer, Eastern Illinois University, Charleston, Illinois, USA
Jamie C Barden, Ohio State University, Columbus, Ohio, USA
Richard E Petty, Ohio State University, Columbus, Ohio, USA

CONTENTS

An attitude is a global and relatively enduring evaluation (e.g. good or bad) of a person, object, or issue. Attitudes can be based on affective, cognitive, or behavioral information and can vary in their strength (e.g. how enduring, how resistant to change, and how predictive of behavior they are).

INTRODUCTION

What drives our behavior? When we choose a candy bar at the grocery store or decide for whom to vote in an election, what determines the choices that we make? Attitudes, the mental representations of what we like and dislike in our world, help to explain these choices.

Attitudes are one of psychology's fundamental concepts because they help to explain people's decisions and actions. An attitude is a global and relatively enduring evaluation of a person, object, or issue – a representation of whether we think the target is generally good or bad, desirable or undesirable. We can hold attitudes towards tangible objects such as ice cream or trees, people such as the President or a sister, ideas such as democracy or wealth, and issues such as the death penalty or tax increases. Simply put, the more favorably we evaluate something, the more positive our attitude towards the object is; the more negatively we evaluate something, the more negative our attitude is.

Attitudes serve various functions. As noted by Daniel Katz and others, some attitudes serve a utilitarian function in that they help us to achieve rewards and avoid punishments (e.g. having the correct evaluation of one's mortgage company can save you money). Other attitudes serve an ego-defensive function in that they foster our own self-images (e.g. holding prejudiced attitudes might make some people feel superior). A number of additional functions have also been identified.

MEASUREMENT

Researchers have developed a wide array of tools to measure attitudes. These techniques can be categorized into two broad groups. *Explicit* measures directly ask people to report their attitudes; in contrast, *implicit* (or indirect) measures are assessments that allow inferences about a person's attitude without having to ask him or her directly. The latter method is commonly used in situations in which people either do not want to or are unable to provide their true evaluations of an object. No measure of attitudes is perfect, however, as assessments can be affected by the measurement context. Seemingly innocent influences like the weather or answers to previous questions can have a considerable impact on people's reported attitudes.

Explicit Measures

Two common explicit measures are the *Likert scale* and the *semantic differential*. The Likert procedure presents respondents with series of evaluative statements along with a series of response options for each. For example, an attitude scale on ice cream might contain the statement 'Ice cream tastes good' and choices of various degrees of agreement from which the respondent can choose ('strongly agree', 'agree', 'neither agree nor disagree', 'disagree', and 'strongly disagree'). Participants report the extent to which they agree or disagree with each statement. Likert scales include a wide variety of evaluative statements regarding the object, and scores from all the statements are combined to create a measure of the attitude.

With the semantic differential technique, developed by Charles Osgood and colleagues, respondents are presented with the name of the attitude object and some evaluative adjectives that might describe that object. Participants then rate how well the adjectives describe the object. For example, a series of items might prompt respondents to report the extent to which they think ice cream is beneficial versus harmful, good versus bad, and pleasant versus unpleasant. These scores are combined to form one global attitude measure.

Implicit Measures

Implicit measures come in various shapes and sizes. They range from monitoring simple behaviors from which evaluation can be inferred (e.g. how close one person chooses to sit next to another) to complex physiological techniques. A good example of an implicit measure is Russell Fazio's priming procedure. To assess racial attitudes with this technique, participants are presented with images of Caucasian or African-American faces to make the concept of one or the other race more accessible. Immediately after being shown a face, participants are asked to judge whether a particular concept (e.g. ice cream) is 'good' or 'bad'. Over many pairings of faces and concept words, the amount of time it takes the participant to report 'good' or 'bad' for each word following a face is measured. The pattern of reaction times is used to infer the person's implicit attitude. Since one negative attitude tends to activate or prime others, if a participant dislikes African Americans, showing an African-American face should make the evaluations of other negatively perceived objects (e.g. 'dirt') faster, but make the evaluations of positively perceived objects (e.g. 'ice cream') slower. Thus, if a person needs more time to report that a good word like 'ice cream' is 'good' after seeing an African-American face and less time to report that a bad word like 'dirt' is 'bad' (compared to seeing a Caucasian face), there is evidence that the person holds a more negative attitude towards African Americans than Caucasians.

TRIPARTITE MODEL OF ATTITUDE STRUCTURE

As global and enduring evaluations, attitudes can be based on up to three separate types of input: affective, cognitive, and behavioral. An attitude can be based on any one or a combination of these three information sources. Attitudes, once formed, also guide affective, cognitive, and behavioral reactions to the object.

The *affective* basis of an attitude is made up of feelings, moods, and emotions that have become associated with the attitude object through past or current experience. It is possible to have multiple affective responses to an object based on the same, or different, experiences with it. Each affective response has an evaluation made up of valence (positive to negative) and magnitude (strong to weak). Researchers often measure the affective basis of the attitude by asking to what extent individuals *feel* good or bad about the object, or the extent to which the attitude object makes them feel 'happy', or 'disgusted', or 'angry'.

The *cognitive* basis is made up of particular attributes that are ascribed to the object. An *attribute* is any characteristic, quality, trait, concept, value, or goal associated with the object. The impact of an attribute is determined by the evaluation of whether the attribute is good or bad, and the perceived likelihood that this attribute applies to the object. Thus, if the attitude object is 'ice cream', one attribute associated with this object might be 'fattening'. If the person thought this attribute was negative and highly associated with ice cream, the attribute would contribute to a generally unfavorable evaluation of ice cream. Of course, any one attitude object can be associated with many attributes that contribute to the overall evaluation.

In practice, researchers such as Martin Fishbein and Icek Ajzen suggest obtaining a listing of attributes about an object and then the evaluation and likelihood associated with each attribute. The evaluation and likelihood are multiplied together for each attribute and the products are added across attributes to estimate the cognitive component of the attitude. One implication of this approach is that two individuals endorsing the same attributes can have different attitudes if they evaluate the attributes differently, and individuals believing in different attributes can hold the same attitude.

The *behavioral* basis is made up of two kinds of information, past behaviors and intentions to commit future behaviors. Daryl Bem's *self-perception theory* holds that we sometimes infer our attitudes directly from our past behaviors towards an object. For example, if a person looks back on his or her life and realizes that he or she has never eaten at a Chinese restaurant even though he or she had many chances to do so, the person might infer that he or she does not like Chinese food. This inference occurs as long as there is no memory of external forces compelling the behavior – the behavior needs to be seen as voluntary.

CONSTRUCTED VERSUS STORED ATTITUDES

When an object is encountered for the first time, there is no information about it in memory. An attitude must therefore be *constructed* by making inferences from the behaviors, thoughts, and feelings that occur in the current social environment. Irrelevant features of the current context can bias the constructed attitude even though they have little to do with the attitude object itself. For example, one's attitude towards the economy might be more favorable on a sunny than a rainy day. Norbert Schwarz and colleagues have documented a wide variety of contextual influences on attitude reports.

After information is gathered about an object and an evaluation is formed, the attitude can be stored in memory and subsequently retrieved directly. A *stored attitude* is an evaluation that is linked to the object in the form of a thought (e.g. 'I like candy'). If the attitude object is brought to mind again, and the object–evaluation link is strong enough, the stored attitude is brought to mind as well.

Generally, the attitudes people report fall somewhere in between purely constructed and purely retrieved. That is, even if a person has already formed a global evaluation, the specific evaluation that is reported at any moment in time is dependent on a wide variety of factors. In general, the stored attitude acts as an anchor point and is adjusted based on affective, cognitive, and behavioral information that is currently salient in memory or in the immediate context. That is, when an attitude is retrieved, some information related to that attitude may also be retrieved and pull the attitude report in its direction. For example, on one occasion the 'taste' attribute of ice cream might be especially salient, but on another occasion, the 'fattening' attribute might be more salient. The immediate context can influence which attitude-relevant information is retrieved, providing a source of contextual bias. Because 'strong' attitudes are less likely to be influenced by context effects than are 'weak' attitudes, the study of attitude strength is also important in attitude research.

STRONG AND WEAK ATTITUDES

Attitudes fall along a continuum from weak to strong, such that stronger attitudes are more durable and impactful. A durable attitude is persistent over time, meaning that it does not decay in memory, and is resistant to change when faced with counter-attitudinal information. An attitude has impact when it influences information processing and guides behavior. Attitudes can possess these strength properties to varying degrees. Also, these strength properties can be independent. Thus, it is possible for an attitude to persist over time but not influence behavior, or to greatly influence thought at a given point in time, but not resist attempts to change it.

A number of variables contribute to making attitudes stronger or weaker. First, extreme attitudes (i.e. when people rate the object as intensely good or intensely bad) tend to be stronger than more moderate attitudes. This may be because extreme attitudes tend to have a number of structural properties that contribute to this strength. For example, extreme attitudes may be based on high amounts of consistent knowledge, and they may come to mind more rapidly (i.e. are more accessible) than more moderate attitudes.

Subjective beliefs about our attitudes are also related to strength. For example, strength can result from perceptions of how much knowledge we have on a topic (regardless of actual knowledge), how important the attitude object is to us personally, or how confident we are in the validity of our attitudes. Finally, the manner in which an attitude is formed can contribute to its strength. Most notably, if an attitude is created through extensive thinking and careful scrutiny of information, it tends to be stronger than if it was formed by means requiring less effort.

EXPLICIT AND IMPLICIT ATTITUDES

To this point, we have discussed attitudes as global evaluations we are aware of and can control. These conscious or *explicit attitudes* result from integrating information from one or more components into an evaluation. These attitudes can vary from strong to weak, and from mostly stored to mostly constructed. Retrieval or construction of these explicit attitudes can either be relatively automatic or require considerable cognitive effort.

In addition to these explicit attitudes, researchers such as Anthony Greenwald and Mazarin Banaji have argued that people can also hold *implicit attitudes* – attitudes of which they are generally not aware. Implicit and explicit attitudes can sometimes be in opposition to each other, such that the implicit attitude can lead people to think and behave in ways they do not consciously intend. For example, a person who holds a prejudiced implicit attitude based on negative stereotypes learned as a child, but now consciously rejected,

may also hold an explicit unprejudiced (and conscious) attitude learned later in life. In such situations, conscious attitudes direct behaviors that are generally under constant conscious control (such as deciding the guilt or innocence of a black defendant). However, more automatic behaviors such as one's body language and eye contact can reflect a person's implicit attitudes.

ATTITUDE CHANGE

Although attitudes are generally considered to be relatively stable and enduring, they are subject to change over time. Being exposed to new information and new experiences can lead people to change their attitudes. Numerous studies have demonstrated the processes by which attitudes change.

Central and Peripheral Routes to Change

Much contemporary research is guided by the idea that attitudes are sometimes changed thoughtfully, but sometimes are changed with very little cognitive effort. The *elaboration likelihood model* (ELM) of persuasion developed by Richard Petty and John Cacioppo presents a framework that helps explain the various processes and outcomes of attitude change. Although the amount of thinking involved in attitude change forms a continuum from none to extensive, the model divides the specific processes of attitude change conveniently into two 'routes' to persuasion.

The first or *central route* to attitude change occurs when people are relatively careful in scrutinizing the issue-relevant information available. If, after careful consideration, a person finds the information to be compelling, attitudes change accordingly. If, however, the information is deemed specious, attitudes will not change, or can even change in a direction opposite to that advocated – a boomerang effect. For example, a person following the central route when processing a magazine advertisement for a car will carefully assess the perceived validity of the information presented in the ad. The person might examine the information presented about the horsepower, price, resale value, safety record, and so forth. The person will be influenced if his or her *cognitive responses* – the thoughts generated during message processing – are positive. The person is not likely to be influenced, however, by the beautiful sunset pictured in the background or the cute puppy sitting in the driver's seat because these are peripheral cues that are unrelated to the central merits of the car.

Sometimes, however, people follow the *peripheral route* when exposed to a persuasive communication. In such cases, people are not likely to pay attention to all of the issue-relevant information within the message. Rather, people seek a shortcut way to evaluate the ad. In this case, they might be influenced by the mere number of arguments in the ad (regardless of their quality). Or, the cute puppy in the driver's seat might lead to a positive feeling that becomes associated with the car.

An important consequence of the route to persuasion that a person takes is the strength of the attitudes that result. Specifically, when people change or form an attitude through the central route to persuasion, attitudes tend to be stronger than those created or changed through the peripheral route. Attitude changes that occur because a person has carefully considered issue-relevant information have a substantive backing which contributes to the durability and impact of the attitude. In contrast, attitudes formed under the peripheral route do not have this substantive support. Because they lack supporting cognitions, these attitudes are much less durable and impactful. This does not mean that peripheral route changes are completely unimportant. For example, advertisers can take advantage of the short-term effects of the peripheral route by continual pairing of peripheral cues with their products in repeated messages. Also, in some cases, what starts out as a peripheral cue can become an argument if people subsequently think about the cue in a way that gives it substantive meaning.

Amount of elaboration

What determines whether a person will follow the central or the peripheral route? This depends on whether the person has the *ability* and the *motivation* to think carefully about the message. Variables influencing ability (whether a person is able to think) include distraction and time pressure. If a person is distracted or under great time pressure while exposed to a persuasive communication, it is simply not possible to follow the central route, and thus the peripheral route to persuasion is more likely. Variables influencing motivation (whether a person wants to think) include personal relevance and accountability. For example, if people are told that a message is of low relevance to them (the product advertised is available only in a faraway country), or that they will not be accountable for the attitude they report on the topic (questionnaires will be completed anonymously), it is likely that they will feel little motivation to think carefully. They are likely to follow the less taxing peripheral

route to persuasion instead. All else being equal, people prefer to save their cognitive energy for the most important tasks and decisions in life. People who are high in their *need for cognition* tend to enjoy thinking about a wide variety of topics and thus tend to follow the central route to persuasion. People who are low in this need tend to follow the peripheral route.

Objective and biased processing

In addition to the amount of information processing that takes place, it is also important to consider whether that processing is relatively objective or biased. Objective processing refers to the case in which thinking is guided by the qualities of the information at hand. If the information is cogent, people's thoughts are favorable, but if the information is specious, their thoughts are largely negative. However, people can process messages in a biased manner. For example, people may be forewarned that a message will attempt to change their attitudes. In such cases, people tend to think negatively about all of the arguments – regardless of their actual quality – in an attempt to assert their individual freedom not to be influenced. There are a number of motivations besides asserting freedom that can induce biased processing, such as the motive to be consistent, or to maintain one's self-esteem. Each of these motivations selectively directs people's information-processing activity to favor one attitudinal position over another.

Multiple roles of variables

The ELM highlights the fact that variables can influence attitudes by serving in different roles in different situations. For example, the physical attractiveness of the source of a persuasive message might influence attitudes in a number of ways. First, such a source might serve as a simple peripheral cue when the situation constrains people's motivation or ability to think about the message to be low. For example, when people are distracted, they might go along just because the source is attractive, regardless of the merits of what the source says (peripheral route). On the other hand, if people are highly motivated and able to think about the message, an attractive source might bias that thinking in a favorable way, or the source itself might be scrutinized to see whether it provides information central to the merits of the issue (central route). Finally, if thinking is not already constrained to be high or low, an attractive person might encourage recipients to pay more attention to the message – leading to more agreement if the message is sound, but to less agreement if the message is not. Under this scenario, then, attractiveness would serve as a determinant of elaboration.

Thus, although a variable can serve as a determinant of elaboration in one scenario (unconstrained elaboration), it can serve as a cue in others (low elaboration) or can bias processing or serve as an argument in still other situations (high elaboration). The ELM thus limits the fundamental roles a variable can play in persuasion situations and provides a guiding framework for assessing when variables take on each role.

Mood and Persuasion

One persuasion variable that has been studied extensively in its multiple roles is a person's mood state – whether he or she is feeling good or bad. As with other variables, the effect of mood on persuasion depends on the amount of elaboration taking place during the message presentation. Under low-elaboration conditions, a person's mood can serve as a peripheral cue. In such situations, people may associate their mood with the message's object. The pairing of a good mood with the object can produce positive attitudes towards that object, but bad mood can produce negative attitudes. Second, when elaboration is high, a positive mood can bias people's reactions to the message arguments. In particular, positive mood states make good consequences (e.g. living longer if you stop smoking) seem more likely than when in a neutral or negative mood state, but make negative consequences (e.g. getting cancer if you don't stop smoking) seem less likely. Negative mood states have the opposite consequences. Finally, under moderate elaboration conditions, positive moods affect the amount of thinking people do about the message. If the message appears to be negative or depressing, positive moods decrease information processing compared to negative moods. People in positive moods do not want to think about negative information. On the other hand, if the message appears to be positive or uplifting, positive moods increase thinking over negative moods.

Persuasion from Our Own Behavior

Leon Festinger's theory of *cognitive dissonance* suggests that sometimes our own behavior can lead to attitude change. Specifically, the theory holds that cognitive conflict occurs when people believe that they have behaved in a way that is inconsistent with their attitudes. This cognitive conflict produces tension that people are motivated to reduce in order to restore consistency. Since behavior is

often difficult to undo, one way to restore attitude–behavior consistency is to change one's attitude to be in line with one's behavior. This is not the only way to reduce dissonance (people could reduce the importance of the conflicting attitude or behavior), but it is a common one. Dissonance theory explains such processes as why people come to favor products more after they purchase them, and why people come to like groups more if they have voluntarily exerted considerable effort to join them. Dissonance can also lead people to process information in a biased fashion. That is, they think about attitude objects in a way that restores consistency.

Resisting Persuasion

Although there are many different ways in which people can be persuaded, there are some techniques through which attitudes can be made more resistant to change. One way to create resistant attitudes is simply to make those attitudes stronger. This can be done by increasing issue-relevant thinking prior to the attacking message. For example, if a positive attitude towards obeying the speed limit is weak, a person could spend time thinking and learning about why he or she holds the attitude. This additional thinking and learning should serve to strengthen the once-weak attitude.

Perhaps surprisingly, an attitude can in some situations be made more resistant to persuasion through attempted counter-persuasion! Some attitudes are weak because they have very little substantive basis at all. These attitudes may have been created through peripheral processes or may simply be 'cultural truisms' – attitudes we hold just because we have always been taught to think that way (such as favorable attitudes towards freedom of speech). If cultural truisms are mildly attacked, they can actually become stronger. This process of *inoculation*, as outlined by William McGuire, occurs because although the weak attack may not be enough to change the attitude, it may be strong enough to make the recipient think (often for the first time) about why he or she holds that attitude in the first place. This additional thought can serve to create a basis for holding the attitude and motivate individuals to effectively counter-argue subsequent attacking messages.

ATTITUDE – BEHAVIOR CONSISTENCY

One reason why attitudes are a principal area of research in psychology is that, under the right circumstances, attitudes guide people's behavior, and thus are useful to know in order to predict voting, consumer purchases, jury decisions, and so forth. According to Russell Fazio's model of attitude–behavior consistency, exactly *how* attitudes guide behavior depends on the type of behavior in question – is the behavior one that is engaged in spontaneously or one that elicits reflection prior to action?

Some behaviors in which we engage are not well thought out. When it comes to impulse purchases, such as the candy people buy while waiting at the checkout line, people may not spend much time in making decisions. In such cases, people simply look to their attitudes to make a choice. In such situations, whether our attitudes drive behavior is determined by whether we can recall the attitude easily and quickly (i.e. if the attitude is accessible).

Other behaviors are not as spontaneous. When we have the motivation and opportunity to choose our behaviors more carefully, accessibility alone is less important. Instead, according to Fishbein and Ajzen's theory of reasoned action, behavior is determined by one's behavioral intention, which is in turn determined by several factors. First, intention is determined by one's attitude towards the particular behavior under consideration. Attitude towards the behavior in any given situation (e.g. baking a cake for your spouse's birthday on Wednesday) will depend on the beliefs that come to mind in assessing this action – if an attitude relevant to this behavior is not readily retrievable. Intentions are also determined by subjective norms – what other people we admire would want us to do in the situation. Perceptions of our own abilities to carry out some action also play an important role in determining deliberative behaviors.

CONCLUSION

Attitudes have a profound impact on virtually every aspect of our lives. From fundamental issues, such as how attitudes can be measured, to more complex ones, such as the nuances of how attitudes can be changed, a long and rich array of research has helped us to understand the nature of the attitude construct. Space limitations have allowed us to provide only a sampling of what is known about attitudes; the extensive literature on this topic requires further exploration.

Auditory Event-related Potentials

Intermediate article

Terence W Picton, Rotman Research Institute, Toronto, Ontario, Canada

CONTENTS

Auditory event-related potentials are electrical changes recorded from the brain in association with auditory stimuli.

INTRODUCTION

Human auditory event-related potentials (ERPs) are evoked by an acoustic stimulus and indicate the cerebral activity occurring as that stimulus is processed in the brain. When recorded from the human scalp, ERPs are intermixed with other electrical potentials. Several techniques may be used to distinguish ERPs from these other activities (Picton *et al*., 1995): one of the most common is averaging – when the responses to multiple stimuli are averaged together, the auditory ERP (which is generally constant from one stimulus to the next) remains the same, whereas the other activity (which varies from one stimulus to the next) attenuates. (*See* **Electroencephalography (EEG)**)

Auditory ERPs can be classified in many ways. In relation to the stimulus, the ERPs may be transient, steady state, or sustained. Transient responses are evoked by rapid changes such as the onset or offset of a sound. Transient evoked potentials are often named according to their polarity and latency, e.g. the N100 is a negative wave recorded with a typical peak latency of 100 ms. Steady state responses are evoked by a regularly changing stimulus such as an amplitude-modulated tone. These can be described in terms of the frequencies at which they are elicited, e.g. the 40 Hz ERP is best recorded when stimuli are presented at rates near 40 Hz. Sustained potentials are recorded through the duration of a stimulus. Some ERPs are characterized by where they are generated in the brain, e.g. the auditory brainstem response, others by where they are maximally recorded, e.g. the vertex potential, and others by their purported function, e.g. the mismatch negativity. The plethora of nomenclatures reflects the paucity of our understanding.

In order for potentials to be recorded at a distance from where they are generated, many neurons must respond, their activation must be synchronous, and the neurons must be oriented in a similar direction so that their fields combine rather than cancel. Much of what goes on in the auditory nervous system does not fulfill these criteria and passes unnoticed in the scalp-recorded ERP. What is recorded, however, can tell us much about the processing of sounds in the brain.

SENSORY PROCESSING

A brief transient stimulus evokes a sequence of potentials that indicate the processing of stimulus information all the way from cochlea to cortex (Figure 1). The upper part of the figure shows an early sequence of vertex-positive waves (numbered with Roman numerals). These waves are usually lumped together as the auditory brainstem response, even though wave I is generated in the auditory nerve rather than the brainstem. Since it can be recorded down to intensities near threshold, wave V can demonstrate that the brain is receiving sounds without the person being tested having to make a subjective response to those sounds. This 'objective' audiometry is important when evaluating the hearing of infants and others who cannot provide reliable behavioral responses.

The middle part of Figure 1 shows a sequence of waves named according to their polarity and alphabetical sequence. The most prominent of these middle-latency waves is Pa, with a peak latency of about 25 ms. The Pa is most likely to be generated in or near the primary auditory cortex. The initial activation of the human primary auditory cortex probably occurs at about 15 ms, but this may not be reliably recorded from the scalp. If stimuli are presented at rapid rates, the middle-latency waves evoked by one stimulus superimpose on those evoked by preceding stimuli to give a periodic response at the frequency of stimulation.

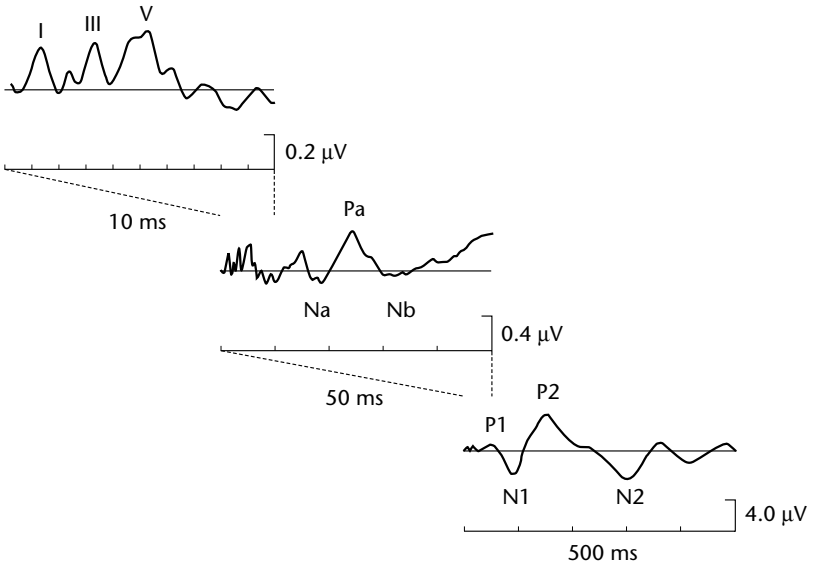

Figure 1. Auditory event-related potentials recorded from the vertex relative to the right mastoid in response to clicks at 60 dB above threshold presented at a rate of 1 s^{-1}. This recording was from a single person showing typical responses. The largest waves occur with latencies between 50 ms and 500 ms, as seen in the lower right waveform. The first 50 ms of this recording can be expanded in time and amplitude to show the middle-latency responses. The first 10 ms of this recording can then be expanded to show the auditory brainstem response.

The most prominent of these steady state responses occurs at 40 Hz (Galambos *et al*., 1981). This response is attenuated by sleep and blocked by anesthesia. The 40 Hz ERP is probably related to bursts of cortical activity that occur at frequencies of 20–50 Hz (the 'gamma band'). These rhythmic responses may reflect the oscillatory transfer of information between sensory areas (Singer, 2000).

The lower part of Figure 1 shows a sequence of waves named according to polarity and numerical sequence. Since these waves are much larger than the earlier waves, they were historically the first to be recognized, and were called 'vertex potentials' because they were maximally recorded from the top of the head. However, since the earlier waves are often also largest at the vertex, the terminology is more nostalgic than definitive. The most prominent of the late waves is N1, which has a peak latency of about 100 ms. Several different intracerebral generators contribute to the scalp-recorded N1 (Picton *et al*., 1999). As well as being evoked by the onset of a stimulus, an N1 also follows the offset of a stimulus or a change in any of its attributes. The N1 wave remains an enigma. Why does such a large response occur so late in the processing of auditory information? The N1 may represent a process whereby the nonspecific detection of a change in the auditory world, perhaps through the brainstem reticular system, initiates a read-out of specific information from the auditory cortex to other regions of the cortex.

SENSORY MEMORY

Memory for a stimulus can be demonstrated by a change in the response to that stimulus when it occurs at a later time. A common demonstration of memory involves the habituation of a response when a stimulus is repeated. This is most efficiently measured in ERPs by recording the responses at different interstimulus intervals. The N1 wave of the auditory ERP decreases quite strikingly with decreasing interstimulus intervals. This decrease is specific to the stimulus attributes; for example, if the tonal frequency of a test stimulus is different from the frequency of a repeating stimulus, the N1 is larger than when the stimuli are the same.

In addition to a change in the N1, a later mismatch negativity (MMN) occurs when a repeating auditory stimulus changes. In this context, the repeating stimulus is usually called the 'standard' and the changed stimulus the 'deviant'. The MMN is typically measured in a difference waveform obtained by subtracting the response to the standard stimulus from the response to the deviant. This subtraction removes elements of the response that are common to both stimuli, leaving the MMN (Figure 2). The MMN differs from the N1 in many ways. First, it has a longer latency, typically

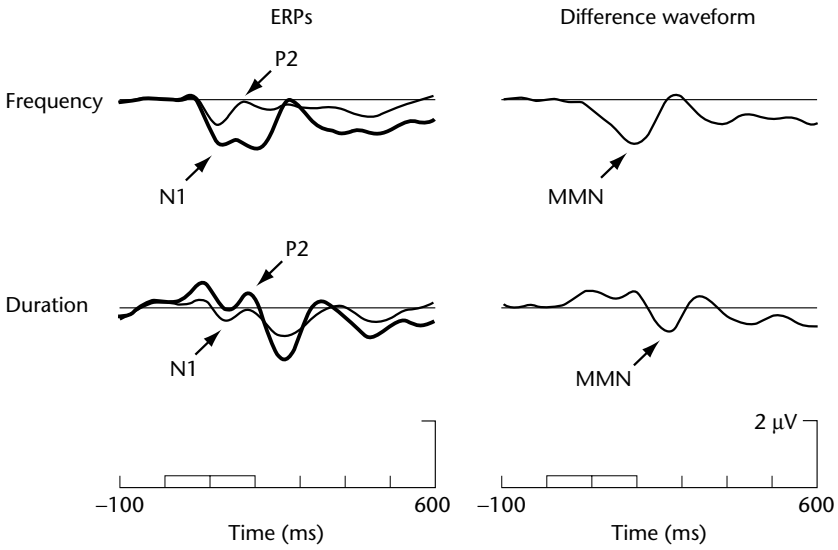

Figure 2. The mismatch negativity (MMN) in response to changes in the frequency or duration of a brief tone. The standard stimuli were 1000 Hz tones with a duration of 200 ms and an intensity 60 dB above threshold. Recordings were obtained from the midfrontal scalp using an average reference. Deviant stimuli occurred with a probability of 0.2. For the upper tracings the deviants had a frequency of 1100 Hz; for the lower tracings the deviants had a duration of 100 ms. Deviant–standard difference waveforms are shown on the right. These event-related potentials (ERPs) are averaged over ten test participants. Deviant ERP, thick line; standard, thin line.

peaking about 50 ms later than the N1. Second, this latency increases with decreasing difference between the deviant and the standard. Third, the latency is determined not by the onset of the stimulus but by the time when the deviant can be distinguished from previous stimuli. When the deviance is a change in duration, the MMN occurs approximately 150 ms after the time of the shorter stimulus, regardless of whether the deviant is the shorter or the longer stimulus. Fourth, the MMN is more related to the size of the deviance than to the parameters of the stimuli. A decrease in the intensity of a stimulus can thus elicit a MMN even though the N1 is smaller for the less intense stimulus. Fifth, the MMN has a different scalp topography, with a maximum amplitude anterior to that of the N1. The intracerebral sources for the MMN may vary with the nature of the deviance, for example being larger in the left hemisphere for changes in speech sounds (Näätänen, 2001).

The MMN is related to sensory (or echoic) memory through the time during which a sensory regularity must be detected. The system generating the MMN must recognize that the deviant does indeed break some perceived regularity in the stimuli. It can only do this when the information is maintained in sensory memory (Picton *et al.*, 2000). Since the MMN occurs whether or not the person is attending to the stimuli, it seems to represent an automatic processing of stimulus changes. However, attending to the stimuli can enhance the wave (Woldorff *et al.*, 1998), particularly when detecting the deviance is more complicated, such as noting a change in the temporal pattern of the stimuli (Alain and Woods, 1997).

The role of the MMN is unknown. It may indicate the increased processing that is evoked by a deviant stimulus, either to detect it as different from the standard or to initiate processing once it is detected. In the latter case, it might serve to alert other parts of the brain, particularly the right frontal regions, that a deviant has occurred.

AUDITORY ATTENTION

The effects of attention on the auditory ERP can be studied by presenting two or more trains of information, like hearing different conversations at a party, and asking the participant to attend to one and ignore the others. Attention can be monitored by measuring how well the participant detects occasional changes in the stimuli ('targets'). The difference between the ERPs evoked by the attended and ignored stimuli then indicates a specific effect of selective attention, independent of nonspecific changes in arousal. Despite some contrary reports, the bulk of the evidence indicates that the early auditory ERPs are unaffected by whether the

participant pays attention to the stimuli or ignores them (Hackley *et al*., 1990). This suggests that the brain automatically processes auditory information to the level of the auditory cortex. The earliest undisputed evidence of an attentional effect on the auditory ERPs is a change in the middle latency potentials between 20 ms and 50 ms after the stimulus (Woldorff and Hillyard, 1991). This change occurs in demanding selective attention tasks and probably reflects some facilitated processing of the attended information in the auditory cortex. (*See* **Attention**)

The most striking effect of auditory attention is an increased negativity beginning at about 50 ms after the onset of a sound and overlapping the N1 wave. This effect can also be demonstrated as a negative difference wave or Nd, obtained by subtracting the response to ignored stimuli from the response to the same stimuli when they are attended. The effect probably indicates both an enhancement of the processing normally represented by the N1 wave and extra processing independent of the N1. The size and duration of the Nd varies with the amount of processing needed for the attentional task and the time pressure under which it occurs. Two parts of the Nd wave have been distinguished: an early wave, which is probably related to processing attended information, and a later wave, which may be related to task monitoring. The early Nd wave is mainly generated in the auditory cortices of the supratemporal plane. The neurons contributing to this wave probably vary with the different attentional tasks, e.g. whether the person is attending to the loudness of the stimulus or its frequency. Differences in Nd between tasks are difficult to demonstrate because neurons specific to different tasks have similar locations on the supratemporal plane. Nevertheless, the Nd for attended stimuli clearly varies with the location of the stimulus in space (Teder-Sälejärvi *et al*., 1999).

WORKING MEMORY

Once the information in an attended stimulus is processed, it is available to working memory for further evaluation. The ERP evoked by the detection of an improbable auditory target (or 'oddball') in an attended train of standard stimuli contains, in addition to the P1–N1–P2 waves, an N2–P3 complex and a later 'slow wave' (Figure 3). The P3, the largest of these attention-dependent waves, typically occurs with a peak latency of about 300 ms, and therefore also goes by the name of P300. It is maximally recorded from the vertex and midparietal regions of the scalp. The amplitude of the wave is

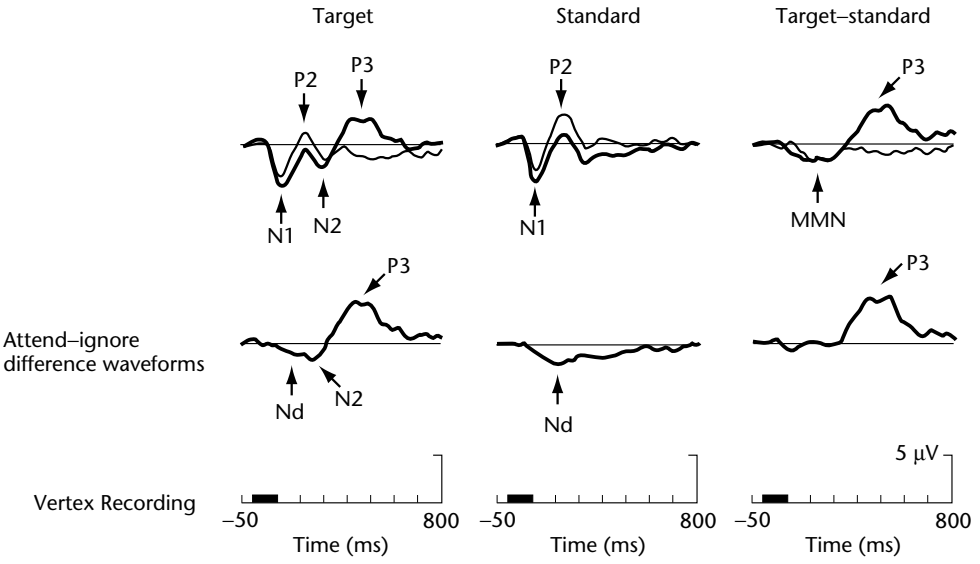

Figure 3. Effects of attention on the auditory event-related potentials (ERPs) to tones presented 65 dB above threshold at a rate of 2 s^{-1}. The participant's task was to detect occasional ($p = 0.2$) targets with a slightly different frequency or to ignore the stimuli and attend to a concurrent set of stimuli in the other ear. The ERPs for ten participants were averaged across the ears according to whether the stimuli were targets versus standards, and attended (thick line) versus ignored (thin line). The attend–ignore difference waveforms show a Nd wave for both targets and standards, and a P3 wave for the targets. The target–standard waveforms show a mismatch negativity (MMN) for the target regardless of attention and a P3 wave during attention.

inversely related to the probability of the stimulus. Its peak latency increases and its amplitude decreases with increasing difficulty in distinguishing the target from the standard. The peak of the P3 may occur before a motor response in difficult tasks, but often occurs at the same latency or later than the motor response in easy tasks. It therefore probably represents cerebral activity that is unrelated to the motor response. In general, the latency is more closely related to the duration of sensory processing and is relatively unaffected by manipulations that alter the subsequent selection of perceptual or motor responses. Several hypotheses have been proposed for the function of the P3 wave, including the updating of working memory, the access of information to conscious processing, and the resetting of perceptual analyzers once their processing has finished. (*See* **Working Memory**; **Event-related Potentials and Mental Chronometry**)

Intracerebral recordings and blood flow studies indicate that many different regions of the brain are active during the P3, most prominently regions of the hippocampus and the parietal lobe (Linden *et al*., 1999). All these regions probably contribute to the scalp-recorded waveform during the P3 and the subsequent slow wave. A network of intracerebral events overlapping in time and in potential occur in relation to recognizing the target, associating it with the required response, initiating the response, and updating memory about the occurrence of both target and response. Working memory is probably manifest in these interactive connections.

CONCLUSION

The auditory ERPs can time the different activities that occur as auditory information is processed in the human brain. Studies of the increased blood flow that occurs with these activations can indicate the locations of the processing. Studies of animals can indicate the underlying neuronal mechanisms. Combining information from all these approaches should elucidate the 'when', 'where' and 'how' of human hearing.

CONTENTS

The production of all sounds creates regularities in the air-pressure sound wave that reaches the listener. The physiological mechanisms and cognitive processes involved in locating and identifying the source of those sounds take advantage of these regularities.

INTRODUCTION

We can identify our friends, rainfall, doorbells, and screeching chalk on a blackboard by sound alone. The key to understanding the diversity of auditory perceptions is to comprehend the complementary nature of the production and subsequent perception of those sounds. The production of all sounds creates regularities in the physical air-pressure wave that reaches the listener. The physiological mechanisms and cognitive processes necessary to locate and identify the source of those sounds take advantage of these regularities.

The first step is to describe the regularities in the sound wave, namely 'what is out there to perceive'. The second step is to describe the physiological adaptations of the auditory system that transform the amplitude of the air-pressure wave into the neural signal which is transmitted to the cortex. The third step is to describe the cognitive heuristics (where a *heuristic* is a rule that usually works but which can lead to a wrong outcome in some instances) that are used to make sense of the neural signal in order to perceive what is happening in the external world.

THE PRODUCTION OF SOUND
