The basic notion is that a 'source' (e.g., a violin string, or puffs of air coming through the vocal cords) is excited by energy. The source then imposes its vibration pattern on the filter (e.g., the wooden sound body of the violin, or the shape of the mouth), which modifies the vibration of the source into the pressure wave that is radiated to the environment.

The source can vibrate at several component frequencies which are determined by its physical construction, material, and method of excitation. The frequencies of the vibrations usually form a harmonic series (the frequencies of the components are integer multiples of the lowest frequency: 1:2:3:4:5…). The amplitudes of each component vary depending on the above characteristics and, within limits, component vibration starts and ends at the same time. The source vibrations then stimulate the filter. The latter also has specific vibration frequencies (resonances) and is thus capable of being excited when the source vibration frequencies match the filter's vibration frequencies. Owing to the match and mismatch of frequencies, certain source vibrations are transmitted if the source and filter frequencies match, and others are 'stilled' if the frequencies do not match.

Thus the vibrations in the sound pressure wave coming from one source are typically harmonically related (albeit at different amplitudes), start at the same time, evolve slowly across their duration due to frictional decay or changes such as vibrato, and finally end at approximately the same time. All of these regularities can be used to detect and identify the source of the sound.

Transparency of Sound Waves

If only one sound occurred at any particular time, then the problem of auditory perception would be easy. If each unique sound wave represented one

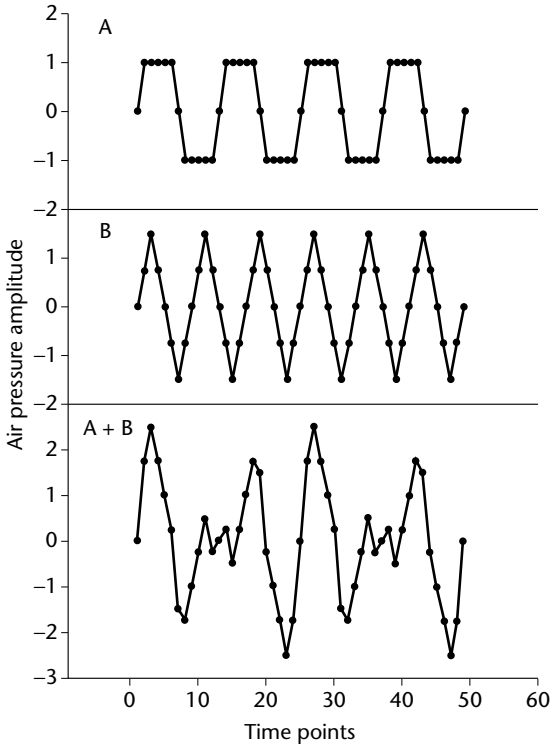

Figure 1. The addition of two waves gives rise to a combination wave that is the sum of the two individual waves. The 'square wave' in A takes 8 time periods to go through one cycle, repeating at 9, 17, 25, and so on. The 'triangle wave' in B takes 12 time periods to go through one cycle, repeating at 13, 25, and so on. The sum of A and B takes 24 time periods to go through one cycle, repeating at 25, 49, and so on.

source, it would merely be a problem of memorization. Unfortunately, the sound waves coming from two or more overlapping sources (e.g., a radio, street noise, and someone talking) are added together to give one wave in which the individual sound waves from each source are lost in the composite (Figure 1). The frequency components from each sound source are completely intermingled. The unique problem for auditory perception is to untangle this mixture in order to recover the individual waves created by each separate source. We hear each source easily without conscious calculation, but this effortlessness belies the difficulty involved. No computer can do this task. In contrast, nearly all visual objects are opaque rather than transparent, so that the light ray from each point in space invariably comes from light reflecting off just one object.

The goal of the auditory system must be to analyze the composite sound pressure wave into its frequency components, and to assign sets of components to different sound sources. The heuristics used to make this assignment are based on the regularities inherent in the production of sound, namely that the frequency components from one sound source tend to be harmonically related, start and end at the same time, change in quality slowly and continuously, and occur at one location in space. Thus we would expect that the physiological mechanisms would be designed to analyze the sound wave into the amplitude pattern of its component frequencies, to maintain the onset and offset timing of the components, and to maintain the location of the components. Essentially, this is what the auditory pathways accomplish.

PHYSIOLOGICAL STRUCTURES

The Ear

The fundamental problem is to convert the changes in air pressure into neural impulses that travel to the auditory cortex. The physical construction of the ear is designed to overcome the large mismatch in physical properties between the air medium of the sound and the fluid-filled medium in the vertebrate inner ear.

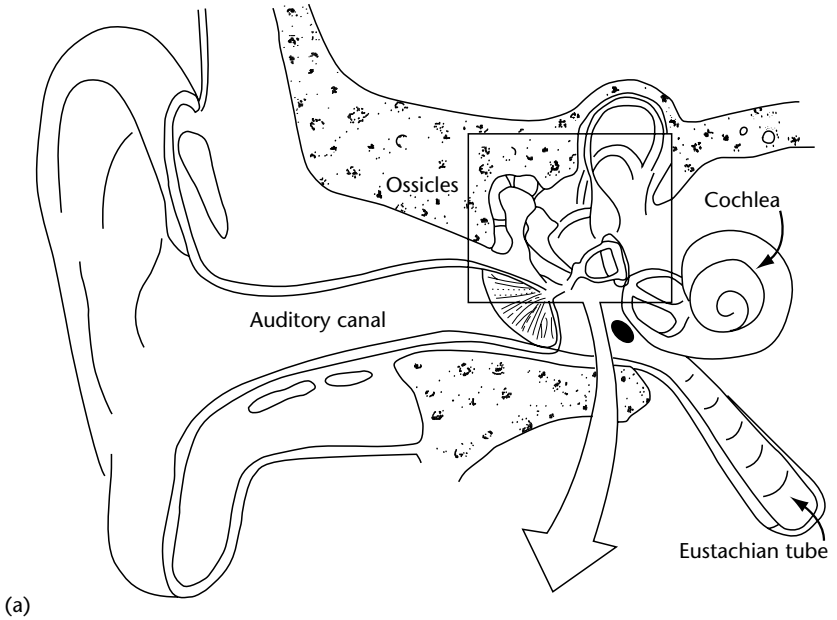
The outer ear consists of the visible pinna and the hollow ear canal terminating at the ear-drum that captures sound energy at frequencies mainly used for speech (Figure 2). The middle ear consists of three tiny bones that provide a bridge between the vibration in air at the ear-drum and the fluid vibration at the base of the inner ear. Together, the motion of the bones and the relative size of the ear-drum compared with the oval window at the base of the inner ear convert most of the air pressure vibration into fluid vibration. The inner ear consists of the cochlea, which is responsible for transforming the vibration pattern into neural firing (Figure 3). The cochlea is a coiled fluid-filled tube, about the size of a small bean, with a complex membrane that divides the tube into two halves. Vibration of the middle ear bones creates fluid pressure waves that travel down the cochlea, causing the center membrane to move, and that in turn distorts the neural cells (known as hair cells) attached to the membrane. This distortion causes the hair cells to stimulate neural firing, which eventually reaches the auditory cortex.

Frequency Analysis

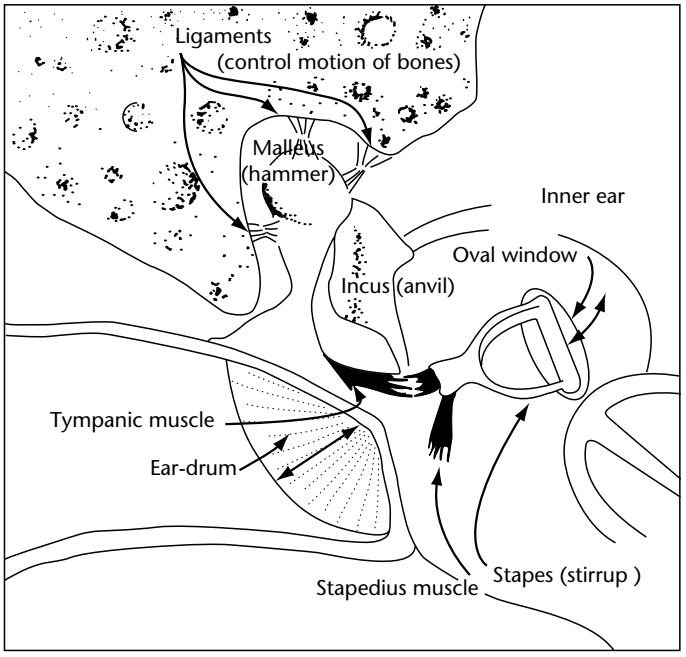
The goal of the auditory system is to isolate the frequency components and to maintain the onset

and offset timing between the components. This is achieved in two complementary ways in the inner ear.

First, the membrane changes its shape and stiffness along its length so that it distorts maximally to higher frequencies of vibration at the base, close to the vibrating bones, and it distorts maximally to lower frequencies at the apex, where the membrane ends. For a complex vibration composed of many frequencies, the membrane would distort at several



(a)



(b)

Figure 2. (a) A schematic view of the outer, middle, and inner ear. (b) A detailed view of the middle ear. The middle ear consists of three connected bones, namely the malleus, incus, and stapes. The stapedius and tympanic muscles control the acoustic reflex that protects the ear from loud prolonged sounds by loosening the connections between the middle ear bones. Reproduced from Handel (1989, p. 466) with permission.

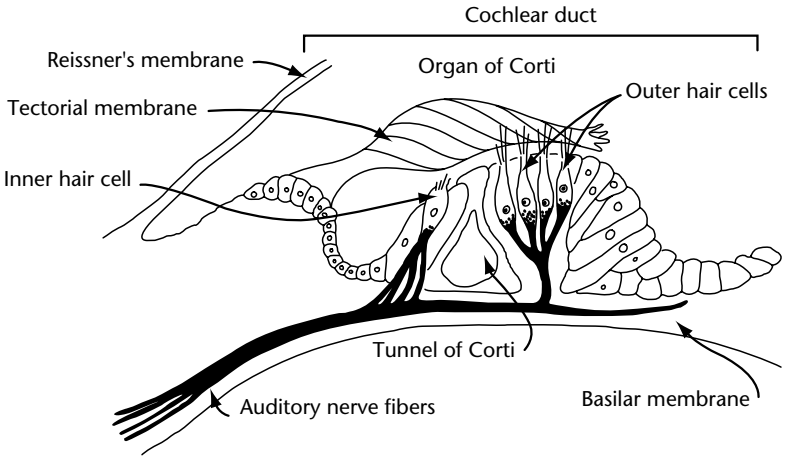


Figure 3. View of the inner ear showing the center segment bounded by Reissner's membrane on the top and the basilar membrane on the bottom. The firing of the inner hair cells creates the neural signal, while the outer hair cells act to change the mechanical properties of the basilar membrane. Reproduced from Handel (1989, p. 471) with permission.

points, each representing one component frequency. This has been termed *place coding*, and a larger amount of distortion will result in a higher rate of neural firing.

Secondly, the membrane essentially makes one 'up-and-down' movement for one cycle of the vibration. For most of the frequencies used for speech and music, the hair cells track that motion and cause the attached neurons to fire once per cycle. This firing pattern has been termed *frequency coding*, and the timing between firings can be used to code frequency. If the hair cells fire at the same point in the movement, this is termed *phase-locking*.

Even though the inner ear seems to be physically rather crude, its frequency, intensity and temporal resolution is remarkably good. In terms of the ability to detect differences, the resolution is about 0.5% for frequency (a difference of between 1000 Hz and 1005 Hz), about 10% for intensity, and about 2 ms for onset. These values are more than sufficient to identify sound objects.

As the neural signal travels to the cortex, it passes through many brain nuclei, where there is much neural elaboration. Although there are only about 2000 hair cells per ear, there are about 1 000 000 cells in each side of the auditory cortex.

PERCEPTION OF LOCALIZATION

Although each ear analyzes the pressure wave only in terms of frequency, the auditory image is one of objects that appear to be fixed in space outside the head, and which do not appear to move despite head and body movements. It is the human body that generates the physical cues to object localization. If we were simply points in space, there would be no way of localizing sounds, and if sound is presented directly to the ears using headphones, objects appear inside the head and not out in space.

The perception of direction depends on two acoustic cues that are produced by the difference in position of the two ears. First, with the exception of sounds exactly in front of or exactly behind the listener, all sounds will reach the near ear before they reach the far one. The time differences are quite small, reaching a maximum of about 0.5 ms if the sound is directly opposite one ear. Secondly, the head casts a sound shadow so that the intensity of the sound reaching the far ear will be less than that of the sound reaching the near ear (Figure 4).

Both time and intensity differences are used to assess direction. Time differences appear to be more important for frequencies lower than 1500 Hz, whereas intensity differences appear to be more important for higher frequencies. The head reflects all frequencies, but at the lower frequencies the sound wave can 'bend' around the head, reducing the intensity difference. At frequencies higher than 2500 Hz the sound waves still bend around the head, but they converge at a distance behind it. Therefore there is a strong intensity shadow that can be used to detect the direction of the sound. There are always ambiguities. For example, a source 45° in front of one ear creates the same time and intensity cues as a source 45° behind the same ear. These types of ambiguities can be resolved by simple head motions.

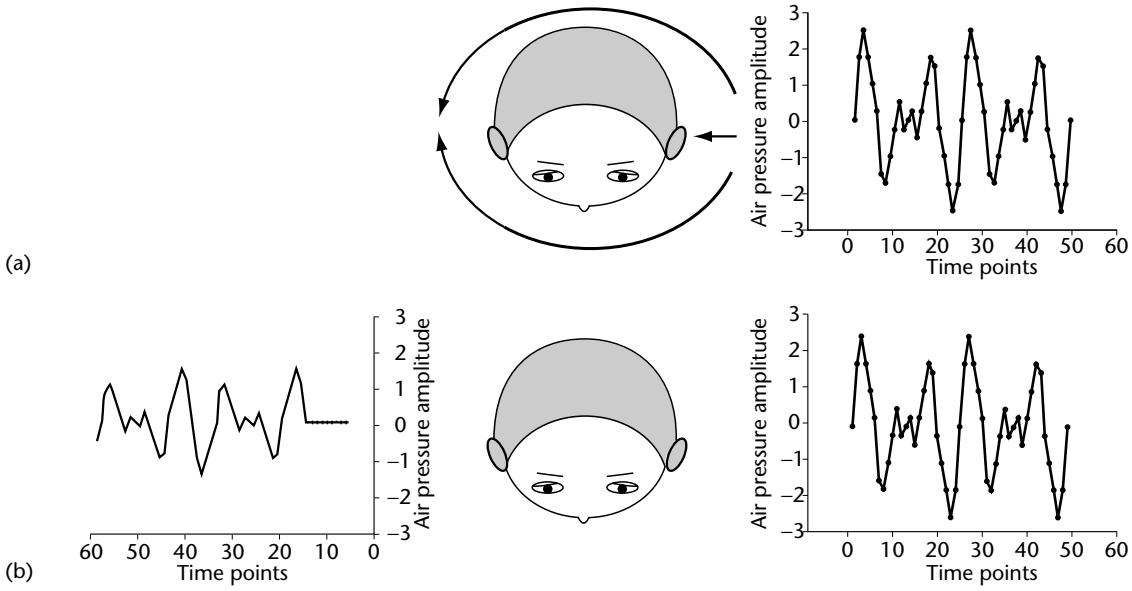

Figure 4. Sound localization. (a) A sound pressure wave is directly opposite the left ear. The wave travels directly to the left ear, and circles the head to travel to the right ear. (b) The wave to the left ear is unchanged, but the wave arriving at the right ear is delayed in time and reduced in amplitude. Note that the right ear wave is reversed in time.

MAKING SENSE OF THE SOUND WAVE: WHAT ARE THE OBJECTS IN THE WORLD?

To hear the singer of a jazz combo, the listener must group together the frequency components produced by the singer separately from those produced by the instruments. Surprisingly, the most important acoustic cue leading to the grouping of the components is synchrony of the onsets. Remember that the auditory system has very fine temporal acuity – it can distinguish differences of less than 2 ms. Several experiments have placed the various cues in conflict and have found that listeners will group frequency components that begin at the same time, even if the components are not harmonically related or they are presented to different ears. If the components start at slightly different time points, listeners do not report that they hear two sounds starting at different time points. Instead, they simply report hearing two sounds, and they are unable to report the order of those sounds. Thus, curiously, short time asynchronies are converted into source information and not order information.

The second most important cue is that of harmonic relatedness. If all of the frequency components are harmonically related, the obvious decision would be that all of the components come from a single source, and the percept is that of one complex tone. If one of the components is mistuned so that its harmonic relationship is lost (e.g., 200, 415, 600, 800 Hz), the percept is divided – the mistuned component is heard as one emergent tone, and the remaining components are heard as a second tone that has changed in sound quality because the mistuned harmonic has been segregated out. If the frequency components are inharmonic (e.g., 100, 125, 200, 250, 300, 375 Hz…), the auditory system partitions the components so that each set is harmonically related – one complex tone based on a fundamental frequency of 100 Hz and a second one based on a fundamental of 125 Hz. For speech, fundamental frequency differences as small as 2% are sufficient to lead to the perception of two vowels or syllables, each spoken by a different voice.

The rank order of synchrony, harmonicity, and location reflects the predictability of the cues. It is extremely unlikely that two different sounds will start at exactly the same time. However, there are sounds in which the components are not harmonic (e.g., any type of static or noise) and, owing to the possibility of multiple reflections off hard smooth surfaces, the timing and intensity cues to direction may be seriously distorted.

The final step is to categorize, identify, and label each set of frequency components. Although this process is not understood, it is clear that the fundamental frequency and the overall amplitude pattern of the frequency components (its *shape*) as

well as short-term variations influence identification. For example, male voices are distinguished from female ones on the basis of fundamental frequency, but female (and male) voices are often distinguished within gender on the basis of the pattern of frequency components.

CONCLUSION

Although there are striking differences in the stimulus energies and physiology of the auditory and visual perceptual systems, both are concerned with the description of objects in the world. The auditory system is maximally tuned to the timing and rhythm of events (after all, we don't dance to lights alone), and the cognitive rules that are used to interpret the neural firings make use of those regularities.

Autism, Psychology of

Introductory article

Christopher Jarrold, University of Bristol, Bristol, UK
Francesca Happé, Institute of Psychiatry, London, UK

CONTENTS

Autism is a disorder that has a biological cause but is diagnosed on the basis of problems in socialization, communication, and imagination. Psychological explanations of the condition aim to account for this pattern of behavioral difficulties, and for the strengths that individuals with autism show in other areas.

BACKGROUND

Autism is a disorder that is most often diagnosed in childhood. It affects five to 10 in every 10,000 individuals, and is about four times more common among males than females. It is clear that autism has a biological origin, rather than being the result of psychogenic factors, but as yet the precise cause or causes of autism are unknown. One thing that is clearer is that the condition has a genetic component. This does not mean that it only occurs among children of people who themselves have autism. However, if a mother has one child with autism then the chances of a subsequent child having autism are increased approximately 50-fold – although of course this is still relatively unlikely.

The absence of a clearly specified biological cause of autism means that the condition is currently diagnosed on the basis of individuals' behavior. The term 'autism', which comes from the Greek word *autos* for 'self', was first used to refer to the condition by an American clinician, Leo Kanner. Writing in 1943, Kanner identified the key feature of 'autistic aloneness' among his patients, describing their apparent reluctance to engage in social interaction with other people. At approximately the same time, and independently of Kanner, an Austrian physician, Hans Asperger, identified 'autistic psychopathy' among a sample of children showing similar patterns of social peculiarity.

Difficulties in socialization are now seen as one of the key behavioral features of autism, along with problems of communication and imagination, and this 'triad' of impairments forms the basis of most current diagnostic schemes. Problems in *socialization* are seen in individuals' reluctance or inability to engage in social interactions with others. Some individuals with autism do attempt to talk and interact with other children and adults, but often do so clumsily, without a real awareness of the social nuances that underpin our normal everyday contact with others. Problems of *communication* often take the form of severe language delay. Those individuals with autism who have good language skills still have difficulties in understanding subtle aspects of speech, such as the use of irony, metaphor, or jokes, and as a result can often appear rude or blunt when they speak to people. Finally, problems of *imagination* are reflected in the inflexibility and repetitive nature of thoughts and actions. Younger individuals with autism tend not to engage in pretend play, and may show repetitive behaviors such as hand-flapping or rocking. Older individuals tend to be inflexible and like to stick to precise routines. Individuals with autism often develop intense, narrow interests, usually based around predictable or repetitive themes, such as an interest in bus timetables.

Two other aspects of the condition are also worth noting. First, the majority of individuals with autism suffer from a degree of intellectual handicap, which in some cases can severely affect day-to-day functioning. However, it is certainly possible to have autism and to be of normal, or above average, intelligence. The children identified by Hans Asperger had a higher level of intelligence than those seen by Leo Kanner, and today the term 'Asperger syndrome' refers to a condition on the autism spectrum, but which is not associated with mental disability. However, it is not entirely clear whether these two conditions are really distinguishable, and the characteristics which might differentiate them (lack of language

or cognitive delay) are a subject of current debate. A second point to emphasize is that autism is characterized by strengths as well as weaknesses. In addition to their problems, individuals with autism perform well in certain (nonsocial) areas, described below.

THEORY OF MIND

Arguably, the most influential psychological explanation of autism at present is the 'theory of mind deficit' hypothesis. The term 'theory of mind' refers to our normal ability to predict and explain what others are doing on the basis of their beliefs and desires. For example, if we see someone leave their house, walk down the road, stop, check the pockets of their coat, turn around, and re-enter their house, then we assume that they have realized that they have forgotten something which they believe to be still inside the house. On the basis of people's behavior we infer what they are thinking, and equally, if we know what people are thinking we can predict what they will do.

Psychologists often assess individuals' theory of mind by asking them to predict what someone will do on the basis of a 'false belief'. For example, if someone doesn't see that an object is moved from one location to another, they will incorrectly believe that it is still in the original location. Typically developing children younger than around four years of age fail to appreciate that someone in this situation will have a false belief, and instead predict that they will look for the object where the child themselves knows it to be. Around the age of four children come to realize that others can have beliefs which differ from their own – an important marker of theory of mind.

Many studies have shown that individuals with autism have severe difficulties on this kind of task, even when they are much older than four years of age or have intellectual abilities well above the four-year-old level. The majority of individuals fail to appreciate that others can have false beliefs, and those that do pass this kind of test show more subtle problems in 'reading other people's minds'. This has led to the claim that autism is associated with a failure to acquire a theory of mind, or at least, is linked to severely delayed acquisition of this ability.

A major strength of this hypothesis is its potential to explain the triad of symptoms seen in autism. Problems of socialization are the result of a failure to appreciate what motivates social interaction, as most of our dealings with others rest on an appreciation of what people know or don't know, and what they want or don't want. Similarly, communication requires an understanding that others intend to communicate ideas to us, that others' beliefs can be changed by what you tell them, and that others may or may not know what you know. Some of the problems in imagination may arise from an inability to make sense of the mental state of 'pretence'. It has also been suggested that repetitive behaviors may reflect an attempt to impose order on what is, to individuals with autism, a confusing and unpredictable social world. However, there is no direct evidence to support this suggestion, and while this may explain a preference for routines among individuals with autism it is not clear how a 'theory of mind' problem would lead to more basic repetitive behaviors such as hand-flapping.

EXECUTIVE FUNCTION

The theory of mind hypothesis can therefore account for many of the features of autism, particularly problems in socialization and communication, but the explanation it offers for problems of imaginative flexibility is less strong. Instead, lack of imagination and inflexibility appear more likely to be related to problems of 'executive functioning' which are also thought to be associated with the condition. The psychological notion of executive function concerns our ability to control our actions. In the same way that a chief executive in a company guides the 'behavior' of the company by instigating procedures, stopping other actions, monitoring progress, and planning for the future, so we need executive control to allow us to consciously control our actions, and to prevent us from making inappropriate automatic responses. This ability appears to be linked to the frontal regions of the brain, as individuals who have suffered damage to these regions become impulsive and show inappropriate repetitive behaviors. Individuals with autism often show similar problems, and make impulsive and inappropriate responses on the kinds of tasks used to assess executive control. There is also some evidence of frontal lobe abnormalities in individuals with autism (see below).

SAVANT ABILITIES AND CENTRAL COHERENCE

The theory of mind account and executive function theory struggle to explain why individuals with autism show strengths in certain areas, as noted above. One example of this is the 'savant abilities' seen in a small minority of individuals with autism.

This term refers to skills that are far superior to what would be expected given an individual's general level of intellectual ability. For example, some individuals with autism can tell you the day of the week that corresponds to any given date – for example, the 3rd of October 1907 was a Thursday – even though they might find simple maths problems difficult. Other individuals with autism have an incredible memory for music and can play a piece note-perfect after hearing it only once. Others have remarkably precise drawing abilities, and can recreate complex scenes accurately from memory.

Savant abilities are seen in only a few individuals with autism, but most, if not all, individuals show strengths in visual and spatial areas, rote memory, or attention to detail. Many people with autism are good at doing jigsaw puzzles, and individuals with autism perform relatively well on psychological tests that require them to look for details in a complicated visual image. These strengths are thought to relate to a particular bias among individuals with autism. When ordinary people are presented with a visual image or a story, they typically remember the overall pattern of the picture, or the gist of the story, at the expense of the details. In other words they focus on the 'whole' and not the 'parts'. This tendency has been termed a 'drive for central coherence'. In contrast, individuals with autism focus on the parts of a stimulus and not the whole, and are said to have 'weak central coherence'. They therefore find it difficult to extract the overall meaning from complex information, but are very good at perceiving and remembering the details of this information.

This bias towards parts rather than wholes may explain some of the savant skills described above. In some of these cases it may be that perceiving information in terms of its constituent parts is the best way to remember it accurately. For example, if an individual perceives and remembers a visual image in terms of every individual line that makes up the picture, rather than by remembering the overall pattern of the image, then they may be able to recreate it in great detail.

NEUROLOGICAL UNDERPINNINGS

The exact brain basis of autism is as yet unclear, despite several decades of investigation. Many brain regions have been proposed as the site of abnormality, and studies in this area have produced somewhat contradictory findings, perhaps due to differences of participants, comparison groups, and techniques employed. As a result, there is as yet little agreement as to what differences might be specific and universal to the brains of people with autism. Current suggestions for the site of key abnormalities include the cerebellum and parietal cortex, which have been linked to attentional control; the amygdala and limbic system, important in processing of emotional information; and the prefrontal cortex, responsible for higher-order control functions such as planning and flexibility. There is also a suggestion of greater cell density and larger, heavier brains in autism, perhaps reflecting a failure of synaptic pruning, thought to be an important part of normal brain maturation. Future progress in this area may be made using functional brain imaging techniques.

Studies of the brain basis of normal theory of mind have begun to suggest specific regions for further investigation in autism. Specifically, medial and orbital regions of the frontal lobes, the amygdala, and temporo-parietal regions have all been shown to be more active during theory of mind tasks than during control tests. Recent research suggests that some of these regions (specifically the amygdala, and the medial-frontal region) are not activated when people with autism attempt theory of mind tasks. Future brain scanning studies with children with autism may clarify the role of these and other brain regions in the development of the psychological characteristics of the condition. At present, however, biological or genetic therapy appears a long way off, and the most effective current interventions are educational and behavioral.

Autism

Introductory article

Karen Pierce, University of California, San Diego, California, USA
Eric Courchesne, University of California, San Diego, California, USA

CONTENTS

Autism is a developmental disorder, five times more common in males, with clinical onset during the first years of life. It is characterized by abnormalities in social behavior, language, and cognition, and is now known to be biological rather than psychogenic in origin.

INTRODUCTION

Autism is a pervasive developmental disorder, affecting males five times as often as females, with clinical onset during the first years of life. The prevalence is approximately 1 out of every 600 live births. This biological disorder is characterized by abnormalities in social behavior, language, cognition, and environmental interests that persist throughout the affected individual's lifetime. Although symptoms are probably mediated by diverse brain defects, no physical abnormalities are apparent in individuals with this disorder.

BEHAVIORAL SYMPTOMS OF AUTISM

Social Behavior

One of the first indicators of social abnormality in autism is a deficit in the ability to engage in joint social attention, which in normal infants is the merging of attention between two people and an object or activity of interest. Joint social attention is normally achieved by 14 months of age, and is an important precursor to both social and language development. The absence of such a skill in autism has thus been implicated as fundamental to the cascade of developmental problems that ensue. As the autistic toddler matures, other social abnormalities become apparent, such as low rates of eye contact and reciprocal social interaction, and difficulties in identifying and interpreting the emotions of others. Social abnormalities in autism have often been referred to as the hallmark of the disorder, probably because such abnormalities are not only severe, but also obvious in affected individuals.

Language

Approximately 50% of all individuals with autism fail to develop functional speech; in those who do, language is characterized by several abnormalities including pronoun reversals (saying 'he went to the market' instead of 'I went to the market'), use of neologisms (nonsensical or made-up words), stereotyped or rigid speech and abnormalities in intonation. The speech of autistic individuals is also characterized by echolalia, which is the repetition of words either immediately after someone has spoken them or after a delay of hours, days, or even months. For example, an autistic individual may repeat the phrase 'How old are you?' hundreds of times in a single day, after hearing the phrase only once.

Cognition

Seventy-five per cent of autistic individuals also suffer from mental retardation, ranging from mild to severe. Since social interactions and language ability are important for learning about the world and developing cognitive skills, it has been difficult to establish whether impaired mental development in the autistic child occurs independently of the main symptoms of autism (social and language impairment) or occurs in part because of the early failure of normal social and language skills. Although it is difficult to disentangle secondary effects of early social and language impairment from mental retardation *per se*, some scientists believe that deficits in higher-order memory abilities, conceptual reasoning (e.g., categorization skills), executive function (e.g., switching between two or

more mental sets) and auditory information processing may exist as important features of this disorder.

One robust finding, however, has been in the domain of attention. Behavioral as well as functional neuroimaging studies have consistently demonstrated dysfunction in three primary attention abilities: disengaging attention from one source of information, orienting attention to a new source, and shifting attention back and forth between two separate sources of stimulus information. Autistic individuals are slow and inefficient in each of these abilities. Also, they are unable to properly adjust their 'spotlight of attention' so that they may have an excessively narrow focus of attention on visual details or an abnormally broad focus. Understanding attention deficits in autism is important because the ability to attend is required for an infant to follow the rapid and unpredictable ebb and flow of human social activity, such as words, gestures, and facial expressions. Dysfunctions in attention thus significantly interfere with the general ability to learn, as well as being likely to amplify other areas of difficulties for autistic individuals, such as language and social behavior.

Restricted and Repetitive Interests

Individuals with autism commonly display restricted, repetitive and stereotyped patterns of interests and activities. This general category of behavior manifests itself in many ways, such as an inflexible adherence to specific routines, stereotyped and repetitive motor mannerisms such as hand-flapping (Figure 1) or a preoccupation with an object or part of an object. In general, autistic individuals display a limited interest in their environment, instead focusing their attention on one specific aspect or obsessive idea (e.g., amassing facts about cars). Further, individuals with autism may insist on sameness and show distress over trivial changes in their surroundings, such as movement of a piece of furniture. Such restricted and repetitive environmental interests are likely to interfere with learning and may have significant developmental implications for autistic children, because they may miss many learning opportunities that fall outside their scope of interest. Combined with attention deficits described above, the autistic child is ill-prepared to learn from the environment.

ETIOLOGY

Autism is among the most heritable of neuropsychiatric disorders. Twin studies report pairwise concordance rates as high as 90% for monozygotic (identical) twins but only 5–10% for dizygotic (fraternal) twins, suggesting the disorder is strongly genetic. Studies of the location of chromosomal abnormalities and break points can be extremely useful in the identification and mapping of genes that predispose an individual to disease. Although chromosomal abnormalities have been reported on many chromosomes in autism, the most consistent site is on chromosome 15. For example, reports indicate a duplication in a specific region on this chromosome (15q11–13) in approximately 2–4% of autism cases. This finding has prompted scientists to look closely at this chromosome for a particular candidate gene or genes that might contribute to autism.

Figure 1. A 7-year-old girl with autism. The left picture illustrates a commonly found repetitive motor behavior in children with this disorder, known as hand-flapping. Other odd hand mannerisms such as finger posturing (right) are also common.

Another common approach in genetic studies of autism is the 'genomic screen', where the whole genome in multiplex families (families with more than one person with autism) is screened in order to identify autism susceptibility loci. As with studies of chromosomal abnormalities, genomic screening studies have reported linkage to specific locations on many chromosomes; however, the strongest evidence seems to point to linkage to chromosome 7 and also chromosome 2. Although such linkages are encouraging, the genes related to autism have not yet been identified.

In addition to genetic inquiries, the search for the causes of autism has led some researchers to suggest a viral, toxic, or teratogenic etiology. Although certain viral or teratogenic agents (e.g., environmental toxins, anticonvulsant medicines)

are known to produce brain defects similar to some of those present in autism, research has not yet shown these agents to be significant in the etiology of most individuals with autism.

CLINICAL ONSET AND COURSE

There is almost complete scientific consensus that autism is a disorder with biological onset prenatally or shortly after birth, but clinical symptoms may not be recognized until late infancy or early childhood. Prompted by their child's failure to achieve normal developmental milestones in speech, language and social behavior, most parents seek professional help when their child is aged 2–3 years. Documentation of behavioral characteristics prior to this age is therefore sparse. There is, however, some evidence based on retrospective analyses (e.g., videotapes of children at their first birthday parties) of defects in attention patterns as well as in motor behaviors such as walking or crawling in infants and toddlers with autism. As the autistic child develops, the symptoms described above become pronounced, and many children enter a specialized treatment program in the home, clinic or school setting. Treatment may take the form of behavioral intervention (e.g., repeated practice of a target skill, such as pointing, followed by reward), occupational therapy (e.g., integrating fine and gross motor skills) or pharmacological intervention (e.g., drugs that facilitate serotonin transmission). Most children with the disorder live at home with their families and attend ordinary schools, although some children (usually those with severe symptoms, including mental retardation) may be placed in residential settings under the exclusive care of professionals. As adults, however, many with the disorder move into assisted living facilities.

NEURAL DEFECTS

Interestingly, when autism was first described by Leo Kanner in 1943, people formulated the idea that autism was a psychological disorder, caused by poor parenting or other environmental factors. By the 1970s, however, scientists began to investigate biological explanations for the bizarre behaviors noted in this disorder.

Among all types of biological abnormalities in autism, evidence for defects in the structure of the brain is the strongest. This evidence comes from two primary sources: magnetic resonance imaging (MRI) and autopsy studies. Magnetic resonance imaging is a relatively new technology that allows scientists to image the living brain. The size of specific brain regions in autism can be easily obtained from MRI scans and compared with the brains of nonautistic people. Autopsy cases of autism are rare, but provide essential information not only about size, but also about more microscopic details, such as the type, density or number of individual neuronal cells, that are not possible to obtain with MRI.

Studies show that in autism most major brain structures may be affected (Figure 2); these include the frontal lobes, parietal lobes, cerebellum, brainstem, corpus callosum, basal ganglia, amygdala, and hippocampus. Within the cerebellum and cerebrum, abnormalities have been found in gray matter (where neuronal cell bodies are located) and also in white matter (which contains axons

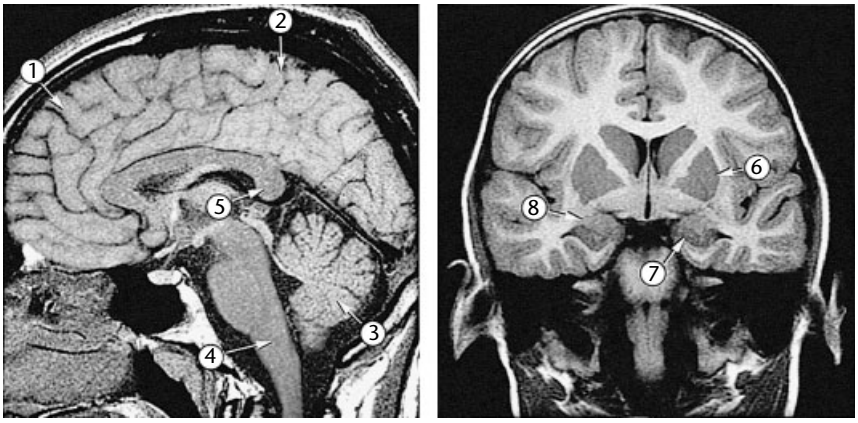

Figure 2. [*Figure is also reproduced in color section*.] Cortical and subcortical structures reported as abnormal in autism from autopsy or magnetic resonance imaging data from laboratories across the USA and Europe. 1, frontal lobes; 2, parietal lobes; 3, cerebellum; 4, brainstem; 5, corpus callosum; 6, basal ganglia; 7, hippocampus; 8, amygdala.

carrying signals from neurons in one location to those in another) in the youngest autistic children. These cerebellar and cerebral growth abnormalities are so commonly found in these patients and so extreme, that quantitative measures of them could potentially be used in clinical settings in conjunction with psychological information to assist in the diagnosis, prognosis and treatment recommendations at the youngest possible ages. Such widespread anatomic abnormality may explain why autism involves pervasive and persistent neurological and behavioral dysfunction. It is important to note, however, that not every autistic person has every neuroanatomic abnormality. For example, MRI studies suggest that approximately half of autistic adults have decreased volume of brain tissue in the parietal lobes, whereas the other half do not. One consistent neuroanatomic finding, however, has been that the cerebellum is abnormal in the majority of individuals with autism, both young and old. For example, in brain autopsy studies, 95% of all autism cases had reduced numbers of cerebellar Purkinje cells, a type of neuron crucial to cerebellar learning functions.

Certain defects in the autistic brain are signs of prenatal maldevelopment, which makes it likely that autism has a biological onset prior to birth. Such signs include, for example, incomplete formation of a group of neurons in the brainstem called the inferior olive, which is part of a learning circuit involving cerebellar Purkinje neurons.

Abnormal brain growth appears to continue after birth. For example, although whole brain volumes appear to be normal at birth, by the time an autistic child is 2–3 years old, the brain is far larger than normal. This pattern of inflated growth early on in the disorder is followed by a period of reduced growth so that eventually the normal brain outgrows the autistic brain. This illustrates the likelihood that neuroanatomic abnormalities in autism both interact and compound over time, and is consistent with the complex symptom profile seen in this disorder.

Two rules should guide interpretation of neuroanatomical findings in autism. First, apparently 'normal' measures of a particular brain structure (e.g., the parietal lobes in about 50% of autistic patients) do not necessarily imply normal function. The results from functional neuroimaging techniques such as functional magnetic resonance imaging (fMRI) suggest that several regions in the autistic brain may be functionally abnormal, in spite of appearing structurally normal. Second, 'normal' macroscopic structure does not necessarily mean normal microscopic structure. That is, given that much of what we know about the neurobiology of autism is obtained from MRI – an excellent technique for macroscopic analysis but less suitable for microscopic investigation – subtle defects in structure, such as dendritic or synaptic density, may be missed. As the number of histological cases examined increases, important and detailed questions about the neurobiology of autism will be answered.

Biochemical markers have also recently been reported in autism. For example, increased levels of several brain proteins, specifically neurotrophic factors, have been reported in the blood samples of newborn babies who were later diagnosed with autism. Neurotrophic factors are known to regulate cell growth and proliferation, and thus this finding is provocative in light of reports of increased brain growth early on in the disorder. The relationship between these two biological excesses (increased brain chemicals and increased brain growth) in autism may afford important insights into biologically based treatments and ultimately prevention of the disorder.

In conclusion, developmental brain defects, abnormal brain protein levels from birth, combined with the strong heritability component as shown by twin studies, together provide clear evidence that autism is a biological disorder, not a psychogenic one as was thought in the past.

Relationship Between Neural Defects and Behavioral Symptoms

Only a few studies have investigated the relationship between the brain and behavior in autism. Given the consistency of anatomical defects noted in the cerebellum, it should not be surprising that much of what is known about brain–behavior relationships in autism relates to this structure. For example, it is known that individuals with autism with one type of cerebellar defect, namely smaller vermis lobule VI–VII area measures, are less likely to explore their environment and more likely to engage in repetitive and stereotyped behavior than those with a more normal area measure. Similar relationships between the cerebellum and other behaviors such as attention have also been reported. For example, individuals with autism with more vermis VI–VII lobule abnormality take longer to orient their attention and make more errors when asked to respond to an attention-orienting stimulus than those with less damage. As another example, autistic patients with parietal defects are abnormally slow in disengaging their attention from a source of visual information in

order to attend to an unexpected different source of information.

Interesting work has also been done investigating the neural basis of social abnormalities in autism using fMRI. One finding has been that when autistic individuals look at the faces of strangers, neural activity in the expected brain region (i.e., the 'fusiform face area') is drastically reduced. However, when autistic subjects look at the faces of the people closest to them (e.g., mother or classmate), many brain regions are active including those essential to emotion processing. This fMRI evidence suggests that autistic individuals may not be as socially detached as once thought, and is one example of how neuroimaging techniques can add insight into our understanding of the behaviors found in autism. Many functional abnormalities, however, have been found in the autistic brain when processing more complex social stimuli, and many believe that social dysfunctions are related to abnormalities in the amygdala.

CONCLUSION

The constellation of symptoms that constitute autism are severe and affect almost every domain of functioning including language, cognition, social behavior, and environmental interests. Such symptoms are likely to be mediated by equally complex and diverse systems of biological abnormalities. Although treatment efforts have been successful at ameliorating some symptoms for some children with the disorder, currently there is no cure. Significant strides have been made, however, in understanding the neurobiology as well as the etiology of this disorder. For example, it is now known that multiple neuroanatomical sites are affected both structurally and functionally in autism, brain chemical levels are abnormal at birth, and some individuals present defects at the chromosomal level. Such insights may lead to biologically based interventions, and ultimately prevention of this disorder.

Autobiographical Memory

Intermediate article

David Rubin, Duke University, Durham, North Carolina, USA

CONTENTS

Autobiographical memory refers to the store of memories of events that have happened to an individual.

A TAXONOMY: RECOLLECTIVE MEMORY AND AUTOBIOGRAPHICAL FACTS

There is no universally agreed definition of autobiographical memory, but there is a taxonomy based on philosophical and behavioral considerations developed by Brewer (1986, 1996) that makes many issues clear. Two factors underlie the classification: (1) whether what was recalled was a single or a repeated occurrence and (2) whether the memory involves having an image. What is often called an *autobiographical memory*, a *personal memory* or a *recollective memory* occurs when a single event is recalled that involves an image. Thus you may have a memory of typing an email at a computer on one particular occasion in which you have an image, although it may be quite vague, of the email, the computer and your surroundings. A memory of the same event without the image would be an *autobiographical fact*.

In terms of the remember/know distinction commonly used in experiments of laboratory recognition, you know that you typed the letter but you would not remember, or more precisely you do not recollect, doing so. If the memory involves an image but is not for one instance of typing a particular email, but rather of sitting in your usual surroundings typing an email the way you usually do, you would have a *generic personal memory*. If all that you remember is the fact that you generally type emails on a particular computer, then you would have a *self-schema*. The four types of memories seem different to the lay person and the courts, and for a particular event that is one of a series of similar events these four types of memories can be lost independently either with the simple passage of time or as a result of neurological damage. Experimental psychologists who studied memory strived for a long time not to make introspection or phenomenology a part of the definitions of their terms or objects of study, but as I hope Brewer's analysis demonstrates, it appears to be needed.

RECOLLECTIVE MEMORY: MEMORY FOR THE PERSONAL PAST

From the previous description, autobiographical or recollective memory can be regarded as a small subset of memory – memory for an event that comes with an accompanying image. However, when one considers what is needed in order to have an autobiographical memory, the latter becomes a synthesis of many cognitive systems that are often put to other uses. To have a recollection one needs a memory for some details of an event, a sensory image (usually visual, but often in several modalities), a spatial sense of the location of actors and objects in the event, and usually emotional connotations. One does not need a sense of when the event occurred, as this is inferred or remembered independently of the other types of information just listed (Brewer, 1986, 1996; Larsen *et al*., 1996). The sensory, spatial and emotional information must be strong enough to lead to the metacognitive judgment that you recollect, as opposed to just know, that the event occurred. Moreover, there is almost always a belief that the event really happened to you – a belief that can exist in the face of counter evidence (Brewer, 1986, 1996). For many autobiographical memories there is a coherent narrative that links the memory to one's self or life narrative and helps to organize it (Conway and Pleydell-Pearce, 2000; Habermas and Bluck, 2000). The memories may arise as a

result of a conscious search or unbidden as involuntary memories through associations with ongoing thoughts or environmental cues without effort (Berntsen, 1998). Thus much of our cognitive and emotional ability comes into play in an autobiographical memory.

The visual image, sense of reliving or recollection, and belief that are part of autobiographical memories cause problems in the real world. For example, eyewitnesses and people who recover childhood memories of trauma have a strong belief in the accuracy of their memories, but at least on some occasions these beliefs have been shown to be unjustified. Although autobiographical memory is generally accurate, there are well-documented cases in which it is not. In many cognitive tasks, people use visual imagery as a basic form of mental models – objects and their locations in images can be transformed and manipulated at will. For instance, if you see yourself in an autobiographical memory, you have transformed the view seen out of your own eyes to that seen by an outside observer (Nigro and Neisser, 1983). However, in autobiographical memory people tend to view images as permanent, unchanging and accurate photographs. Thus you can manipulate an image yet later believe that it is unchanged. The sense of recollection and the belief that one's memories are generally true add to this problem.

VIVID OR 'FLASHBULB' MEMORIES

Brown and Kulik (1977) coined the phrase *flashbulb memory* to describe vivid memories of important public events, because it suggests surprise, relatively indiscriminate although not necessarily complete illumination, and brevity. According to Brown and Kulik, flashbulb memories are 'memories for the circumstances in which one first learned of a very surprising and consequential (or emotionally arousing) event' (Brown and Kulik, 1977, p. 73). Two issues raised by Brown and Kulik's paper, namely whether flashbulb memories are different in kind from other autobiographical memories, and whether they are more accurate, have fueled much research. There is no strong evidence that flashbulb memories are a different type of memory to other recollective memories; they might be nothing more than the most extreme case of vivid recollection outside the flashbacks discussed in the section below on memory for traumatic events. Nonetheless, the extreme sense of reliving that characterizes them makes them a special and interesting topic of study and a battleground for the issue of whether recollective memories are accurate. Here it appears that flashbulb memories are often accurate, but that major distortions can occur. A common error involves recalling two different times when one 'first learned' of an event; a relatively minor error in noting where one first heard of the event can result in large differences in the details and even major points of what is recalled. For example, in reporting when they first learned of the explosion of the *Challenger* space shuttle, people who initially reported hearing about it from a person later reported, often with great clarity and confidence, that they initially learned about it by watching television (Winograd and Neisser, 1992).

AUTOBIOGRAPHICAL MEMORY FOR EMOTIONAL AND TRAUMATIC EVENTS

The relationship between emotions and autobiographical memory is complex. The literature on this issue, although as rigorous as any on autobiographical memory, produces few generalizations (Christianson and Safer, 1996). For instance, the flashbulb memory literature shows good recall of the circumstances and context in which a shocking event occurred, while studies of similarly shocking events tend to show poor recall of the context and more focus on and better recall of the central events. Whereas in diary studies pleasant events tend to be much better recalled than unpleasant ones, most studies of emotion and autobiographical memory use unpleasant events, and these studies have found that increased intensity of emotion increases recall. At more extreme levels, such as traumatic memories, concepts from clinical psychology (e.g. dissociation and repression) are often invoked.

Traumatic events often violate one's expectations, making them difficult to integrate into a life narrative. They involve strong emotions, and when they return in memories they can bring with them an overpowering and unwanted sense of reliving in the form of intrusive memories. Thus autobiographical memories for traumatic events are at the extremes of the systems for and phenomenology of autobiographical memory noted earlier. In some case, traumas lead to post-traumatic stress disorder, a syndrome that is defined by reliving, avoidance and arousal symptoms (American Psychiatric Association, 1994). The reliving symptoms can occur in the form of intrusive memories, which makes autobiographical memory part of the diagnosis and, for the patient, part of the problem. The intrusive memories may occur as flashbacks – an

extreme form of flashbulb memories which takes the patient back to the time and setting of the original trauma.

THE DISTRIBUTION OF AUTOBIOGRAPHICAL MEMORY OVER THE LIFESPAN

One of the most regular quantitative findings in the literature on autobiographical memory is the distribution of memories over the lifespan. Autobiographical memories for such analyses have been obtained in many different ways, such as having people give their lives in narrative form, just list events, or provide memories of specific types (e.g. important memories, or memories cued by odors). Although the results are similar, most work has been done with word cues, so this approach is the easiest to synthesize over many studies. This method was developed by Galton over a century ago and revived by Crovitz and Schiffman (1974). Individuals give a memory to each of a set of randomly chosen words, and after all autobiographical memories have been obtained, they date them. The distribution of memories over the lifespan of undergraduates can be described as a power function of the time since the event occurred (i.e. $y = at^{-b}$) (Crovitz and Schiffman, 1974). The fits to the curve are surprisingly good, with correlations usually being greater than 0.95. If we assume that undergraduates encode an equal number of events each day of their lives, then the curve is a retention function. Because the power function is a common choice for a retention function, it appears that as a first approximation, laboratory and autobiographical memory have similar patterns of forgetting.

The data for older adults are more complex, requiring three components. The first component is the retention function, which can be described mathematically as a power function, that covers the whole lifespan, but which has its main quantitative contribution over the two most recent decades of life; for periods longer than two decades ago, it is too small to produce a measurable number of memories. The second component is childhood amnesia. This component is very stable over numerous studies, having the same basic shape irrespective of the method used to produce the data, so long as the participants come from the USA (Rubin, 2000). Based on an average of the available data, the percentage of memories from before the age of 8 years for when a person was 0, 1, 2, 3, 4, 5, 6 and 7 years old, respectively, are 0.1, 0.4, 1.7, 5.5, 13.1, 22.1, 27.0 and 30.1% (or only 2.2% before the third birthday). Figure 1 shows this component.

The third component, known as the bump, is an increase in the number of memories from when older adults were between 10 and 30 years of age compared with what would be expected from the other two components or from any monotonically

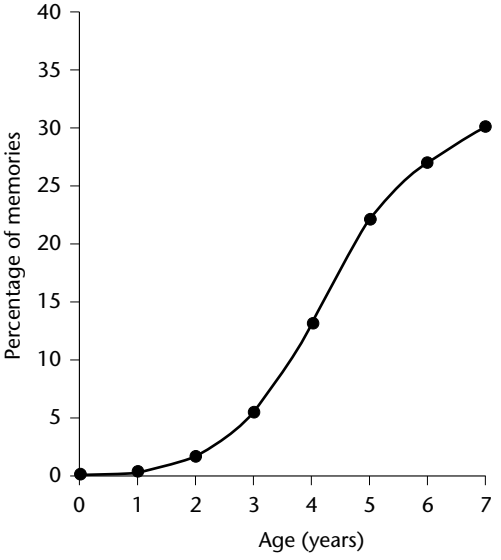

Figure 1. The distribution of 10 118 memories dated as occurring before the age of 8 years from published studies. From Rubin (2002).

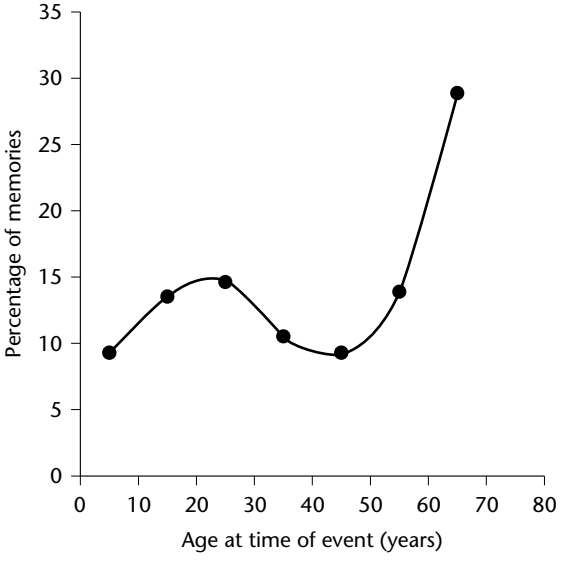

Figure 2. The distribution of autobiographical memories over the lifespan for older adults; events dated as occurring in the most recent year are excluded. From Rubin *et al*. (1986).

decreasing function. The initial description of the bump in 1986 was based on data from several laboratories. Since that time there have been consistent findings using the word cue technique with older adults (Rubin, 2002; Rubin *et al*., 1998). Minor differences exist in the shape of the distribution with changes in procedure, but the bump appears repeatedly, even for individuals. Figure 2 shows this component.

Automaticity

Introductory article

Thomas J Palmeri, Vanderbilt University, Nashville, Tennessee, USA

CONTENTS

Automaticity refers to the way we perform some mental tasks quickly and effortlessly, with little thought or conscious intention. Automatic processes are contrasted with deliberate, attention-demanding, conscious, controlled aspects of cognition.

INTRODUCTION

Try to think back to when you first learned how to drive a car. Your primary aim was to steer the car clear of other vehicles, pedestrians, and trees – a difficult task by itself. But you also had to control the pressure applied to the accelerator pedal to keep within posted speed limits. You needed occasionally to apply the brake to obey traffic signals and to avoid plowing into the car in front of you. Added to this, if you first learned to drive a car with a manual transmission, you had to decide when to change gear and then you needed to coordinate the complex movements involved in doing so – releasing the accelerator pedal, depressing the clutch, shifting to the appropriate gear, carefully releasing the clutch while applying some gas. And you had to do this while continuing to pay attention to the road ahead. On top of that, you probably had to linguistically process the commands, pleas, and screams of the poor soul who (perhaps regrettably) agreed to teach you how to drive. You had to direct all your mental energies to controlling and coordinating the complex sequence of movements involved in safely driving a car. Trying to simultaneously steer, accelerate, brake, shift, and listen was an exceedingly difficult task.

Contrast this scenario with how you may be able to drive after many years of practice. On long trips, you find yourself daydreaming and may not even remember what happened during the last several uneventful miles of highway driving. Shifting gears becomes one smooth continuous action. Indeed, breaking up this complex action into its component parts may require some deliberate thought – in fact, on my initial draft of the previous paragraph, I forgot that the first critical step in shifting was to release the accelerator pedal; this is something I have done thousands of times during my twenty years of driving cars with manual transmissions, but this basic action did not initially come to mind when I tried consciously to decompose the act of shifting gears. Experienced drivers use so few mental 'resources' that some people can drink coffee, talk on a cellular phone, and groom themselves while driving at high speeds on a congested expressway. Things are fine until something unexpected happens – another distracted driver veers into their lane or someone stops very abruptly ahead – now those resources diverted to drinking, talking, and grooming are not available to take immediate action to avert a serious accident.

That effortless way that we perform the various components of skilled actions, such as driving a car, is termed *automaticity*. Many routine daily events become so automatic that we may seem unconscious of them – how many times have I lathered my hair this morning, did I remember to put the freshly ground coffee in the coffee maker, have I checked my mailbox yet this morning? Literate adults read automatically – try not to read the billboards and signs that bombard you when driving through suburban commercial developments. When skilled at playing a musical instrument, reading musical notation, translating notes into finger and hand movements, controlling breathing and embouchure (mouth position), are all automatized procedures, allowing the musician to focus on higher levels of musicality such as style, phrasing, and coordination with the conductor and other musicians. Skilled professionals automatically execute complex tasks that demand years of training. Experienced radiologists may be able to tell automatically, at a glance, whether a patient has a benign growth or a malignant tumor.

Experienced pilots control complex aircraft automatically. Landing a commercial jetliner in good weather is performed with nearly the same fluency as driving to the neighborhood grocery store. This automaticity allows the pilot to monitor for unexpected events – an unauthorized aircraft on the runway, an approaching flock of geese, an engine fire, or wind sheer – and be able to take corrective action immediately to avert potential disaster.

This article describes the properties that distinguish automatic processes from those that require conscious mental control, describes factors necessary for achieving automaticity, illustrates the effects of automaticity with some classic experimental paradigms, and describes some psychological models of the acquisition of automaticity.

CHARACTERISTICS OF AUTOMATIC PROCESSES

A number of characteristics have been emphasized to distinguish *automatic processes* from those that require some kind of overt mental control, what have been referred to as *controlled processes*. Theorists disagree on what particular characteristics are most important for describing a process as being automatic, and disagree on whether some particular properties appropriately characterize automaticity at all. In addition, some theorists have argued that perhaps the concept of automaticity itself should be abandoned entirely, since no cognitive process is ever truly automatic given most lists of critical characteristics. Automaticity is a current topic of active research in the cognitive sciences, and ideas of how best to characterize automatic processing are still evolving.

Table 1. Some proposed characteristics of automatic and controlled processes

Automatic processes	*Controlled processes*
obligatory	intentional
stimulus-driven	executive-driven
stereotypic	reconfigurable
rigid	flexible
no monitoring	monitoring
no dual-task interference	dual-task interference
parallel	serial
well practiced	novel
expert	novice
fast	slow
effortless	effort
unconscious	conscious
no attention	attention

The aim of this section is to survey most of the various characteristics of automaticity that have been proposed. These characteristics, summarized in Table 1, will be elaborated upon below. These characteristics should certainly not be considered independent dimensions of automatic processes because many of them may overlap in some respects.

- Automatic processes are *obligatory*. Given the presence of particular stimuli within particular contexts, automatic processes can execute without the conscious intention of the individual. Automatic processes seem to occur reflexively. Controlled processes require conscious intention to become initiated.
- For this reason, automatic processes are said to be *stimulus-driven*. Given the appropriate triggering conditions, automatic processes execute without intention. Controlled processes are intentionally initiated by the individual, often with the guidance of central executive processes.
- Automatic processes are often *rigid* and *stereotypic*. Controlled processes can be reconfigured to deal with novel events, allowing for a far greater degree of flexibility.
- Once initiated, automatic processes require *no monitoring*. They run to completion without any need for overt executive control. Controlled processes require monitoring, and distractions can lead to breakdowns in performance.
- Automatic processes are *free from dual-task interference*; that is, automatic processes are not influenced by other tasks that are executed concurrently. Controlled processes suffer from dual-task interference. It is often extremely difficult to perform more than one controlled process at the same time.
- Because automatic processes can execute simultaneously, they are said to be processed in *parallel*. Not only can independent automatic processes be executed in parallel, but the various component processes of a complex skill may overlap one another in a parallel manner. Controlled processes execute serially. They are processed one step at a time and cannot be processed simultaneously.
- Many automatic cognitive processes are *well practiced*. Controlled processes may be novel or less practiced.
- Automatic processes often characterize *expert* performance. Controlled processes often characterize novice performance.
- Because automatic processes can be performed in parallel without conscious monitoring, automatic processes are often *fast* compared to controlled processes.
- Automatic processes seem *effortless*. Controlled processes require mental effort.
- Automaticity is often discussed in the context of consciousness. Automatic processes may be *unconscious*. Controlled processes are conscious.
- Automaticity is also often discussed in the context of attention. Automatic processes may require *no attention*. Controlled processes do require attention.

FACTORS NECESSARY FOR AUTOMATIC PROCESSES

Some processes may be automatic because the human brain is equipped with special-purpose neural mechanisms for carrying out certain critical aspects of perception and cognition. Such automatic processes are obligatory because a specialized neural 'module' operates autonomously, triggered by particular stimulus events in the environment. These are hard-wired mechanisms, making them rigid and stereotypic. Because these modules operate independently, they are not influenced by other concurrent processes operating within other parts of the brain, they do not require monitoring, they operate unconsciously, and they require no overt deployment of attentional resources.

Let us illustrate an example of an automatic process that may reflect the operation of one such hard-wired perceptual mechanism. Search for a yellow **X** in each panel of Figure 1. The target automatically 'pops out' from the distractors in the left panel but an active search is required to locate the target among the distractors in the right panel. In the left panel, the yellow **X** differs from the red **X**s by a single feature, but in the right panel, the yellow **X** differs from the yellow **O**s and red **X**s by the particular combination of color and form features. Salient singleton features are thought to pop out automatically because of the way early stages of the visual system process elementary visual information. Indeed, visual search tasks have often been used to distinguish automatic, pre-conscious processing of elementary visual features from the more high-level, attention-demanding processing of conjunctions of multiple visual features necessary for object recognition. Similarly, we may also automatically notice other kinds of perceptual events such as abrupt onsets of visual stimuli (a flash of lightning), auditory stimuli (a clap of thunder), or somatosensory stimuli (a crawling insect), because our perceptual systems may be hard-wired to process sudden unexpected changes in the environment automatically. So some aspects of perception and cognition may be automatic, and truly reflexive in nature, because there exist special-purpose neural mechanisms that operate autonomously, below the level of conscious awareness and control.

Clearly there do not exist innate hard-wired mechanisms for reading a book, driving an automobile, or flying an airplane. Yet people can become automatic at the elements of these tasks with sufficient practice. Therefore, a great deal of automaticity must be learned. How can a process go from being one that requires overt cognitive control to one that is automatic? And are there limitations on what kinds of tasks can become automatized?

For most aspects of human cognition that can become automatized, no one achieves automaticity without a great deal of practice. But some tasks may become automatized more quickly than others. Clearly, a simple task may be automatized more quickly than a complex task. Some real-life tasks may take only a few hours of practice to become automatized. Others require many years of training. But complexity is not the only factor, nor the most critical factor in determining how rapidly a task can become automatized.

To illustrate, let us consider another example of a search task that has been used to study the development of automaticity. The visual display can contain between one and four letters (call this variable the display size, D). You can be asked to search for between one and four possible target letters (call this variable the memory set size, M). The task is to decide whether a target is present or absent in each display as quickly as possible without making any errors. The time to make a correct response will be recorded. A display size of one ($D = 1$) and a memory set size of one ($M = 1$) is a relatively easy search. As shown in the top of Figure 2, if the target is an **X**, the 'search' is simply a matter of deciding whether the single presented letter on each display is an **X** or not. As the number of items in the display is increased, the task gets harder, and as the number of items in the memory set increases, the task gets harder. As shown in the bottom of Figure 2, suppose I tell you that the target memory set is now **T**, **L**, **Z**, and **V** ($M = 4$). Each display will contain four letters ($D = 4$) and you must decide if any of those four letters is one of the four target letters in the memory set. This search is quite hard. To accomplish this task, people generally search through each item in the display one at a time and compare it with each item in the memory set one at a time until a target is found. As such, search times increase systematically as a function of both the display size and the memory set size. This is a slow, deliberate, attention-demanding, serial search process.

Can this controlled search become automatized through training? Imagine that the set of targets and distractors changes throughout training such that a target on one trial may be a distractor on another trial. In such *varied mapping* conditions, it is very difficult, if not impossible, for the search task ever to become automatized, even with

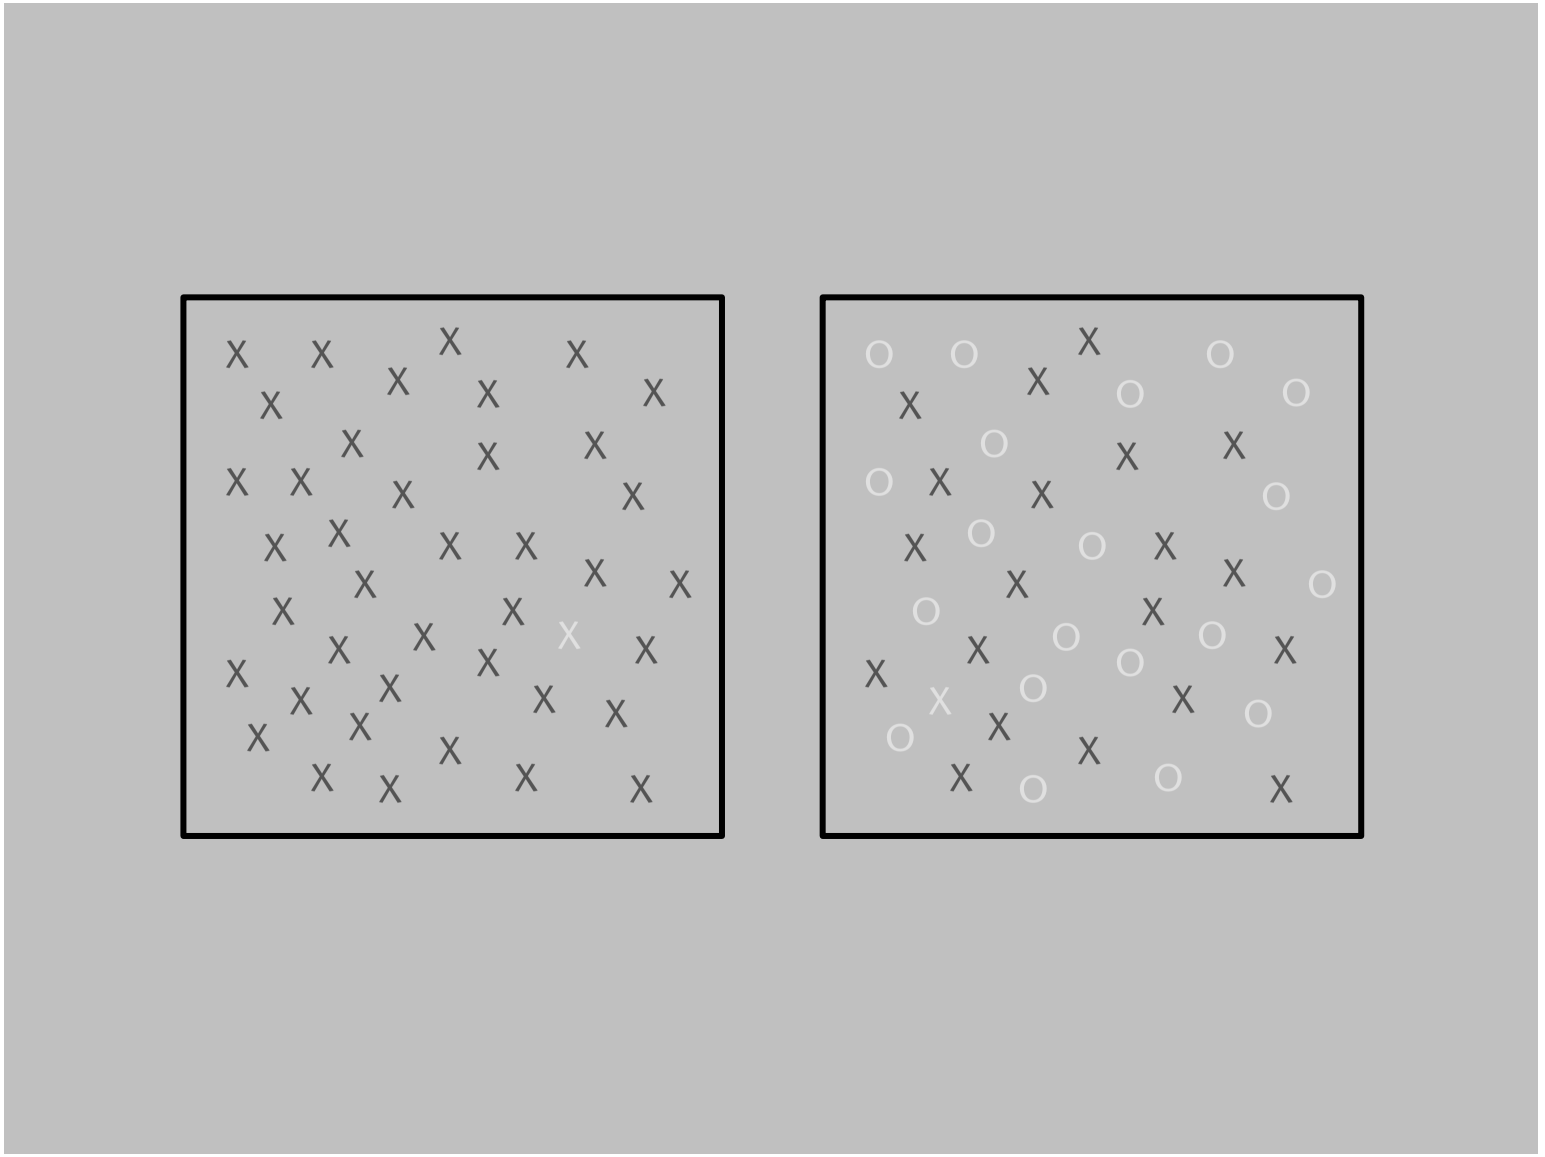

Figure 1. [*Figure is also reproduced in color section.*] Find the yellow **X**. The left panel illustrates a feature search task in which the target automatically 'pops out' from the field of distracters. The right panel illustrates a conjunction search task in which the target must be actively searched for with deliberate shifts of attention.

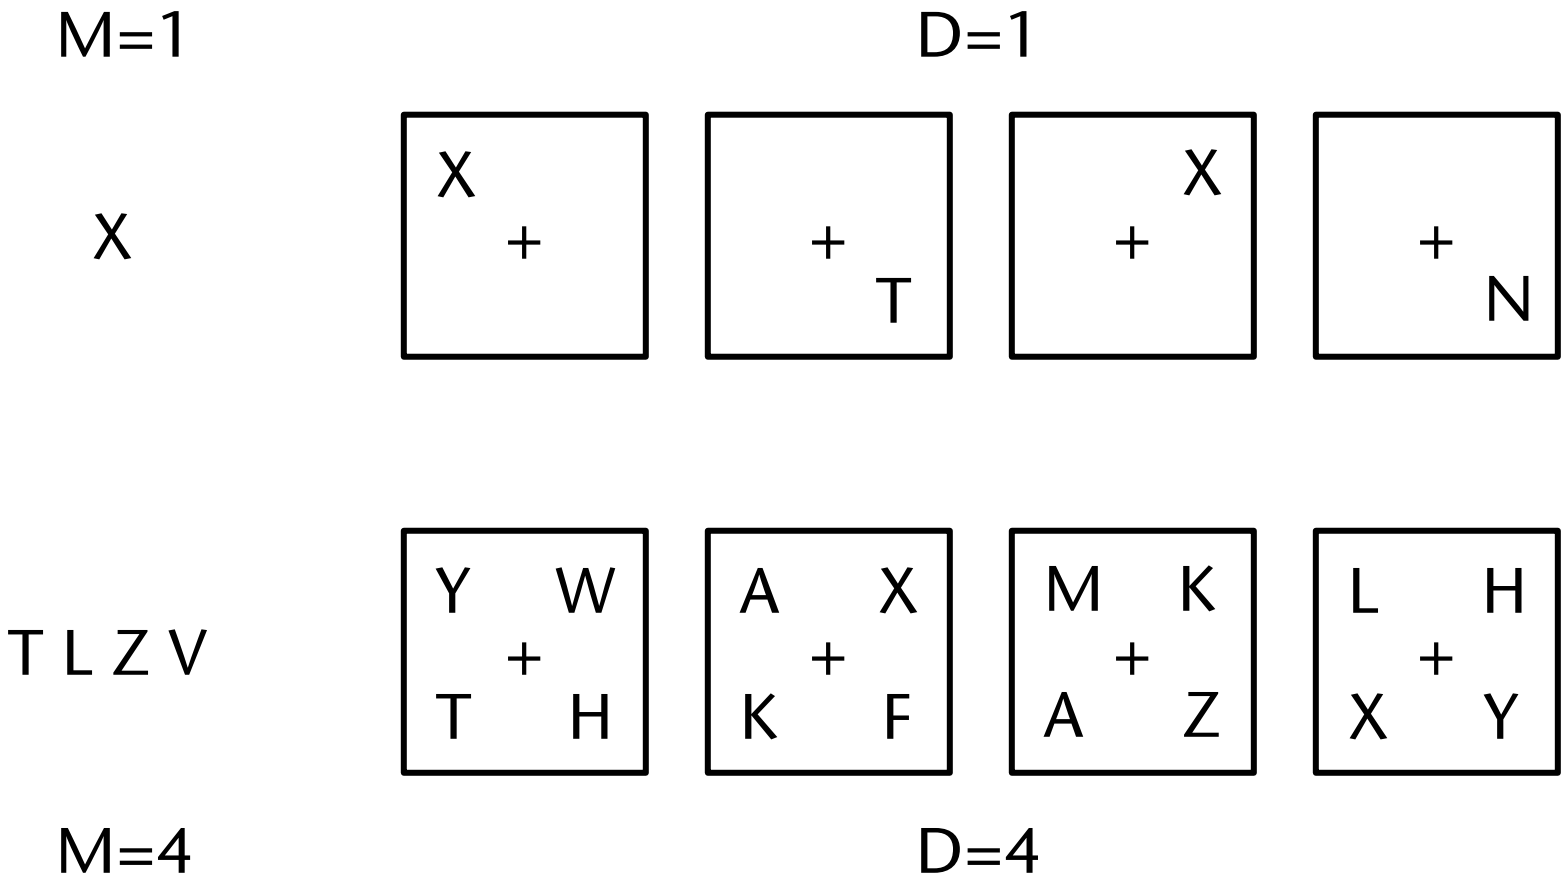

Figure 2. Illustration of search task that manipulates display size (D) and memory set size (M). The top search has a single target (M = 1) and a single display item on every trial (D = 1). The bottom search has four possible targets (M = 4) and four display items on every trial (D = 4). The task is to detect a target as quickly as possible without making errors.

extended practice over several weeks. So practice by itself is not guaranteed to produce an automatic process.

Instead imagine that the set of targets and distractors remains consistent, such that the targets must be drawn from one set of letters and the distractors must be drawn from a different set of letters, and this differentiation is maintained throughout the entire course of training. In such *consistent mapping* conditions, automaticity can be achieved with practice. Indeed, after extended practice, the time taken to search for targets does not vary with display size or memory set size. That is, a target pops out from the display much like the color pop-out shown in the left panel of Figure 1. But this is a learned automaticity, not a hard-wired one. This automaticity is immune to dual-task interference. This automaticity is rigid and inflexible in that switching to a varied mapping condition causes the search to revert back to a slow, deliberate, attention-demanding, serial process. Moreover, switching targets to distracters and distracters to targets causes performance to become even worse than it was before any training whatsoever, and it takes a long time to 'unlearn' the original automatization of target searches. So one important criterion for developing automaticity is that there is a consistent mapping between stimuli and responses. This may be one reason for the stimulus-driven nature of much automatic processing.

STROOP INTERFERENCE AND OTHER RELATED MEASURES

A different manifestation of automaticity can be seen in the classic Stroop effect. Named after John Ridley Stroop, the psychologist who developed it as part of his doctoral dissertation in the 1930s, the Stroop task has been used in thousands of experiments to study automaticity. First, find a stopwatch or a clock with a second hand. Now, time how long it takes you to *name the ink color* of the words in the first column of Figure 3 (i.e. BLUE, RED, PURPLE, etc.) – name the ink color, don't read the words. Next, time how long it takes to name the ink colors in the second column (i.e. RED, BLUE, ORANGE, etc.). And then do the same with the third column (i.e. PINK, RED, YELLOW, etc.). In all cases, try to respond as quickly as possible without making errors.

The classic Stroop interference effect is that the identity of the word can have a large effect on the speed of color naming. In the first column, the words themselves have no color association. In the second column, each word is congruent with its ink color, such as 'red' in RED ink or 'green' in GREEN ink. People are generally a bit faster to name the colors in the second column (congruent condition) than to name the colors in the first column (control condition). In the third column, each word is incongruent with its ink color, such as 'red' in GREEN ink or 'blue' in YELLOW ink. People are generally far slower to name the colors in the third column (incongruent condition) than to name the colors in the other columns. In the original paper by Stroop, subjects took nearly twice as long to name colors in the incongruent condition than in the control condition, a finding that has since been replicated thousands of times across numerous experimental variations. Even without a stopwatch, you surely found naming ink colors in the third column quite difficult and perhaps a bit frustrating. This is the fundamental Stroop interference effect.

Stroop interference is not simply caused by having an incongruency between words and their ink color. Time how long it takes you to *read the words* in the first column of Figure 3 (i.e. TRUCK, HOUSE, GRASS, etc.). Then time how long it takes to read the words in the second column (i.e. RED, BLUE, ORANGE, etc.). Then do the same with the third column (i.e. GREEN, PINK, BLUE, etc.). Ink color has little or no effect on the speed of reading words. Even for color words like 'red', the speed of word reading is not influenced by whether the word 'red' is written in RED ink or GREEN ink.

Stroop interference is asymmetric. In the incongruent condition, words interfere with color naming but colors do not interfere with word reading. One acknowledged explanation for this is that word reading is a more highly automatized process than color naming. Word reading happens rapidly and effortlessly, without conscious intention, and cannot generally be suppressed. Naming colors requires more attention, conscious intention, and effort. Even when the task is to name the colors, and to ignore the words, word reading happens anyway, automatically, and can interfere with color naming.

The Stroop effect is not limited to interference of word reading on color naming. Figure 4 shows incongruent conditions from three variants of the Stroop task. In the first column, the task is either to read the digits (i.e. 4, 3, 5, etc.) or to count the number of digits (i.e. THREE, FIVE, FOUR, etc.). Reading digits is more automatized than counting, so digit identity interferes with counting, but the number of digits does not interfere with digit naming. In the second column, the task is either to

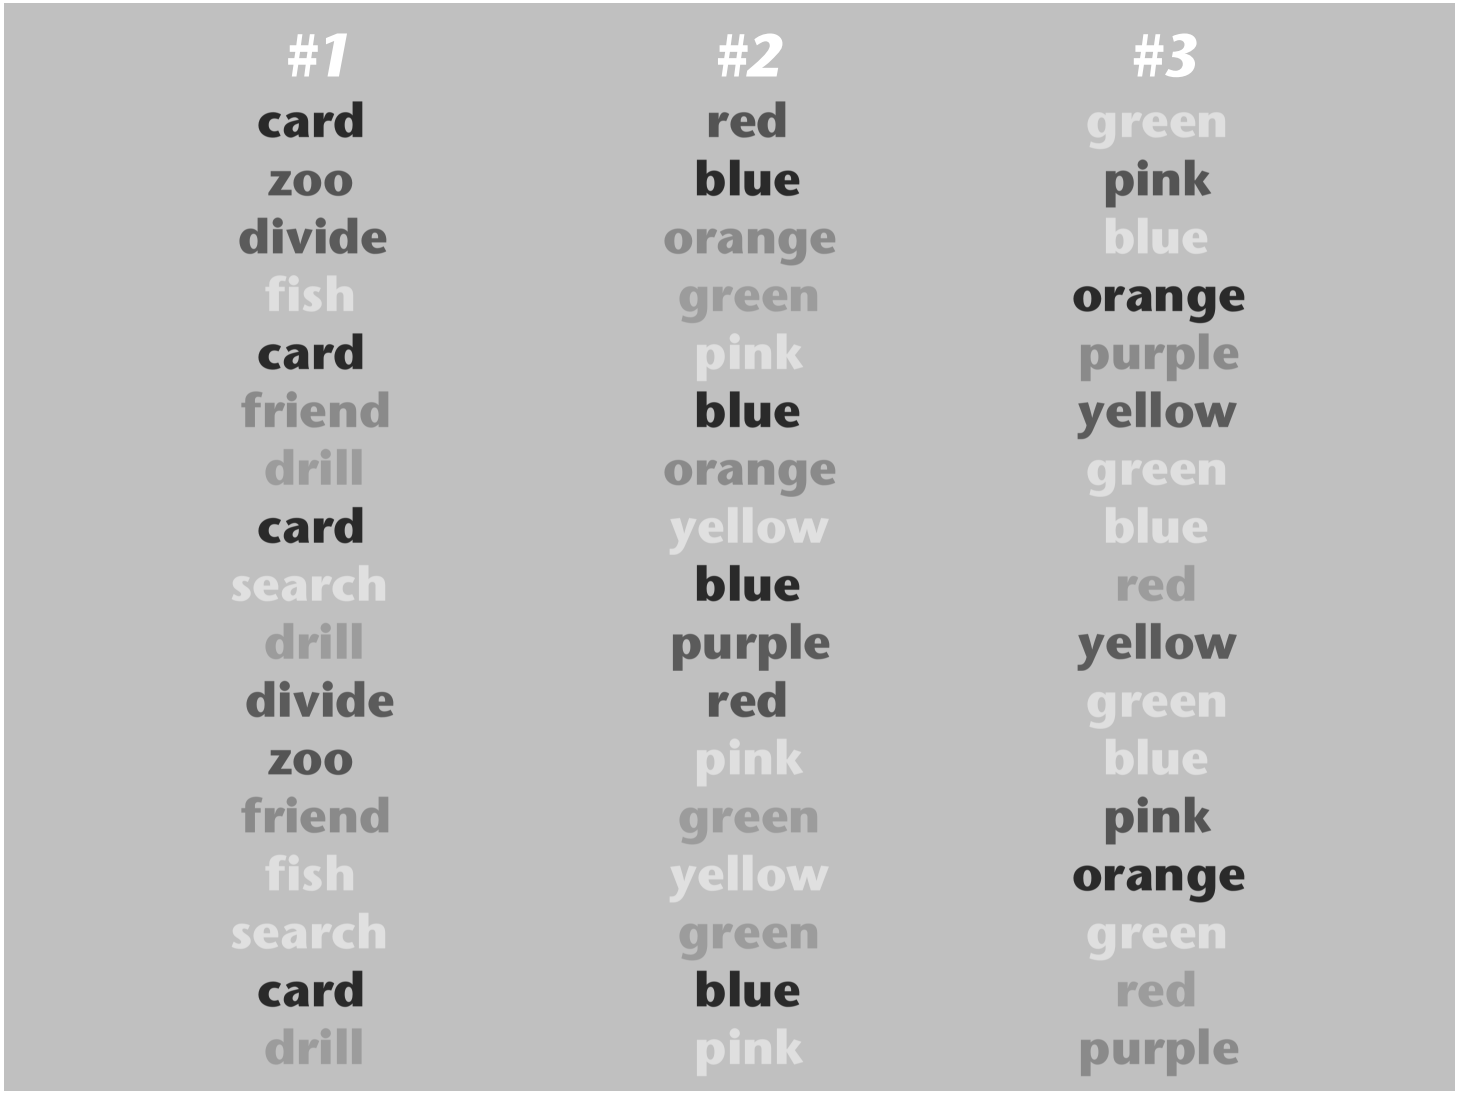

Figure 3. [*Figure is also reproduced in color section*.] Demonstration of the Stroop task. Using a stopwatch, separately time how long it takes to *name the color* of each printed word in column 1, column 2, and column 3. Then separately time how long it takes to *read each word* in column 1, column 2, and column 3. Column 1 is a *control condition* in which the word and the color bear no relationship. Column 2 is a *congruent condition* in which the word and the color match. Column 3 is an *incongruent condition* in which the word and the color mismatch.

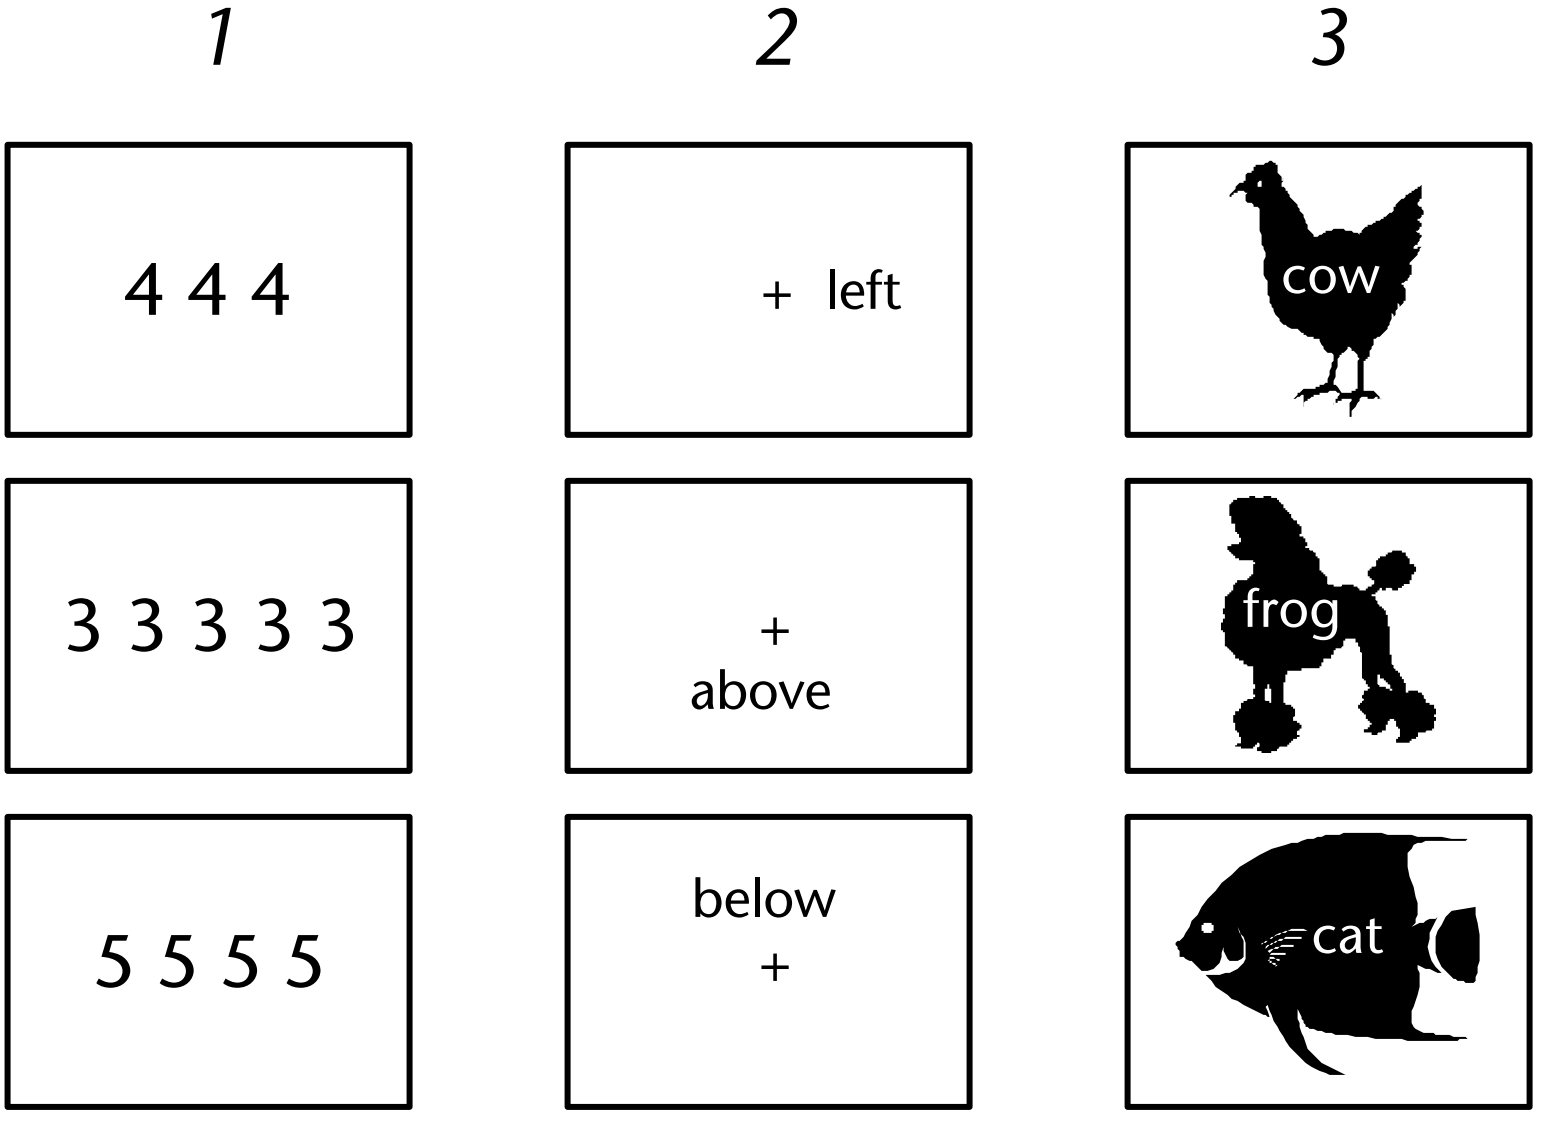

Figure 4. Illustration of incongruent conditions from three variants of the Stroop task. In column 1, you either name the digit or count the number of digits. In column 2, you either read the word or describe the spatial position of the word with respect to the central cross. In column 3, you either read the word or name the picture.

read the spatial terms (i.e. 'left', 'above', 'below', etc.) or to specify the location of the term with respect to the central cross (i.e. RIGHT, BELOW, ABOVE, etc.). Word identity interferes with specifying spatial locations, but not vice versa. Finally, in the third column, the task is either to read the animal name (i.e. 'cow', 'frog', 'cat', etc.) or to name the animal (i.e. BIRD, DOG, FISH, etc.). Word identity interferes with object naming, but not vice versa.

The classic case of Stroop interference is thought to occur because word reading is more automatic than color naming. If automaticity can be achieved through training, might it be possible to influence the direction of Stroop interference by manipulating practice with color naming? In principle, it should be possible to have color names interfere with word reading if color naming has been sufficiently practiced. But even with practice, it is extremely difficult to overcome the great prior advantage of word reading over color naming.

Instead imagine that you have just memorized that the symbols shown in Figure 5 are glyphs in some ancient language for the concepts blue, yellow, green, and red, respectively. The glyphs can be filled with various colors, creating congruent stimuli (e.g. 'blue' glyph in BLUE) or incongruent stimuli (e.g. 'red' glyph in YELLOW), as illustrated in the figure. When asked to name the color of the glyph, color naming is not influenced by the identity of the glyph, but when instead asked to name the glyph, glyph naming is strongly influenced by the color of the glyph. Because color naming is much more automatized than glyph naming, color interferes with glyph naming, but not vice versa. Now imagine that you are trained on glyph naming for several weeks, causing glyph naming to become more automatized than color naming. The direction of Stroop interference now reverses. Glyph identity interferes with color naming, but not vice versa. Results such as these suggest a continuum of automaticity, with the direction of Stroop interference a potential marker for which cognitive process is more automatized.

MODELS OF THE ACQUISITION OF AUTOMATICITY

Resource theories are based on the intuitive notion that people seem to have a limited amount of mental 'energy' that can be allocated to performing various tasks. Controlled processes require a certain amount of these limited mental resources whereas automatic processes do not. Automatic processes are fast because they are not limited by available resources. Automatic processes are effortless because mental 'effort' is proportional to the amount of resources needed to execute a process. Automatic processes are free from dual-task interference because they do not have to compete for the limited pool of resources. Automatic processes are obligatory because they do not need to wait until resources have been specifically allocated for their execution. The development of automaticity is viewed as a fundamental change in a process that makes it go from a resource-demanding controlled process to a resource-free automatic process. One criticism of resource theories has been that the learning mechanism by which processes reduce their resource demands is generally unspecified.

Another problem for resource theories is that complex patterns of interference have sometimes been observed. Some tasks interfere with one another, others do not. To deal with this complexity, some theorists have proposed that there may be multiple pools of mental resources. As an analogy, we could imagine that some processes consume electricity, other processes consume gasoline, and others consume coal. Any time that two tasks interfere with one another, they must be dipping from the same pool of limited resources. While intuitively appealing, *multiple resource theories* have been criticized as being inherently untestable assertions. Any complex pattern of task interference effects is explained *post hoc* by positing multiple pools of resources.

Instead of viewing resources as mental energy that is allocated to different tasks, resources may instead be conceptualized as specific processing components of the cognitive system that different tasks may need to share. As an analogy, we could imagine a mental toolbox, with some tasks requiring a screwdriver, others requiring a hammer, and others a saw. When two tasks need to use the same tool, they have to wait their turn. For example, working memory is limited. To the extent that two tasks both store information in working memory, they may interfere with one another. There is evidence for multiple modality-dependent working memory systems for verbal, spatial, and object information, so complex patterns of interference may be the result of different tasks placing demands on different working memory systems. To the extent that an automatic process is divorced from its reliance on working memory, it will not interfere with other processes that demand those limited processing resources.

In an extreme case, there may be some central process that must be shared by all aspects of

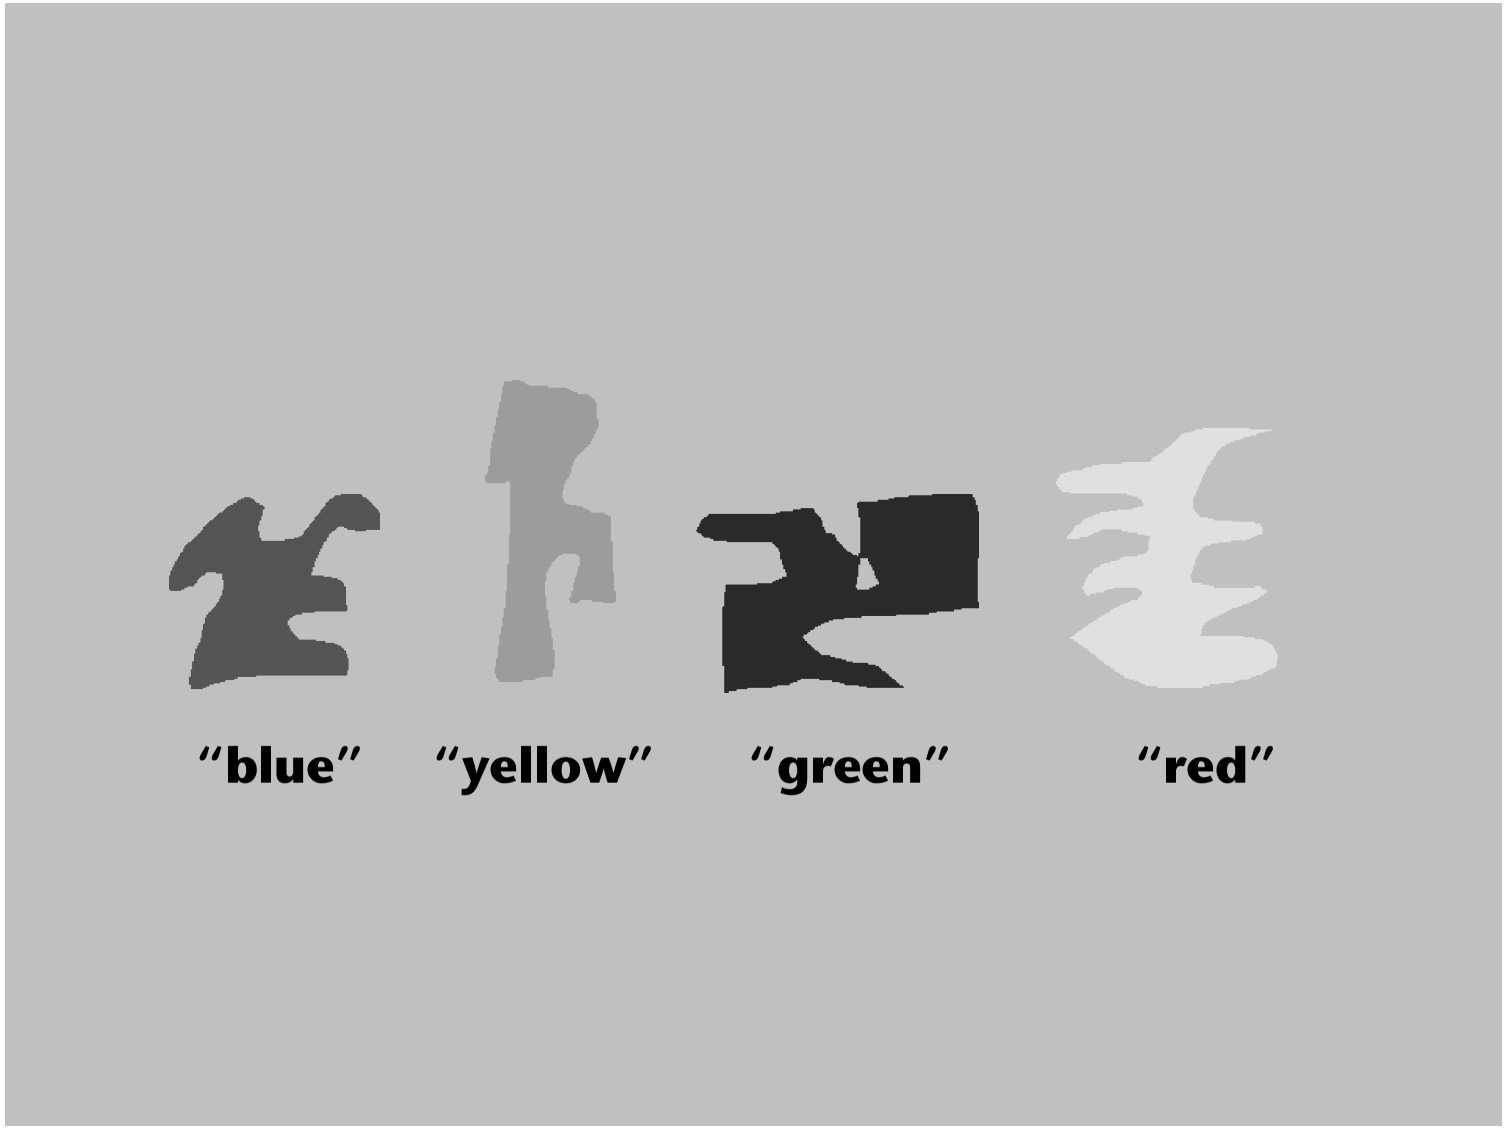

Figure 5. [*Figure is also reproduced in color section*.] Illustration of novel stimuli used to manipulate the direction of Stroop interference through training. Each shape (glyph) is associated with one of four color names that must be learned. Each shape can also be filled with one of four colors. Subjects either name the shape ('blue', 'yellow', 'green', or 'red') or name the color of the shape (RED, GREEN, BLUE, or YELLOW). Early in training, color interferes with shape naming. Later in training, shape interferes with color naming.

cognition that require selection among competing responses, what has been termed a *central bottleneck theory*. All tasks can be decomposed into a series of processing stages that extend from stimulus to response. Bottleneck theory posits that a particular one of these stages, that responsible for selecting among competing responses, can only be dedicated to one task at a time. All other stages prior to and subsequent to the response selection stage may proceed in parallel, but only one process can access response selection – other processes must wait. According to this theory, no cognitive process, no matter how highly practiced, can ever become truly automatic because all processes must share the limited response selection resource.

Our discussion of the Stroop effect should convince you that automaticity is not an all-or-none phenomenon. Word reading interferes with color naming because word reading is more automatic than color naming. But color naming interferes with shape naming because color naming is more automatic than shape naming. But with training, shape naming interferes with color naming because shape naming is now more automatic than color naming. It is not clear how a resource account could explain these asymmetric interference effects, nor how the direction of interference effects can be modulated by training. *Strength theories* represent learning in terms of the strength of association within pathways from particular stimuli to particular responses. Such theories have been implemented within a variety of frameworks from production systems to connectionist networks. The development of automaticity is seen as the strengthening of particular associations – be they production rules or connection weights – as a function of experience. Where these pathways intersect, interference can be observed. Stronger pathways interfere more with weaker pathways, leading to asymmetric interference effects.

Finally, *instance theories* propose a different account of the development of automaticity. Controlled processes are the result of the execution of some explicit algorithm whereas automatic processes are the result of memory retrieval. The development of automaticity is caused by a transition from algorithm to retrieval. When first engaged in some task, people may use an algorithm or rule to execute that behavior. For example, when first learning to add single digits, children typically adopt a strategy of starting with one of the digits and counting the requisite number of additional digits to generate the answer. Instance theory equates automaticity with memory retrieval. With experience, children (and adults) just remember that $2 + 2$ equals 4 without needing to explicitly count. Automatic processes are fast because memory retrieval is fast. Automatic processes are obligatory because memory retrieval is obligatory. Automaticity is effortless because memory retrieval seems effortless, especially compared with the execution of a multistep algorithm. Automatic processes are free from dual-task interference because a single memory retrieval offers less opportunity for interference than a multistep algorithm.

Execution of the algorithm and memory retrieval are assumed to take place concurrently, racing against one another to completion. The winner of the race determines what response is made. Early in learning, the algorithm is used because it completes before memory retrieval can finish (or because no memories can be retrieved). The development of automaticity is caused by the obligatory encoding of stimuli and responses in memory. As more memories of solutions are stored, memories can be retrieved more quickly. Thus, with experience, memory retrieval can eventually complete before the algorithm can complete. Consistent mappings are important because they yield consistent information from memory; varied mappings yield conflicting information from memory.

SUMMARY

Automatic processes are the autopilots of human cognition. They seem to execute outside our awareness and without our conscious control. They seem to execute quickly, and we may be entirely unaware of the steps involved in their execution. They can execute while we are doing other things at the same time. Some processes are automatic because our brains have evolved special-purpose mechanisms that respond without our conscious intention, and even sometimes against those intentions. Other processes can become automatic because of our experiences. Automaticity can be learned. But automaticity can be achieved only under certain circumstances: it may well be that some processes may just never become automatic, regardless of how much experience a person has had. The concept of automaticity is intimately tied with concepts of attention, consciousness, learning, and memory. Some research aims to relate attention and automaticity, with some attempts to relate both to the far more elusive concept of consciousness. Other research aims to relate the development of automaticity to what we know about learning and memory more generally, examining how they all manifest themselves across the full spectrum of human cognition.

Behavior, Genetic Influences on

Intermediate article

M Frank Norman, University of Pennsylvania, Philadelphia, Pennsylvania, USA

CONTENTS

Studies of twins have established that individual differences in intelligence, personality, and psychopathology are strongly associated with genetic variations. Environmental variations are also important.

INTRODUCTION

The program of traditional (i.e. nonmolecular) behavioral genetics is to use correlations of relatives (especially twins) to make inferences about genetic and environmental contributions to behavioral variation. There are two major conclusions from such studies. First, a substantial percentage of behavioral variation seems to be due to genetic variation. Second, although environmental variation is also important, it appears that unique, idiosyncratic, experiences are more important for behavioral variation than experiences shared by twins. Both findings represent challenges to traditional social science, the first because social science does not emphasize biological factors, and the second because the environmental factors that are the focus of social science research (parents, homes, socioeconomic status, neighborhoods, and schools) are shared by twins and are thus seen by behavioral genetics as being in a sense less potent than social science supposes. The 'in a sense' qualification is necessary since twins obviously have unique experiences with common environmental factors. A 'strict' or 'cultured' home environment may be experienced in different ways by different children (Maccoby, 2000).

TWIN STUDIES

The following text provides a moderately detailed example of a behavioral genetic analysis that supports the first and second conclusions outlined above; it exposes the weaknesses as well as the strengths of such analyses. The analysis applies to studies that include twins reared apart as well as twins reared together. Thus these studies involve twins separated early in life by adoption. Analysis of twin studies without adopted subjects is considered later.

Fundamental Equations

Behavioral genetic analyses typically lead to equations expressing correlations in terms of genetic and environmental parameters. Consideration of 'identical' (monozygotic, MZ) and 'fraternal' (dizygotic, DZ) twins reared apart (A) and together (T) leads to four equations, the character of which varies somewhat with the precise assumptions that are in force. The following set is representative:

$$r_{\mathrm{MZA}} = h^2 + d^2 + i^2 \quad (1)$$

$$r_{\mathrm{DZA}} = 0.5h^2 + 0.25d^2 \quad (2)$$

$$r_{\mathrm{MZT}} = h^2 + d^2 + i^2 + c^2_{\mathrm{MZ}} \quad (3)$$

$$r_{\mathrm{DZT}} = 0.5h^2 + 0.25d^2 + c^2_{\mathrm{DZ}} \quad (4)$$

where h^2 is the additive genetic variance, d^2 is the dominance genetic variance, i^2 is the epistatic genetic variance, c^2_{MZ} is the common or shared environmental variance for MZ twins raised together, and c^2_{DZ} is the common or shared environmental variance for DZ twins raised together. These equations instantiate the model that is the focus of this section. In the present interpretation there are four population correlations (r) on the left, identified by the subscript abbreviations defined above, and five population parameters on the right. Our objective is to use these equations to develop estimators of the parameters based on sample correlations. Before doing this, however, we must make a long digression to define the parameters and discuss the kinds of assumptions that lead to the equations.

All of these variances are relative to the total phenotypic variance of the trait under discussion. Additive genetic variance is associated, fundamentally, with the sum of effects of the gene derived

from the mother and the gene derived from the father at a single genetic locus. *Dominance* is the interaction of these effects. However, it is clear that most if not all of the traits discussed here are influenced by many genetic loci, and our h^2 and d^2 correspond to the sums of additive and dominance effects over all contributory loci. Variance i^2 associated with multilocus interaction is epistatic. Dominance and epistasis are termed 'nonadditive effects'. Remarkably, it is possible to see the signature of such low-level effects in molar correlational data.

Additive genetic variance, h^2, is called 'heritability' or 'narrow heritability'. The sum of all three genetic variances is termed 'broad heritability' and denoted h_b^2. According to eqn [1], this quantity equals r_{MZA}.

Both genetic variation and environmental variation contribute to behavioral variation. Behavioral genetics usually treats environmental variation as the sum of two uncorrelated components. The first reflects parts of the environment such as parents, home, neighborhood, and schools that are shared by twins reared together. The second represents such things as unique friends and unique experiences that are not shared. The extent of the latter is indexed by yet other parameters, u_{MZ}^2 and u_{DZ}^2. It is assumed that only shared experiences contribute to psychological similarity. That is why only shared environmental variances appear on the right in eqns [3] and [4].

Obviously, different twins may have unshared experiences with common parents, houses, neighborhoods, and schools, and such experiences would be recorded in the unshared column, if it were really necessary to tally them up. Fortunately, it is not. Although effects of particular environmental variables can be studied (e.g. Caspi *et al*., 2000), behavioral genetics can and usually does make inferences about aggregate shared and unshared environmental effects without explicitly measuring their constituents.

Measurement error (m^2) is a source of differences between twins' test scores. It is sometimes implicitly included in unshared environmental variance, but it can be separated from other sources of uniqueness if the reliability of the test is known.

Newcomers to this subject may be puzzled by the 'squares' in these parameters. The unsquared genetic and common environmental parameters are correlations of a single individual's test score with an underlying genetic or environmental component. The squares arise in correlations between relatives because the 'path' between the relatives has two links: from one relative to a common genetic or environmental factor and then on to the other relative.

Now that we have defined the parameters that appear in eqns [1] to [4], we can begin to discuss the equations themselves. The 0.5 coefficient of h^2 in eqns [2] and [4] reflects the fact that DZ twins share half their genes, on average. The 0.25 coefficient of d^2 is explained by the observation that, at a single locus with only two alleles, 0.25 is the probability that two twins receive copies of exactly the same gene from both parents, and thus inherit precisely the same genotype at this locus.

Absence of covariances on the right-hand sides reflects the assumption that all sources of variation are uncorrelated. Also absent by assumption are genotype–environment interaction and effects of assortative mating. It is easy to think of concrete environmental factors (such as parental education, in the case of cognitive ability) that are definitely correlated with children's genotype. This brings out the point that the environmental factors in our equations should not be thought of as composites of concrete, directly measurable, environmental factors, but rather as akin to regression residuals, so that they are, by construction, uncorrelated with genetic 'main effects'. It is possible that the oversimplified model instantiated in our equations may allow interactions and correlations involving concrete environmental factors to be disproportionately absorbed into genetic terms.

Substantial assortative mating is known to occur for some of the traits to which we will apply the model (e.g. cognitive ability). The main defense that can be offered for omitting it, and for our other questionable assumptions, is that the model gives an adequate fit to most of the data to which we will apply it. This is not a strong justification, since MZA twin correlations are based on relatively small numbers of twin pairs, so the corresponding tests of goodness of fit are not very powerful. Thus, successful fits can be regarded only as showing that our assumptions are probably not flagrantly inappropriate.

Fitting the Model

One's first impulse is to replace population correlations in the equations by sample correlations, and solve the resulting linear equations for the quantities on the right. The solutions would then be estimators of the corresponding population parameters. However, this is not feasible because there are five unknowns but only four equations. Fortunately, it is possible to eliminate one unknown by

reparameterization, in such a way that our ability to test interesting hypotheses is not seriously compromised. This involves appending half of d^2 to h^2 and the other half to i^2, yielding the new parameters $h_d^2 = h^2 + 0.5d^2$ and $i_d^2 = i^2 + 0.5d^2$. These parameters can respectively be called 'intermediate heritability' (since it lies between broad and narrow heritability) and 'nonadditivity'. In terms of these quantities, eqns [1] to [4] take the following attractive form:

$$r_{\mathrm{MZA}} = h_d^2 + i_d^2 \quad (5)$$

$$r_{\mathrm{DZA}} = 0.5h_d^2 \quad (6)$$

$$r_{\mathrm{MZT}} = h_d^2 + i_d^2 + c_{\mathrm{MZ}}^2 \quad (7)$$

$$r_{\mathrm{DZT}} = 0.5h_d^2 + c_{\mathrm{DZ}}^2 \quad (8)$$

These equations are easily solved for the four parameters on the right in terms of the correlations on the left, and it is somewhat amusing to apply the resulting formulas to sample correlations to obtain parameter estimates. However, this 'equation-solving' approach is a sterile exercise, since it does not yield a test of the framework within which the estimation takes place. Consequently, one does not know whether the estimates are of any interest. Thus we will proceed directly to a more modern model-fitting approach, in which we explicitly test various hypotheses about the parameters, and implicitly test the underlying framework. The specific hypotheses to be tested are:

- equal environments assumption (EEA): $c_{\mathrm{MZ}}^2 = c_{\mathrm{DZ}}^2$
- no common environmental effects: $c_{\mathrm{MZ}}^2 = c_{\mathrm{DZ}}^2 = 0$
- no nonadditive effects (NNE): $i_d^2 = 0$
- no additive or dominance effects: $h_d^2 = 0$
- no genetic effects: $h_b^2 = 0$

Note that $h_b^2 = h_d^2 + i_d^2$, so the last hypothesis is equivalent to the conjunction of the two preceding it. Note also that, if EEA fails, one expects $c_{\mathrm{MZ}}^2 > c_{\mathrm{DZ}}^2$.

Any of these hypotheses reduces the number of parameters to less than four, so eqns [5] to [8] cannot be solved exactly. Instead, one accepts approximate equality in place of exact equality, and seeks parameter values that yield the best approximate solution. Different estimation methods correspond to different overall measures of the approximation error. We will use the error function and associated tests described by Loehlin (1989) in a slightly different context. The computer programs MX and LISREL provide other approaches to model fitting (Neale and Cardon, 1992).

INTELLIGENCE AND PERSONALITY

The Swedish Adoption/Twin Study of Aging

The Swedish Adoption/Twin Study of Aging (SATSA) is a study of elderly twins. The basic design and many results are summarized by Pedersen *et al*. (1991), and twin correlations and analyses of different types of variables appear in separate papers (Pedersen *et al*., 1992; Bergeman *et al*., 1993). Table 1 summarizes the results of a reanalysis of a few variables using the approach described above.

Cognitive ability is the first principal component of a number of tests of special abilities, and is thus a variant of intelligence quotient (IQ). The next seven variables in the table are standard dimensions of personality. The type A variable is derived from the famous Framingham type A scale, which measures the degree to which an individual is hard-driving, ambitious, and feels as if he or she is under pressure. Variables 'F-Cohesion' and 'F-Control' relate to the twins' recollections of the warmth and strictness of the families in which they were raised. Bear in mind that, for twins reared apart, these were different families, so these variables explore the possibility that twins' perceptions of family warmth and strictness may, to some extent, derive from the twin instead of from the family. Variable BMI is the body mass index, a measure of fatness. This is not a personality variable, but relates to eating habits, which are of great psychological interest in connection with eating disorders.

The χ^2 and p-values in the last two columns correspond to tests of the equal environments assumption. This assumption is rejected only for the last variable, 'F-Control'. This rejection confirms that the tests of EEA are not hopelessly insensitive. The parameter estimates given in the table are optimal assuming EEA, and are thus meaningful for all variables except 'F-Control', which will not be considered further. The c^2 parameter in Table 1 is the common value of c_{MZ}^2 and c_{DZ}^2 under EEA. Asterisks refer to tests of hypotheses that the corresponding parameters are zero, with one, two, and three asterisks indicating $p < 0.05$, 0.01, and 0.001, respectively. These tests are based on increments in the χ^2 goodness of fit index, beyond its value assuming just EEA. The $u^2 + m^2$ values cannot be tested for significance within this framework, but these values are large for all variables except cognitive ability and BMI.

Table 1. Components of variation for variables in the Swedish Adoption/Twin Study of Aging

Variable	h_d^2	i_d^2	h_b^2	c^2	$u^2 + m^2$	χ^2	p
Cognitive ability	0.55***	0.24	0.79***	0.00	0.21	0.54	0.46
Extraversion	−0.02	0.40***	0.38***	0.12	0.50	2.27	0.13
Neuroticism	0.49***	−0.16	0.33***	0.04	0.63	1.81	0.18
Openness	0.38**	0.11	0.49***	−0.01	0.52	1.24	0.26
Agreeableness	−0.06	0.21	0.15	0.26**	0.59	0.00	1.00
Conscientiousness	0.08	0.21	0.30**	0.12	0.58	2.65	0.10
Impulsivity	0.25*	0.18	0.44***	−0.01	0.57	0.56	0.46
Monotony avoidance	0.27*	−0.05	0.22*	0.03	0.75	0.06	0.80

The table confirms the overall conclusions presented in the introduction, which are, in turn, consistent with those of the original SATSA papers. In 10 out of 12 cases, broad heritability is statistically significant whereas common environmentality is statistically insignificant. The reversal of this pattern for 'Agreeableness' indicates that this pattern is not forced by an artefact of the method. The very high estimate of broad heritability for cognitive ability is consonant with values obtained for IQ in other studies involving adult MZAs (Neisser *et al*., 1996).

Negative estimates arise because the χ^2 minimization routine varied $a = h_d^2$, $b = i_d^2$, etc., without restricting these quantities to positive values. In no case would the fit have been significantly worse if the negative quantity had been assumed to be zero, so the negative values should simply be regarded as negligible.

Of the 11 variables with significant h_b^2, 9 had h_d^2 but not i_d^2 significant, suggesting that genetic variation is mainly additive. One, 'Conscientiousness', had neither h_d^2 nor i_d^2 significant, leaving us little basis for inference about the distribution of broad heritability among its three components. Finally, 'Extraversion' had i_d^2 but not h_d^2 significant, suggesting that genetic variation is mainly epistatic. (Dominance and epistasis do not contribute to parent–child correlation, so they contradict the common misconception that genetic effects are always revealed by parent–child resemblance.)

We close this section with the results of analysis of a variable from the Minnesota study of twins reared apart (Bouchard *et al*., 1990), by the methods used in Table 1. There is a personality scale called 'well-being' that is, roughly speaking, a measure of happiness. For this scale, EEA was not rejected, $c^2 = -0.04$ is negligible, and $h_b^2 = 0.48$. Happiness in adults thus appears to be highly heritable (Lykken and Tellegen, 1996).

Studies Involving Only Twins Reared Together

Monozygotic twins reared apart are uniquely informative, but they are scarce. The analyses reported in Table 1 involved between 44 and 95 pairs of such twins. This leads to high variability of estimates and low power of tests. On the other hand, dizygotic and monozygotic twins reared together are plentiful, so it is not surprising that studies involving only twins reared together are the mainstay of traditional behavioral genetics. Unfortunately, the gain in precision from large samples is matched by a loss of generality due to the necessity of extra assumptions. For a feeling for the difficulties involved, consider

$$h^2_{\text{est}} = 2(r_{\text{MZT}} - r_{\text{DZT}}) \tag{9}$$

the traditional rough-and-ready estimator of heritability using sample correlations of twins reared together. For population correlations,

$$2(r_{\text{MZT}} - r_{\text{DZT}}) = h_b^2 + i_d^2 + 2\left(c^2_{\text{MZ}} - c^2_{\text{DZ}}\right) \tag{10}$$

as a consequence of eqns [7] and [8], so h^2_{est} will tend to overestimate h_b^2 when EEA fails or nonadditive effects are present.

There is a companion formula, $2r_{DZT} - r_{MZT}$, that is traditionally used to estimate common environmental variance. According to eqns [7] and [8],

$$2r_{DZT} - r_{MZT} = c_{DZ}^2 - i_d^2 - \left(c_{MZ}^2 - c_{DZ}^2\right) \qquad (11)$$

so the companion formula has a tendency to underestimate c_{DZ}^2 when EEA or NNE fails. Sizeable negative values of the companion formula strongly suggest that use of h_{est}^2 is inappropriate, but one sees many instances in the literature where this warning has not been heeded.

Modern behavioral genetics uses model-fitting techniques in place of h_{est}^2 (see, for example, Loehlin, 1992), but model-fitting analyses, like their less sophisticated predecessors, typically assume EEA and sometimes also NNE.

MENTAL ILLNESS

A characteristic feature of many studies of mental illness is a categorical 'sick versus well' classification of each patient's condition. In place of twin correlation for (say) IQ, we have concordance for (say) schizophrenia, estimating the likelihood that a second twin is affected given that the first twin is affected. Concordances carry some of the same intuitions as correlations, but they are not the kinds of correlations to which behavioral genetic theory can be directly applied.

The liability threshold model provides a simple bridge from concordances to behavioral genetics. According to this model, there is a normally distributed liability, L, to the condition under consideration, and the condition is manifested if and only if L exceeds a threshold parameter T. Assuming that the distribution of liability has a mean of zero and a standard deviation of 1, one can estimate T from the prevalence of the condition.

Assuming a bivariate normal distribution of twins' liabilities, computer programs like PRELIS can estimate the liability correlations corresponding to concordances. These are sometimes referred to as *tetrachoric* correlations, and their variances are different from those of ordinary, Pearson, correlations. Taking account of this, behavior genetic analyses of liability correlations can be done in a manner analogous to behavior genetic analyses of Pearson correlations. In particular, there are older studies that calculate h_{est}^2 from liability correlations.

Modern studies apply model-fitting techniques via LISREL or MX to twins reared together, usually assuming EEA and, often, NNE. Substantial differences between MZ and DZ liability correlations are invariably associated with substantial heritability in these analyses. Such differences have been found for autism, attention deficit hyperactivity disorder, depression, bipolar disorder, and schizophrenia (McGuffin and Martin, 1999).

There is great uncertainty concerning the extent of possible genetic contributions to bulimia and anorexia (Fairburn *et al*., 1999). Though it is not a mental illness, it is interesting to note that McGue and Lykken (1992) have reported a heritability estimate of 0.525 for liability to divorce.

THE SEARCH FOR DEFINITE GENES

Traditional behavioral genetics operates at a tremendous level of abstraction (some might call it vagueness). It provides information only about aggregate quantities, though these quantities are of considerable interest. Some results are available showing behavioral effects of specific genes. In the future, one expects increasing emphasis on studies seeking to demonstrate such effects.

Specific gene effects on behavior vary greatly in size. One imagines that many genes affect each of the personality and ability dimensions, as well as most of the psychopathologies, considered above. If many genes contribute to a dimension, most of these contributions will be small and thus relatively hard to detect.

There are a number of cases where variation at a single genetic locus has drastic effects on the organism, including mental retardation. An especially interesting case of such a single major gene effect is phenylketonuria, in which neither of the alleles at a certain locus on chromosome 12 supports production of an enzyme that breaks down phenylalanine. The consequent build-up of the latter substance in the brain causes mental retardation. Such build-up and retardation can be prevented by a special diet. Since the genetic deficiency leads to a behavioral deficiency only in the presence of a certain environment (normal diet), this is an example of a genotype–environment interaction. At a more basic level, phenylketonuria illustrates that genetic involvement in a behavioral deficiency does not imply that the deficiency is immutable. One of the major thrusts of modern medical science is to discover environmental compensations (medicines) for genetic conditions.

Definite genes, or small chromosomal regions, have been implicated with various degrees of certainty in the following conditions: early-onset and late-onset Alzheimer disease, autism, bipolar disorder, dyslexia, and schizophrenia (McGuffin and Martin, 1999; Owen and Cardno, 1999). For example, the apolipoprotein E ε4 allele appears to be associated with late-onset Alzheimer disease.

Information from the human genome project will doubtless make great contributions to this rapidly developing area.

EVOLUTION

Although we have considered genetic variability in a number of psychologically relevant dimensions, we have not considered genetic variability in fitness or reproductive success, the additive component of which directly controls evolution. In so far as certain traits are prevalent today, it is natural to think that they might somehow have conferred enhanced fitness long ago. Such evolutionary speculation is among the most powerful heuristics in biological science in general and evolutionary psychology in particular. Although the disciplines that incorporate it are flourishing, it is important to be aware that inference from present predominance to past superior fitness is fallible. This can be shown by examples involving variation controlled by a single genetic locus with only two alleles, A_1 and A_2. Assuming random mating, the heterozygotic genotype A_1A_2 has relative frequency $2p(1-p)$, where p is the relative frequency of the A_1 allele. Thus, regardless of its fitness, the relative frequency of A_1A_2 cannot exceed 1/2. In fact, it is not difficult to construct examples where the homozygote A_1A_1 predominates after many generations of evolution, even though the heterozygote is the fittest genotype.

Variants of such simple genetic examples can be constructed within the frameworks of W. D. Hamilton's kin selection theory and J. Maynard Smith's (1982) evolutionary game theory, two of the pillars of evolutionary psychology (Norman, 1981). A frequently cited part of Hamilton's theory suggests that one can predict the evolutionary fate of altruistic and selfish genotypes just by examining their inclusive fitnesses, but it turns out that superior inclusive fitness is not sufficient for asymptotic predominance of, say, an altruistic genotype, if that genotype is heterozygotic. Similarly, the standard version of Maynard Smith's criterion for an evolutionarily stable strategy (ESS) depends entirely on fitness 'payoffs', irrespective of genetic structure. However, a behavioral strategy exhibited by a heterozygote cannot be evolutionarily stable, regardless of associated payoffs, since a population composed entirely of heterozygotes will give rise to a mixed population in the next generation.

These examples represent relatively minor blemishes on these theories, but the examples do suggest that the theories should be applied with caution.

Categorical Perception

Intermediate article

Stevan Harnad, University of Quebec, Montreal, Canada

CONTENTS

CATEGORIES: CATEGORICAL AND CONTINUOUS

A category, or kind, is a set of things. Membership in the category may be (1) all-or-none, as with 'bird': something either is a bird or it isn't a bird; a penguin is 100 percent bird, a platypus is 100 percent not-bird. In this case we would call the category 'categorical'. Or membership might be (2) a matter of degree, as with 'big': some things are 'more big' and some things are 'less big'. In this case the category is 'continuous' (or rather, degree of membership corresponds to some point along a continuum). There are range or context effects as well: elephants are relatively big in the context of animals, relatively small in the context of bodies in general, if we include planets.

Many categories, however, particularly concrete sensorimotor categories (things we can see and touch), are a mixture of the two: categorical at an everyday level of magnification but continuous at a more microscopic level. Color categories are good examples: central reds are clearly reds, and not shades of yellow. But in the orange region of the spectral continuum, red/yellow is a matter of degree; context and contrast effects can also move these regions around somewhat. Perhaps even with 'bird', an artist or genetic engineer could design intermediate cases in which their 'birdness' was only a matter of degree.

RESOLVING THE 'BLOOMING, BUZZING CONFUSION'

Categories are important because they determine how we see and act upon the world. As William James noted, we do not see a continuum of 'blooming, buzzing confusion' but an orderly world of discrete objects. Some of these categories are 'prepared' in advance by evolution: the frog's brain is born already able to detect 'flies'; it needs only normal exposure rather than any special learning in order to recognize and catch them. Humans have such innate category-detectors too: the human face itself is probably an example. So too are our basic color categories; although, according to the 'Whorf hypothesis' (Whorf 1956; also called the 'linguistic relativity' hypothesis) colors are determined by how our culture and language happens to subdivide the spectrum (we will return to this).

But if one opens up a dictionary at random and picks out a content word, it is probable that it names a category we have learned to detect, rather than one that our brains were innately prepared by evolution to detect. The generic human face may be an innate category for us, but surely all the specific people we know and can name are not. 'Red' and 'yellow' may be inborn, but what about 'scarlet' and 'crimson'?

THE MOTOR THEORY OF SPEECH PERCEPTION

And what about the very building blocks of the language we use to name categories. Are our speech sounds – ba, da, ga – innate or learned? The first question we must answer about them is whether they are categories at all, or merely arbitrary points along a continuum. It turns out that if one analyzes the sound spectrogram of ba and pa, for example, both turn out to lie along an acoustic continuum called 'voice-onset-time'. With a technique similar to the one used in morphing visual images continuously into one another, it is possible to 'morph' a ba gradually into a pa and beyond by gradually increasing the voicing parameter.

Liberman *et al*. (1957) reported that when people listen to sounds that vary along the voicing

continuum, they hear only ba's and pa's, nothing in between. This effect – in which perception jumps abruptly from one category to another at a certain point along a continuum, instead of changing gradually – he called 'categorical perception' (CP). He suggested that CP was unique to speech, that it made speech special, and that its explanation lay in the anatomy of speech production. This came to be called 'the motor theory of speech perception'.

According to the (now abondoned) motor theory, the reason we perceive an abrupt change between ba and pa is that the way we hear speech sounds is mediated by the way we produce them when we speak. What is varying along this continuum is voice-onset-time: the 'b' in ba is voiced and the 'p' in pa is not. Unlike the synthetic morphing apparatus, our natural vocal apparatus is not capable of producing anything in between. So when I hear a sound from the voicing continuum, my brain perceives it by trying to match it with what it would have had to do to produce it. Since the only thing I can produce is ba or pa, I will perceive any of the synthetic stimuli along the continuum as either ba or pa, whichever it is closer to. A similar CP effect is found with ba/da; these too lie along a continuum acoustically, but vocally ba is formed with the two lips, da with the tip of the tongue and the hard palate, and our anatomy does not allow any intermediates.

The motor theory of speech perception explained how speech was special and why speech sounds are perceived categorically: sensory perception is mediated by motor production. Wherever production is categorical, perception will be categorical; where production is continuous, perception will be continuous. And indeed vowel categories like a/u were found to be much less categorical than ba/pa or ba/da (less categorical, but not altogether continuous either; we will return to this).

ACQUIRED DISTINCTIVENESS

If motor production mediates sensory perception, then one assumes that this CP effect is a result of learning to produce speech. Early research, however, found that infants show speech CP before they begin to speak. Perhaps, then, it is an innate effect, evolved to 'prepare' us to learn to speak. But Kuhl found that chinchillas also show 'speech CP' even though they never learn to speak, and presumably did not evolve to do so (Kuhl, 1987). Lane (1965) went on to show that CP effects can be induced by learning alone, with a purely sensory (visual) continuum in which there is no motor production discontinuity to mediate the perceptual discontinuity. He concluded that speech CP is not special after all but merely a special case of Lawrence's (1950) classic demonstration that stimuli to which you learn to make a different response become more distinctive, and stimuli to which you learn to make the same response become more similar.

It also became clear that CP was not quite the all-or-none effect Liberman had originally thought it was: it is not that all pa's are indistinguishable and all ba's are indistinguishable. We can hear the differences, just as we can see the differences between different shades of red. It is just that the within-category differences (pa1/pa2 or red1/red2) seem to be much smaller than the between-category differences (pa2/ba1 or red2/yellow1), even when the size of the underlying physical differences (voicing, wavelength) are the same.

WITHIN-CATEGORY COMPRESSION AND BETWEEN-CATEGORY SEPARATION

This evolved into the contemporary definition of CP that is no longer peculiar to speech or dependent on the motor theory: CP occurs whenever perceived within-category differences are compressed and/or between-category differences are separated, relative to some baseline. The baseline might be the actual size of the physical differences involved, or, in the case of learned CP, it might be the perceived similarity or discriminability within and between categories before the categories were learned.

A typical learned CP experiment would be the following. A set of stimuli is tested for pairwise similarity or discriminability. In the case of similarity, multidimensional scaling might be used to scale the rated pairwise similarity of the set of stimuli. In the case of discriminability, same/different judgments and signal detection analysis might be used to estimate the discriminability of a set of stimuli. Then the same subjects or a different set are trained, using trial and error and corrective feedback, to sort the stimuli into two or more categories. After the categorization has been learned, similarity or discriminability are tested and compared against the untrained data. If there is significant within-category compression and/or between-category separation, this is operationally defined as CP (Harnad, 1987).

THE WHORF HYPOTHESIS

We can now return both to the 'Whorf hypothesis' and the 'weaker' CP for vowels: according to the

Whorf hypothesis (of which Lawrence's acquired similarity/distinctiveness effects would simply be a special case), colors are perceived categorically only because they happen to be named categorically; our subdivisions of the spectrum are arbitrary, learned, and vary across cultures and languages (Whorf, 1964). But Berlin and Kay (1969) showed that this was not so: not only do most cultures and languages subdivide and name the color spectrum the same way, but even for those who don't, the regions of compression and separation are the same. We all see blues as more alike and greens as more alike, with a fuzzy boundary in between, whether or not we have named the difference. So there is no Whorfian learning effect with colors; or is there?

EVOLVED CP

First, let us go back to vowels. The signature of CP is within-category compression and/or between-category separation. The size of the CP effect is merely a scaling factor; it is this compression/separation 'accordion effect' that is CP's distinctive feature. In this respect, the 'weaker' CP effect for vowels, whose motor production is continuous rather than categorical but whose perception is by this criterion categorical, is every bit as much of a CP effect as the ba/pa and ba/da effects. But, as with colors, it looks as if the effect is an innate one. Our sensory category detectors for color and speech sounds are born already 'biased' by evolution: the perceived color and speech sound spectrum is born 'warped' with these compression/separations.

LEARNED CP

Is that all there is to it? Apparently not. There are still the Lane/Lawrence demonstrations, lately replicated and extended by Goldstone (1994, 1999), that CP can be induced by learning alone. And there are also the countless categories cataloged in our dictionaries that could not possibly be inborn (though nativist theorists such as Fodor (e.g. 1983) have sometimes seemed to suggest that all of our categories are inborn). There are even recent demonstrations that although the primary color and speech categories are probably inborn, their boundaries can be modified or even lost as a result of learning, and weaker secondary boundaries can be generated by learning alone (Roberson *et al*., 2000).

Perhaps CP performs some useful function in categorization? In the case of innate CP, our categorically biased sensory detectors pick out their prepared color and speech sound categories far more readily and reliably than if our perception had been continuous. Could something similar be the case for our repertoire of learned categories too?

COMPUTATIONAL AND NEURAL MODELS OF CP

Computational modeling (Tijsseling and Harnad, 1997; Damper and Harnard 2000) has shown that many types of category-learning mechanisms (e.g. both backpropagation and competitive networks) display CP-like effects. In backpropagation nets, the hidden-unit activation patterns that 'represent' an input build up within-category compression and between-category separation as they learn; other kinds of net display similar effects. CP seems to be a means to an end: inputs that differ among themselves are 'compressed' onto similar internal representations if they must all generate the same output; and they become more separate if they must generate different outputs. The network's 'bias' is what filters inputs onto their correct output category. The nets accomplish this by selectively detecting (after much trial and error, guided by error-correcting feedback) the invariant features that are shared by the members of the same category and that reliably distinguish them from members of different categories; the nets learn to treat all other variation as being irrelevant to the categorization.

Very little is known yet about the brain mechanisms of category perception and learning. The computational models are really causal hypotheses about what the brain might be doing. Neural data provide correlates of CP and of learning (Sharma and Dorman, 1999). Differences between event-related potentials recorded from the brain have been found to be correlated with differences in the perceived category of the stimulus viewed by the subject. Neural imaging studies have shown that these effects are localized and even lateralized to certain brain regions in subjects who have successfully learned the category, and are absent in subjects who have not (Seger *et al*., 2000).

LANGUAGE-INDUCED CP

Both innate and learned CP are sensorimotor effects. The compression/separation biases are sensorimotor biases, and presumably had sensorimotor origins, either during the sensorimotor life history of the organism, in the case of learned CP, or during the sensorimotor life history of the

species, in the case of innate CP. The neural net I/O models are also compatible with this fact: their I/O biases derive from their I/O history. But when we look at our repertoire of categories in a dictionary, it is highly unlikely that many of them had a direct sensorimotor history during our lifetimes, and even less likely in our ancestors' lifetimes. How many of us have seen unicorns in real life? We have seen pictures of them, but what had those who first drew those pictures seen? And what about categories I cannot draw or see (or taste or touch)? What about the most abstract categories, such as goodness and truth?

Some of our categories must originate from a source other than direct sensorimotor experience, and here we return to language and the Whorf hypothesis. Can categories, and their accompanying CP, be acquired through language alone? Again, there are some neural net simulation results suggesting that, once a set of category names has been 'grounded' through direct sensorimotor experience, they can be combined into Boolean combinations (man = male and human) and into still higher-order combinations (bachelor = unmarried and man). These combinations not only pick out the more abstract, higher-order categories in much the way the direct sensorimotor detectors do, but also inherit their CP effects, as well as generating some of their own. Bachelor inherits the compression/separation of unmarried and man, and adds a layer of separation/compression of its own (Cangelosi *et al*., 2000; Cangelosi and Harnad 2001).

These language-induced CP-effects remain to be directly demonstrated in human subjects; so far only learned and innate sensorimotor CP have been demonstrated (Pevtzow and Harnad 1997; Livingston *et al*., 1998). The latter show the Whorfian power of naming and categorization, in warping our perception of the world. That is enough to rehabilitate the Whorf hypothesis from its apparent failure on color terms (and perhaps also from its apparent failure on eskimo snow terms – see Pullum, 1989); but to show that it is a full-blown language effect, and not merely a vocabulary effect, it will have to be shown that our perception of the world can also be warped, not just by how things are named but by what we are told about them.

Categorization, Development of

Intermediate article

Jean M Mandler, University of California, San Diego, California, USA

CONTENTS

Categorization occurs when individual items that can be discriminated from one another are considered to be the same or belong together because they are alike in some way.

INTRODUCTION

Categorization is an automatic part of perceiving and conceptualizing. Whether perceiving something or thinking about it, the mind tends to subsume individual items into larger classes. The term 'categorization' is also applied to a task that individuals perform. Such tasks require deliberate choice as to the basis of similarity that is used to do the grouping: for example, in a set of red and green dogs and cats, one might choose to group them on the basis of similar color or similar kind. One can categorize in this way on many bases ranging from taxonomic categories to categories made up on the spot.

Behavior on deliberate categorization tasks changes dramatically in the early years, but the reasons for the changes are complex and varied. Children's understanding of the instructions, their construal of what is wanted, and the salience of different aspects of objects vary depending on school and home experiences. These variables influence the developmental change that has been reported on these tasks, from the preference of young children to categorize objects by their overall similarity to the preference of older children and adults to concentrate on dimensions of the objects such as size or shape (Smith and Kemler, 1978). Schooling is also implicated in the tendency of children and young adults to categorize taxonomically on these tasks, compared with preschool children and older adults, who are more likely to categorize objects by their functions or the events in which they take part (Smiley and Brown, 1979).

There is a good deal of research on categorization in infancy using instructionless tasks that rely on infants' spontaneous categorizing behavior, and that therefore provide information about the earliest bases of categorization. A typical experimental procedure familiarizes infants with one category and then measures preferential looking or examining to a member of another category. This article concentrates on the infancy period when the first perceptual and conceptual categories are formed.

MODELS OF CATEGORIZATION

One model of categorization posits that encountering similar stimuli leads to the formation of a prototype of the presented items. For example, upon seeing many dogs, one extracts the central tendency or principal components (as in factor analysis) of 'dogginess' in terms of physical features and presumably in terms of behavior as well. Even 3-month-old babies extract a perceptual prototype from a set of similar stimuli. For example, if shown a number of squares or triangles, each of which is somewhat distorted in shape, they will treat a regular square or triangle as more familiar than any of the distorted figures they have seen (Bomba and Siqueland, 1983).

Another model of categorization is that we accumulate many instances and compare new instances with this accumulated knowledge base. This procedure enables us to recognize a prototypical instance of a category because it is most similar to the largest number of examples. Although much published research differentiates these two theories of categorization, there is little to choose between them at a behavioral level and in terms of development almost no relevant data to decide between them.

PERCEPTUAL VERSUS CONCEPTUAL CATEGORIES

People categorize perceptually ('this dog looks like that dog') and conceptually ('courage and honesty

are both virtues'). Both kinds of categorization can be characterized as involving similarity (e.g. in shape or value system), and so some researchers describe both kinds of categorization in terms of a single process of computing similarity (either in terms of similarity to a prototype or similarity of exemplars). However, it is not always easy to specify the similarities among exemplars of conceptual categories such as virtues (exactly how are courage and kindness similar?), so some researchers find it preferable to say that conceptual categories are based on a definition or rule. On this view, then, there are two different processes involved in categorization: assessing similarity, and applying a rule. (*See* **Concept Learning**; **Conceptual Change**)

It seems plausible that current debate on this topic reflects differences in the way that perceptual and conceptual categories are formed. The items being categorized differ greatly in the two cases, and there appear to be a number of differences in their formation, suggesting that a two-process account may be necessary. Perceptual categories are almost certainly based on similarity, but many conceptual categories may be more rule-like in nature. For example, there is evidence that the perceptual categorization of faces as male or female is an automatic part of the operation of the visual system and is implicit in nature. We have all been able to categorize male and female faces since infancy, but we cannot say accurately what the differences are. Conceptual categories, on the other hand, are based on notions that are open to our inspection and we can often give a rule for why two things belong to different classes. Even a category of objects such as animals can be described as rule-based. For example, for infants an animal might be anything that moves itself and acts on other objects, regardless of what it looks like.

Perceptual categorization happens automatically and does not require conscious attention. The process, which enables generalization from prior instances of a category to new instances, is a fundamental aspect of perception and is present very early in life. For example, using a familiarization/preferential-looking technique, 3-month-old babies have been found not only to extract perceptual prototypes but also to categorize realistic pictures of cats after only a few exposures and differentiate them from pictures of dogs (Quinn *et al*., 1993). If the stimuli are more variable, the process takes longer; hence, it takes more exposure to categorize pictures of dogs than of cats.

Unfortunately, most of the research on perceptual categorization of realistic stimuli at this young age has been conducted with pictures of animal kinds, which may not be representative of category formation in general. It has also tended to contrast objects at what is known as the basic level (Rosch *et al*., 1976). For example, dogs have been contrasted with cats, as opposed to a subordinate comparison of poodles contrasted with terriers, or a superordinate comparison of animals contrasted with vehicles. However, there are some data indicating that babies at 3 months and 6 months of age can also categorize pictures of tables, differentiating them from chairs. They also discriminate pictures of mammals from vehicles at this age, although more trials are required, presumably because of the greater perceptual variability of these global categories. (Superordinate categories are usually termed 'global categories' in the infancy literature, because infants typically make few conceptual subdivisions within such large classes.)

By about 6 months, as infants begin to manipulate objects, a familiarization/preferential-examining technique is used with models of objects to assess categorization. Seven-month-old infants categorize animals as different from vehicles. By 9 months, they categorize animals as different from furniture as well, and by 11 months categorize both these classes as different from plants and utensils. The range of perceptual variation in these global categories is much greater than for basic-level categories and even for four-legged mammals (compare dogs with horses versus dogs with birds). Nevertheless, 9-month-old infants have no difficulty in differentiating models of birds with outstretched wings from airplanes in spite of the high degree of similarity in appearance of the two classes. Because of the apparent lack of difficulty posed by within-category variability in the case of animals, and between-category similarity in the case of birds and airplanes, it has been suggested that perceptual similarity alone cannot account for this kind of categorization, and more conceptual information, as opposed to the physical appearance of the exemplars, is being used (Mandler, 2000).

GLOBAL VERSUS BASIC-LEVEL CATEGORIES

The infants who at age 7–11 months categorize animals, vehicles, and furniture as different kinds do not categorize dogs versus cats or tables versus chairs on object examination tests. Nevertheless, infants aged 3–6 months who categorize pictures of dogs versus cats and tables versus chairs have more difficulty categorizing furniture versus

vehicles. Although the dissociations shown on these various categorization tests do not perfectly differentiate global from basic-level categories, there are enough differences in categorizing behavior to make it likely that different processes are being measured when infants categorize objects rather than pictures. Eventually, of course, pictures and objects produce similar data, but this is not the case in infancy, which makes the study of categorization at this period of life particularly informative.

Perceptual processes are capable of categorizing differently shaped pictures, even if the patterns are novel or meaningless. Hence, 3-month-old infants who have had no experience with dogs and cats nevertheless quickly learn to tell pictures of them apart. However, when perceptual variation is great, as is often the case for superordinate (global) categories, it may not be possible for the perceptual system to extract the principal components of the displayed patterns, and so this kind of perceptual categorization fails.

In contrast to the automatic perceptual processes involved in perceptual categorization, global categorization of animals, vehicles, furniture, and plants appears to be a response to a conceptual difference between these very different classes (Mandler, 2000). It is more selective in nature (and hence more 'rule-like'), acting on those aspects of events that have attracted infants' attention and interest. Young infants are particularly interested in differences in the way that animals and inanimate things move and the kinds of interactions in which they engage. Even relatively superficial analysis of the activities of animate and inanimate objects results in concepts that differentiate these classes. For example, such analysis leads to categorization of animals as things that start themselves and interact with other objects from a distance in a contingent fashion, and categorization of inanimate objects as things that either do not move at all or, if they do, do not start themselves and do not act on other objects from a distance. In the early months of life infants may not be able to conceptualize global categories more finely than this. It is relatively easy to differentiate the behavior of an animal from a piece of furniture, but it requires considerably more analysis to conceptualize how a dog differs from a cat or a car from a truck. (*See* **Infant Cognition**; **Object Perception, Development of**)

TIME COURSE OF CATEGORIZATION

Perceptual categorization begins at or near birth. To date, all the research indicating conceptual categorization has involved manipulating objects, which means that no data are available for infants younger than about 6–7 months. One piece of evidence for the conceptual nature of the global categories found in the second 6-month period of life is that it is these categories that are used for purposes of inductive inference. By 9–11 months of age, infants generalize the behavior of an observed animal, such as a dog drinking, to all animals including fish. They generalize using a key on a car to all vehicles, including airplanes (Mandler and McDonough, 1996). At the same time they do not differentiate between cups and pans as appropriate containers from which to drink, or between beds and bathtubs as appropriate places to sleep. The initially global categories become gradually differentiated during the second year, with current evidence suggesting that (at least in American culture) artefacts are differentiated earlier than natural kinds. The vocabulary that children are learning contributes to this development (Waxman, 1999). By the age of 2 years, children's conceptual categories become increasingly differentiated and so basic-level inductions result. By 4 years of age, the adult tendency to be more certain of inductions made on the basis of smaller classes is already established (Gelman and O'Reilley, 1988).

CONCLUSION

Although more research is needed, the preponderance of evidence indicates that beginning in infancy at least two kinds of categorization occur. The first is an automatic part of perception that computes the perceptual similarity of objects. This leads to implicit categorizing at the basic level. In addition, infants attempt to make sense of what they perceive – to construe the meaning or significance of the events they observe. This leads to explicit conceptual categorization, which tends to be global and overly general at the start.

It is not known for certain whether the two kinds of categorization involve the same or different processes. However, there are some distinctive differences that suggest different processes are at work. First, perceptual categorization occurs automatically and seems to use all the information encoded, whereas conceptual categorization depends on selective attention to only certain kinds of information. Second, perceptual categorization initially makes finer groupings than does conceptual categorization, which begins at a more global level. Third, the functions served by the two kinds of categories differ. Perceptual categorization is used to identify exemplars of conceptual categories.

Infants may respond in a global conceptual way to animals as a class, but must learn to identify them by their features. For example, they learn that 'self-starting objects that do things to other objects' tend to have legs or wings, and so forth. Conceptual categories, on the other hand, are created to understand the world, to characterize the important differences among object kinds. Hence it is these categories that are used for purposes of inductive inferences.

Causal Perception, Development of

Intermediate article

Lisa M Oakes, University of Iowa, Iowa City, Iowa, USA

CONTENTS

The perception of causality develops during the first year of life. In general, this development progresses from infants perceiving the individual elements of events (e.g. particular objects, whether or not those objects touch) to their perceiving the relationship between those objects.

INTRODUCTION

Perceiving cause-and-effect relationships is important for understanding how things work, how to produce outcomes and how to link events that co-occur. Philosophers and psychologists have long debated the origins of causal understanding. Hume, for example, argued that real causal connections are unknowable. According to this view, humans determine causality through experience with regularities in the environment and causal perception should develop gradually. Infants may perceive the causality of some events from an early age, but a sophisticated appreciation of causality in a wide range of events develops as they gain experience of the world. Others have argued that the idea of cause and effect is an innate predisposition of the mind. According to this view, causality itself can be perceived without prior experience of events. Therefore young infants should be able to perceive causality in a wide range of events from an early age, and little development should be observed.

PERCEPTION OF LAUNCHING AND COLLISION EVENTS

Psychologists have primarily studied the development of infants' causal perception by assessing their perception of launching events or collisions (e.g. Leslie, 1984; Oakes and Cohen, 1990). At the start of a launching event, an object moves from one side of a display toward a second object sitting at rest in the middle of the display (Figure 1). The first object hits the second object, which begins to move immediately upon contact. Adults report that the first object appears to cause the second object to move (Michotte, 1963). The perception of causality can be interrupted by imposing a delay (i.e. the two objects remain stationary momentarily after they have made contact and before the second object begins to move) or a spatial gap between the two objects (i.e. the second object begins to move before the first object contacts it). Infants' sensitivity to causality is tested using habituation procedures.

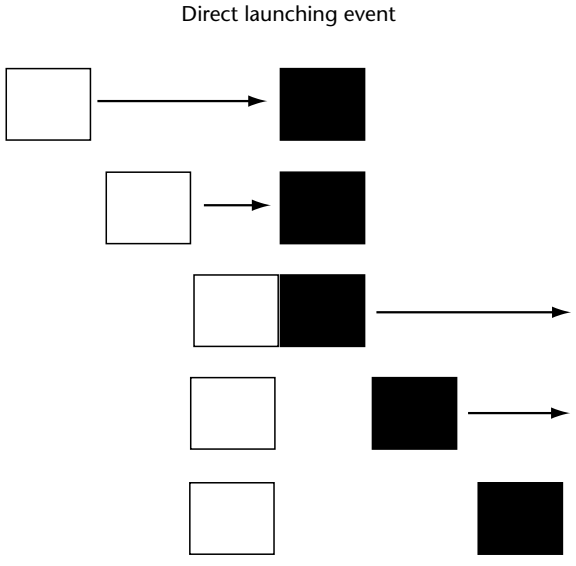

Figure 1. The sequence of actions in a typical launching event. The white object moves from the left of the screen towards the black object, which is initially stationary in the middle of the screen. When the white object makes contact with the black object, the black object immediately begins to move towards the right side of the screen. Reprinted from Oakes LM and Cohen LB (1995) with permission.

They are first shown one event on several trials until their looking time habituates, or decreases to some specified criterion (e.g. 50% of their original level of looking). Then they are shown one or more new events, and if they perceive those events as being different from the familiarization event, they will dishabituate or increase their looking. For example, if infants perceive the causality of events, then infants who are habituated to a delayed launching event, a noncausal event, will dishabituate to a novel causal event but not to a novel no-collision event. However, if infants do not attend to causality, but instead attend to the particular features of the event (e.g. whether or not the two objects touched), then they will dishabituate to novel events that differ in terms of those features regardless of changes in causality.

Using this type of procedure, studies have revealed that young infants are sensitive to causality. Infants aged 6 to 7 months treat the causal launching event as different from noncausal events, and they treat different noncausal events as if they are equivalent (Leslie, 1984; Oakes, 1994; Cohen and Amsel, 1998). Thus we might conclude that some aspects of causal perception are innate. However, causal perception develops considerably during infancy. Infants under 6 months of age do not perceive the causality of launching events. Instead, following habituation with one event, these younger infants dishabituate to changes in other types of features of the event (e.g. whether or not the two objects touched) (Cohen and Amsel, 1998). Even once infants begin to perceive causality, their perception is limited. Infants aged 6 to 7 months only perceive the causality of launching events if the objects are simple (e.g. colored squares). They do not perceive the causality of events if the objects in the event are complex (e.g. multicolored, multi-featured objects). By 10 months of age, infants perceive the causality of launching events involving both complex and simple objects. However, if the objects do not move along the same trajectory, 10-month-old infants fail to perceive causality (Oakes, 1994; Oakes and Cohen, 1995). In general, therefore, the perception of launching events develops over time, and salient perceptual features of the events (or the objects in the events) may overwhelm young infants' ability to perceive the causal relationship in those events.

CAUSALITY VERSUS INDEPENDENT FEATURES MODELS

Clearly, infants over 6 months of age, at least under some conditions, perceive causality (Oakes and Cohen, 1995). The causal event is treated as different from any noncausal event, and different noncausal events are treated as being equivalent. This pattern is consistent with the causality model (Figure 2b). This model is based on the idea that events can be organized in terms of causality, with causal events being perceived as distinct from all noncausal events. According to this model, causal events or spatio-temporally contiguous launching events (events in which the objects touch and there is no delay imposed) are perceived as being different from noncausal events, or launching events with violations of spatio-temporal contiguity. Although this view is called the 'causality model', it is not clear whether causality *per se* is perceived. The same outcome is expected whether observers perceive the causality or are responding to the spatio-temporal contiguity of the events. That is, infants would respond in the same way if they treated a spatio-temporally contiguous event as different from any event that violates spatio-temporal contiguity. What is important is that differences between events are determined along a single dimension that corresponds to causality or spatio-temporal contiguity. As a result, two noncausal events that differ in two ways (e.g. in terms of both the temporal and spatial features) would be treated as the same, and a causal event and a noncausal event that differ in only one respect (e.g. only in terms of temporal features) would be treated as different.

However, infants younger than 6 months do not perceive the causality of events (Cohen and Amsel, 1998). Rather, these younger infants respond to differences in the independent features of the

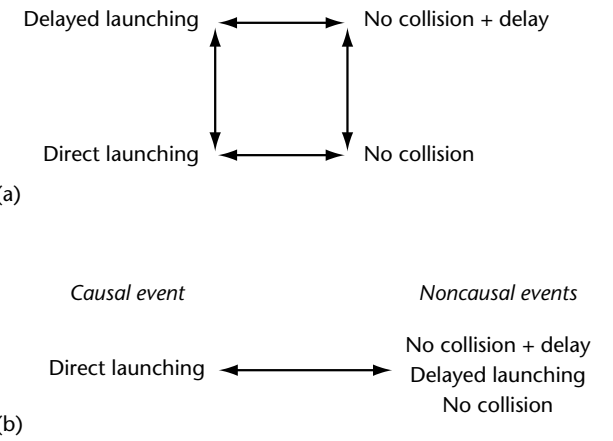

Figure 2. Abstract representations of (a) the independent features model and (b) the causality model of launching events. Reprinted from Oakes LM and Cohen LB (1995) with permission.

event (e.g. whether or not the two objects touch). The perception of launching events by infants younger than 6 months is consistent with the independent features model (Figure 2a). According to this model events are organized in terms of the presence or absence of specific features (e.g. whether or not the two objects touch). If infants process events as sets of independent features, then the perceptual difference between any two events can be represented by an additive combination of the lines shown in the rectangle. Infants would not treat launching events that violate spatio-temporal contiguity as equivalent. Rather, they would respond to differences in the events, such as the presence or absence of a gap or a delay.

In summary, therefore, infants first perceive events according to the independent features model, and in the middle of the first year of life they begin to perceive events according to the causality model. Importantly, this developmental transition is not 'all or none'. Infants can perceive the causality of collisions involving simple objects by approximately 6½ months, but it is not until 10 months of age that they perceive the causality of collisions involving more complex objects.

AGENT VERSUS PATIENT DISTINCTION

Perceiving causality does not simply mean recognizing the difference between causal and noncausal events. Rather, in causal events the two objects have meaningful roles, and a full appreciation of causality requires a recognition of the difference between those roles. Consider the events depicted in Figure 3. For adults, in the initial event the white object appears to cause the black object to move, and it is therefore the causal agent. What makes an object an agent? The agent has the force to cause an outcome, and may be thought of as acting in pursuit of goals (Leslie, 1995). Infants seem to be sensitive to the different roles that objects have in events (Cohen and Oakes, 1993). In this study, 10- to 12-month-old infants were habituated to a causal and a noncausal event in which either the first object was associated with the type of event (e.g. object A was always seen in the agent role of a causal event, and object B was always seen in the agent role of a noncausal event), or the second object was associated with the type of event. The infants were then tested with an event in which the roles were switched (e.g. object A was in the agent role of a noncausal event). Infants dishabituated to this role switch when the agent was associated with the type of event, but not when the patient was

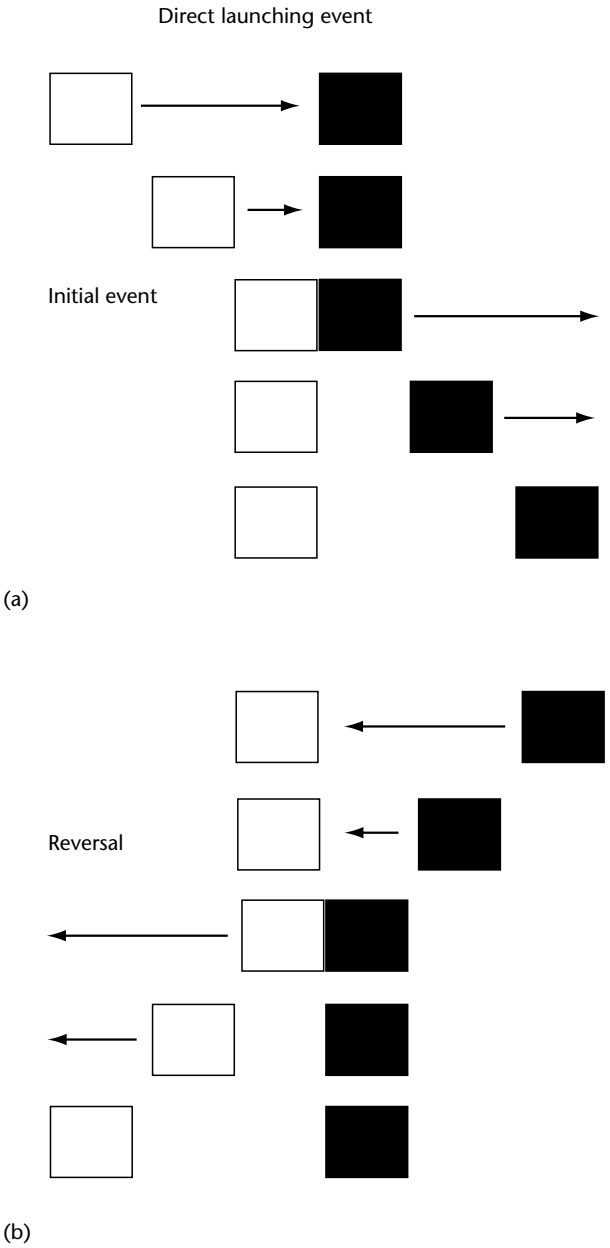

Figure 3. The sequence of actions in (a) a typical launching event and (b) a reversal of that event. Note that when the event is causal, a reversal not only involves a reversal of the direction of movement, but also a change in the roles of the objects in the events.

associated with the type of event. In other words, they linked the agent with whether or not the event was causal, but not the patient. This is an important step in distinguishing between the agent and the patient in the events. However, simply linking the first object with the type of event does not reflect a full understanding of the distinction between the agent and the patient.

The difference in the roles of the two objects is illustrated by the reversal of the event (Figure 3b). In this event, the action occurs in the opposite direction to that in the initial event and, importantly, the roles of the black and white objects have changed. In this reversal, the black object appears to cause the white object to move, and it is now the agent. A reversal of a causal event should therefore be more compelling than a reversal of a noncausal event. Reversals of causal events involve changes in the agent–patient roles, and reversals of noncausal events do not. In fact, infants do find reversals of causal events more interesting than reversals of noncausal ones, which suggests that they are sensitive to the agent–patient distinction (Lesile and Keeble, 1987; Cohen *et al*., 1998). However, their recognition of this distinction develops during infancy. Six-and-a-half-month-old infants notice the agent–patient distinction when the objects involved are simple red and green bricks (Leslie and Keeble, 1987), but it is not until they reach 14 months of age that infants notice the agent–patient distinction when the objects are complex and multi-featured (Cohen *et al*., 1998).

RELATION TO LANGUAGE

The development of general concepts such as causality is believed to be a prerequisite for learning language. Indeed, infants perceive causal relationships long before they learn the corresponding linguistic concepts. Thus we have evidence that the development of cognitive concepts precedes language development. For example, infants perceive the distinction between 'pushing' and 'pulling' at between 10 and 14 months of age. However, they do not associate labels with the type of action until 18 months of age (Cohen *et al*., 1998). In other words, infants first perceive the type of action (pushing and pulling), and only later learn a label for that action. Thus they appear to be able to learn the general concept earlier than they can learn the linguistic concept. Interestingly, by 14 months of age infants can associate labels with objects (Werker *et al*., 1998), which suggests that they can first associate labels with the individual objects in events, and can only later associate labels with the relationships between the objects. In general, therefore, infants are able first to learn words that refer to parts or features of the event, and only later are they able to learn words that refer to the relationships between those parts.

CONCLUSION

In summary, the perception of causality develops gradually during the first years of life. Infants' perception of causality itself develops from initially perceiving the independent features of events, such as the particular objects or some aspects of the relationships between those objects (e.g. whether or not they touch), to distinguishing causal events from noncausal ones. However, the perception of causality does not emerge fully developed. Rather, infants perceive causality earlier in some events than they do in others. They are sensitive to the agent–patient roles in events, but they recognize this distinction earlier in events that involve simple objects. Finally, it is only relatively late in infancy that they become able to associate labels with the actions in the events. Thus, in general, infants first learn about particular objects and only later learn about the relationships between those objects. Therefore an understanding of causality develops gradually with experience.

Causal Reasoning, Psychology of

Introductory article

Barbara A Spellman, University of Virginia, Charlottesville, Virginia, USA
David R Mandel, University of Victoria, Victoria, British Columbia, Canada

CONTENTS

Causal reasoning is an important universal human capacity that is useful in explanation, learning, prediction, and control. Causal judgments may rely on the integration of covariation information, pre-existing knowledge about plausible causal mechanisms, and counterfactual reasoning.

INTRODUCTION

The subject of causal reasoning has engaged psychologists of many kinds (e.g. cognitive, social, animal, clinical, developmental), other cognitive scientists (e.g. philosophers, computer scientists, anthropologists), and others outside the cognitive science community (e.g. lawyers). The question that psychologists want to answer is: how do we go from the information that the world provides us in the form of events occurring (seemingly at random sometimes) to our beliefs about what causes what? Sometimes causal judgments are made in formal settings: in the laboratory, scientists try to find out what causes cancer or heart disease; in the legal system, before liability or punishment is imposed, jurors are required to determine who caused the accident or who caused someone's death. But more informally, we all reason about causality daily. Why did I fail this exam (or all of the exams in this course)? Why is my friend unhappy? Why is my computer likely to crash in the next five minutes? To answer these kinds of questions we may rely on repeated observations, pre-existing knowledge, thought experiments, or all of these cues to causality.

THE ROLE OF REPEATED OBSERVATIONS

One kind of information that we use to assess causality is information from repetitions of the same events: watching causes and effects as they repeatedly occur. Sometimes people use the word 'cause' deterministically, so that '*A* causes *B*' means that every time *A* occurs *B* must follow. But people also use the word 'cause' probabilistically, so that '*A* causes *B*' means that *A* increases the chances that *B* will occur. For example, someone might say that a baseball team has a winning record early in the season 'because' they have played most of their games at home. The argument is that playing at home increases the chances of winning; however, it's still possible for the team to lose some games at home and win some away games. Similarly, scientists claim that smoking causes lung cancer because it increases the chance of getting lung cancer. Yet there are people who smoke and don't get lung cancer, and people who get lung cancer without smoking.

In order to determine whether something might be causal when we have repeated observations, we divide our observations into the following categories (see Figure 1): cause present and effect present (cell *A*); cause present and effect absent (cell *B*); cause absent and effect present (cell *C*); cause absent and effect absent (cell *D*). We then use that information to decide whether the cause increases the probability of the effect. We do this by comparing the proportion of times the effect occurs when the cause is present, $A/(A + B)$, with the proportion of times the effect occurs when the cause is absent, $C/(C + D)$. The difference between these proportions is called the contingency (symbolized by Δp – read 'delta *p*'), which is a measure of the strength or effectiveness of a cause. If the proportion of times the effect occurs is greater when the cause is present than when the cause is absent then the difference will be positive, and we speak of a 'generative' or 'facilitative' cause – it makes the effect more likely to happen. If the proportion of times the

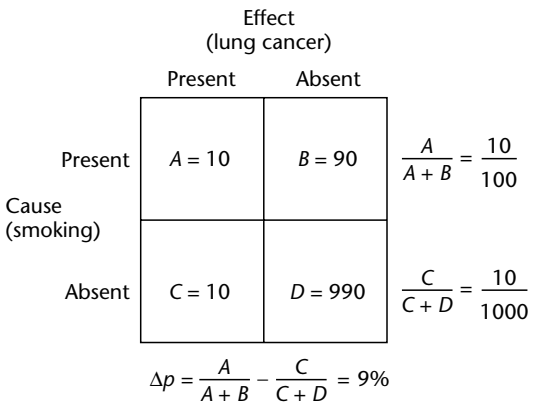

Figure 1. We need four kinds of information to understand the relation between smoking and lung cancer. Note that we do not directly compare the number of people who smoke and get lung cancer with the number of people who don't smoke and get lung cancer. Rather, we look at whether smoking increases the chances of getting lung cancer. For people who smoke, the proportion who get it is 10/100 or 10%, whereas for people who don't smoke, the proportion who get it is 10/1000 or 1%.

effect occurs is smaller when the cause is present than when the cause is absent then the difference will be negative, and we speak of a 'preventive' or 'inhibitory' cause – it makes the effect less likely to happen. (Contingencies can range from -1 to $+1$.) Usually people are concerned with generative causes.

Using all the Information

The above computation of Δp suggests that all of the information should be equally important in evaluating the effectiveness of a cause. However, studies have shown that people tend to overweight the information in cell A – the 'present–present' cell. This overweighting may be one reason why people believe in superstitions or horoscopes. For example, there are people who believe that if they walk under a ladder they will have bad luck. And, in fact, once or twice when they did walk under a ladder they did have bad luck. However, they may fail to remember or consider the times they walked under a ladder and didn't have bad luck (cell B), the (possibly many) times they had bad luck without walking under a ladder (cell C), and the very many times they didn't walk under a ladder and didn't have bad luck (cell D). All of that information is needed before one can correctly evaluate whether walking under a ladder causes bad luck.

Considering the Base Rate of the Effect

Although the Δp computation captures the idea that a cause is something that changes the probability of an effect, the number that results from the computation may be deceptive when one is trying to evaluate the effectiveness of a particular cause. Besides looking at the contingency, people also consider how often an effect occurs in general (called the 'base rate' of the effect).

For example, suppose you have 100 plants in your garden but only 80 of them have flowers. You buy a special plant food, and soon all 100 have flowers. How effective is this product? It may only work 20 percent of the time (and have happened to work on the flowers that hadn't already bloomed); or it may work 100 percent of the time (but you couldn't tell because some flowers had already bloomed anyway).

It appears that people are sensitive to this problem when judging the effectiveness of a cause. For example, compare two plant foods. One was given to 100 plants where there were initially no flowers, and then 20 bloomed ($20/100 - 0/100 = 0.20$). The other, as above, was given to 100 plants where there were initially 80 flowers, and then all 100 bloomed ($100/100 - 80/100 = 0.20$). Both plant foods have a contingency of 0.20, yet the first worked only on 20 percent of the plants that didn't already have a flower whereas the second worked on 100 percent of the plants that didn't already have a flower.

People judge the second plant food as more effective than the first even though the contingencies are equal. Thus, it seems that people take into account the base rate of the effect and adjust their estimates according to how much influence a cause had above and beyond the influence of other causes.

THE ROLE OF PRE-EXISTING KNOWLEDGE

We have seen how we can use statistical covariation information to assess the relation between a potential cause and effect. However, we don't only use statistical information when making causal judgments; our pre-existing knowledge of the world will influence which statistical information we will pick up and use, and how we will limit and interpret the statistical relations we discover.

The most important limitation to note is that even though finding a contingency means that there is a correlation between the two events, that does not mean that the first event causes the second event. As scientists often say: 'correlation

does not prove causation'. For example, every morning, just before dawn, the rooster crows. Then the sun rises. Yet we do not believe that the rooster crowing causes the sun to rise. In many cities, when ice cream sales go up, the murder rate goes up; when ice cream sales go down, the murder rate goes down. Yet we do not believe that eating ice cream causes people to commit murder. Why not? Because we have other knowledge.

Causal Mechanisms

Why don't we believe that the rooster causes the sun to rise even though there is a perfect correlation? One idea is that we don't believe it because we can't conceive of a causal mechanism. How could the noise of a tiny animal affect a powerful celestial object? In fact, belief (or non-belief) in a mechanism can direct, or misdirect, searches for potential causes. For example, in the mid-nineteenth century a physician named Ignaz Semmelweis had a very difficult time convincing physicians to wash their hands after examining a cadaver before turning to deliver a baby (to lessen mortality of the mothers) – a practice that seems obvious and obligatory now – because no one then could imagine a causal mechanism.

So where do our beliefs about causal mechanisms come from? One possibility is that they come from our knowledge of similarities, categories, and other statistical relations. We don't believe that the rooster causes the sun to rise because we know that lions roaring don't cause rain and dogs barking don't cause full moons. There are no statistical relations between one 'kind' of event (animal noise) and the other 'kind' of event (weather), so we never developed the idea that there could be a causal mechanism. On the other hand, these days we are willing to accept that many new ailments can be caused by unseen microorganisms which can be transmitted in many ways (e.g. breathing, touching) because we have noted other similar relations in the past.

Labeling a Cause as a Cause

Given the same combination of events, which gets labeled as a 'cause' of the outcome may differ between situations, individuals, and cultures. For example, suppose a fire breaks out in a nearby warehouse and you are explaining the cause of the fire to a friend. You are likely to mention that there was an arsonist or a stroke of lightning. You are unlikely to mention the presence of combustible material or oxygen, even though both of those are necessary for the fire. Under 'normal' circumstances we just assume that they are present, and so their presence or absence does not covary with the outcome and we do not consider them causes. Now imagine a special furniture factory in which an area is kept free of oxygen so that high-temperature welding can take place. One day there is an oxygen leak, and when the usual welding begins a fire ensues. Under these special circumstances, you would call the oxygen a cause of the fire. Thus, what we point to as being causal is not just something that increases the probability of an effect, but rather something that increases it relative to some background assumption of what is stable or normal.

Which of the many relevant factors a person chooses to pick out from the background and label as a cause may also depend on that individual's beliefs. For example, suppose a young man robs a shop. What caused this behavior? Some people would argue that it was because he was brought up in a bad neighborhood, citing the fact that children brought up in his neighborhood are more likely to go on to commit such a crime than children brought up in better neighborhoods. Other people would argue that it was because he was a 'bad apple', citing the fact that there are many other children brought up in his neighborhood who do not commit such crimes. In such a case, what you label as a 'cause' may influence what you believe is the best treatment for the problem.

Different cultures also tend to pick out different factors as causal. For example, in individualist cultures (such as the United States and Australia) people are more likely to attribute causality for an action to the actor's personality or 'disposition', whereas in collectivist cultures (such as China and India) people are more likely to attribute causality to the situation or circumstances. (*See* **Cultural Differences in Causal Attribution**)

Alternative Causes

Although it seems easy enough to figure out the statistical relationship between one cause and one effect once you know where to look, the world is complicated and it is not always possible to examine one potential causal relation at a time. Sometimes potential causes are independent, so you can evaluate each separately. But often potential causes covary with each other, making it difficult to distinguish the causal contribution of each.

Controlling for alternative causes

When two or more potential causes of an effect act at once, and not independently, we have to control for one cause while evaluating the other. As a simple example, suppose you rush into your favorite coffee shop and assert loudly that drinking coffee must cause lung cancer because people who drink lots of coffee get lung cancer more often than those who do not (a positive Δp). Probably none of the coffee drinkers there would be alarmed: they would point out to you that perhaps people who drink more coffee also smoke more, so although it may look as if coffee drinking causes lung cancer, it is really smoking that is doing the causal work. Here people see an alternative causal mechanism to explain the lung cancer: smoking. To evaluate whether coffee drinking causes lung cancer while controlling for smoking you need to (1) consider all people who don't smoke and ask whether coffee drinking increases their probability of getting lung cancer, and (2) consider all people who do smoke and ask whether coffee drinking increases their probability of getting lung cancer. If the answer is negative in both cases, then coffee drinking is not a cause of lung cancer: it is only because it covaries with smoking that it seems to raise the probability of lung cancer.

When evaluating whether something is a cause of an effect, it is important to control for alternative causes. Obviously, it is never possible to know for certain that one has considered all potential alternative causes, but controlling for known alternative causes is a technique intentionally used by psychologists and other scientists to improve scientific reasoning.

However, controlling for alternative causes is difficult without a theory of what those alternative causes might be. In the coffee example, people don't believe there is a way in which coffee drinking could cause lung cancer, so they seek an alternative causal mechanism. But in the case of ice cream sales and murder rates, it might be plausible to think that increased sugar consumption causes violence, and leave it at that. A mechanism is not necessarily correct just because it is plausible. When temperature is controlled for, there is no correlation between ice cream sales and murders; they only seem related because hot weather leads to more of both. Many experiments have shown that people do control for known alternative causes when judging causal effectiveness. If experimenters tell people about an alternative cause, or if they have a reason to believe that some alternative factor (e.g. smoking) might be causal, then they will think of controlling for that cause. However, in experiments where the alternative factor (like temperature) is not so obvious, people are less good at controlling for it.

Thus, pre-existing knowledge of a causal mechanism may affect what information people acquire from the environment, what they control for, and, ultimately, what they will judge as the causes of other events.

Discounting

Although people do control for known alternative causes, the presence of an alternative cause may lead to a misjudgment of causal strength – known as 'discounting'. Discounting occurs when someone learns about two causes at the same time, and the judgment of the strength of the first cause is affected by the strength of the second cause. For example, suppose you have allergies and your doctor prescribes two medications A and B. Sometimes you take one, sometimes the other, and sometimes both. Medication A works ($\Delta p = 0.33$), but medication B doesn't work ($\Delta p = 0$). You tell the doctor that A is fairly effective in relieving your allergies. Now consider what would have happened had the doctor prescribed medications A and C instead. A still works ($\Delta p = 0.33$), but C works even better ($\Delta p = 0.67$). In your report to the doctor, you are likely to judge A as being less effective when the alternative cause is strong (C) than when the alternative cause is weak (B) – even though A's effectiveness is the same.

Experiments have shown that discounting occurs even in simple cases when the two causes are independent. Discounting might result from a strategic decision or a belief that once we have found a good cause of an effect we need not invest in reliably assessing other potential causes.

JUDGING CAUSALITY IN SINGLE INSTANCES

We have considered how people make causal judgments when they have information about many instances of the cause and effect occurring. But how do we make causal judgments for events that occur only once (e.g. an accident, a crime, or a big promotion)? One theory is that we use counterfactual reasoning to make these judgments.

Counterfactual Reasoning

In many situations, people look back on a past episode and wonder what might have happened if some change had occurred leading up to its conclusion. For instance, suppose you decided to

drive home from work by a scenic route one day because it was particularly beautiful outside, and along the way your car was hit by a reckless driver. Many, if not most, people in this situation would replay the episode in their mind in such a way that the accident is somehow 'undone'. For instance, you might imagine that if only you had taken your usual route home, or if only you had left a few seconds later, the accident would have been avoided. These imaginings of how the past might have been different involve counterfactual (or contrary-to-fact) thinking because the mentally replayed episode differs in some respects from the real episode.

Some philosophers and psychologists have proposed that counterfactual thinking plays an important role in causal reasoning. To explore the possible causes of a particular outcome, a person may mentally change one of the events preceding the outcome (an 'antecedent') and observe whether the outcome still occurs in the mental replay. If it is easy to imagine that the outcome would also be undone, then the antecedent is likely to be seen as one of its necessary causes. If, however, the outcome still seems inevitable, then the antecedent is unlikely to be seen as causally relevant.

Political scientists, historians, and legal scholars sometimes run counterfactual thought experiments to examine the causal implications of a particular change to a complex system. For example, some historians have considered what might have happened if Archduke Franz Ferdinand had not been assassinated in Sarejevo; and some have concluded that if that event had not happened, then the First World War would not have happened either. Although counterfactual thought experiments can be informative, it is usually impossible to verify whether the causal inferences drawn from them are justified – precisely because history cannot literally be replayed.

Similarities and Differences Between Causal and Counterfactual Reasoning

Counterfactual and causal reasoning sometimes focus on different events. For instance, in the car accident scenario, if people are asked directly about the cause of the accident they tend to identify the reckless driver, whereas if they are asked to generate counterfactuals that would undo the accident they tend to mention the route taken home. The counterfactual thoughts that come to mind may represent one's after-the-fact understanding of how the bad outcome could have easily been prevented. Thus, counterfactual thoughts often focus on behaviors that individuals can control. On the other hand, causal explanations often focus on antecedents that our knowledge of the world indicates would covary with the outcome over a set of similar cases. Thus, people say that the reckless driver was the cause of the accident because they realize that reckless driving is predictive of car accidents in general.

Even though the two forms of reasoning sometimes diverge, there is nevertheless a strong interplay between counterfactual and causal reasoning. If one cannot imagine that an antecedent might have been different, then it is unlikely that the antecedent will be identified as a cause. This is why, under normal conditions, oxygen makes a poor causal explanation for fire, even though it is a necessary condition. Similarly, if one cannot imagine an outcome having been different, then it is questionable whether it could be causally explained other than by recourse to concepts such as fate or destiny, which by definition, emphasize the immutability and inevitability of past episodes. (*See* **Counterfactual Thinking**)

DEVELOPMENT OF CAUSAL REASONING

Causal reasoning is necessary for human survival and, not surprisingly, the ability to perform such reasoning develops early. However, it is difficult to study causal reasoning in infants, because researchers cannot ask them direct questions about their judgments. Instead, researchers often use a technique called the 'habituation paradigm'. This technique takes advantage of the fact that when infants see the same events repeatedly (e.g. pictures on a video monitor, animations, objects moving in real life), they gradually get bored and will look at the events for shorter durations. If, however, they see a new or different event, they will 'dishabituate' and look for longer. Researchers can infer what infants count as 'the same thing' or 'a different thing' using this technique.

When using the habituation paradigm to study causal reasoning, researchers may show infants videotapes of collision events. In the 'causal launching' event, object *A* moves across the screen and hits stationary object *B*. When *A* strikes *B*, *A* stops, and *B* immediately begins to move with the same speed and direction as *A* had previously. This event looks natural to an adult, as if *A*'s collision with *B* caused *B* to move. Researchers can then modify these events. For example, a delay may be introduced, so that after *A* hits *B*, *B* remains in place

for a second or two before it begins moving. Or, *B* may begin moving before being hit by *A*. With these modifications, adults will claim that it doesn't look as if *A* caused *B* to move. Do infants treat these modified events as the same as, or different from, the natural-looking causal launching event? Research has shown that by the age of about seven months, infants do perceive a difference between causal launching events and noncausal events. However, they perceive the difference only if the objects involved in the events are simple; for more complicated objects infants may have to be 10 months old to make the distinction.

If it takes infants longer to understand causality regarding more complicated objects, what about more complicated events? Often in life, we don't just say that an outcome was caused by the action that immediately preceded it; rather, we look back in time to see what caused that particular action. For example, when Mum sees milk spilled on the floor and yells at Little Sister to wipe it up because it fell from her tilted glass, if Little Sister says 'Big Brother pushed me' then he, rather than she, is seen as the cause and gets Mum's wrath. It is considered a sign of sophisticated reasoning in adults to be able to look back into the past for causes; this ability also develops over time in infants: at 10 months old they don't look back at earlier causes, whereas at 15 months old they do.

Thus, we see that causal reasoning starts to develop early, but not all at once. Rather, both the complexity of the objects involved in the events and the complexity of the relations between events affect causal understanding. (*See* **Causal Perception, Development of**)

CONCLUSION

Causal reasoning is a pervasive and important form of thinking that begins at an early age. People engage in causal reasoning in order to explain past outcomes, to achieve control over their natural and social environment in the present, and to forecast, plan and prepare for the future. However, reasoning about causality is complicated. It is complicated, in part, because causal judgments depend on multiple cues, such as covariation, spatial and temporal contiguity, and our beliefs about what is normal. It is also complicated because information about such cues may be obtained in a variety of ways, such as by observing new cause–effect sequences, recalling knowledge about the world, and mentally imagining counterfactuals. Moreover, the answer to the question 'What is the cause?' may depend on one's choice of causal background – which may be affected by motivation, knowledge, and culture. Despite the complexity of the concept, the power of such knowledge, when it is accurate, is formidable. Without the ability to understand causality and use causal knowledge, both our internal mental world and the external physical world in which we live would be radically different.

CONTENTS

Change blindness is the tendency to fail to detect changes in a stimulus array while actively exploring it. This happens when the perception of the motion that typically accompanies stimulus change is prevented or disrupted.

INTRODUCTION

As we look around our visual world, we have a sense that we are continuously perceiving most or all of the available information. Thus, it came as some surprise in 1992 when scientists from the University of Illinois reported research indicating that if parts of a rich photographic image are changed while an observer makes a saccadic eye movement, these changes frequently go unnoticed (Grimes, 1996). Such intrasaccadic changes of the presence, location, size, orientation, color, category, or identity of a prominent object often go undetected as a person looks around a picture. Normally a person notices an image change because of the stimulus motion accompanying it; however, when the change occurs during a saccade, that motion is hidden by saccadic suppression. Thus, people cannot notice the change unless information they acquire following the change conflicts with that obtained prior to the change. Such detection failures have been taken as evidence that making a saccade (lasting only 20–80 ms) destroys the iconic image from the prior eye fixation, thus ruling out integration of iconic retinal images across fixations (Irwin, 1992), and further, that only a small amount of information (e.g., an object's identity or category, or perhaps the scene's gist) is actually retained from each eye fixation. The mental representation of a scene that is built up, incrementally, across eye fixations is apparently quite sparse; although visual memory cannot store the rich retinal image that is present during a fixation, it may not need to, since (as Kevin O'Regan has argued) the brain can easily access that information again by simply making an eye movement, so long as the stimulus array remains unchanged. Failure to detect a change in the visual stimulus was later labeled 'change blindness' by Daniel Simons. A lively research area has arisen, investigating what is, and is not, retained from a complex display during its viewing, with numerous theories about the significance this has for understanding perception, attention and cognition.

REQUIREMENTS FOR CHANGE BLINDNESS

Change blindness occurs when an initial stimulus is presented, followed by a change to a different stimulus, but with the transition being perceptually hidden in some way. Normally a local or global change in a picture is easy to detect, since the change induces the perception of motion, which automatically captures attention. In the original paradigm, making the transition during a saccade hid the change. Studies were conducted in which an image was changed for a single eye fixation, allowing a precise examination of whether the changed information was acquired during that particular fixation (McConkie and Currie, 1996). However, a later study (Rensink *et al*., 1997) showed that a saccade was not necessary to elicit change blindness. Rather, the same effect can be produced by alternating between two versions of a picture, blanking the screen for roughly 100 ms or more between them. Here, the visual disruption produced by the blank screen hides the transition. By continuously 'flickering' between images, the experimenter can measure the time taken by the viewer to discover what is changing. Many such

changes are surprisingly difficult to find, as illustrated in Figure 1. Soon other methods for hiding the transition were being employed: changing the image during a blink, briefly introducing irregular blotches ('mud splashes') that compete for attention simultaneously with the image change, morphing between the two images so slowly that the motion is not detected, using film editing techniques to 'cut' from one camera shot to another in motion pictures, or even physically blocking the person's view in a real-world setting.

(a)

(b)

Figure 1. Two versions of a photograph used to study change blindness. These two versions (a) and (b), are repeatedly presented, one after the other, on a computer screen for about 0.25 s each, with a 0.10 s blank period between. After a period of searching, people typically detect a change in one small area, and only later realize the full extent of the change taking place. This demonstrates that people are able to retain only a small amount of information from each presentation of the picture. (used with permission of Gregory J. Zelinsky).

In a dramatic demonstration of the last method, while an experimenter asked a person on the street for directions, their view of each other was briefly occluded by two men who rudely walked between them carrying a door, and an experimenter of different dress and build quickly replaced the questioner (Figure 2). Roughly half of the people tested failed to notice the change in their interlocutor (Simons and Levin, 1998).

PREVIOUS OBSERVATIONS OF CHANGE BLINDNESS

On reflection, it is obvious that the change blindness phenomenon has long been utilized: magicians developed ways of diverting attention so a change is not noticed, and the familiar 'spot the difference' cartoons require people to make saccades (with the attendant disruptions) between two pictures to find what has been changed. In psychology, from the 1950s on, various studies tested people's memory by asking them to look first at one picture, then at another, and indicate any difference. However, only recently has the change blindness phenomenon elicited particular theoretical interest among those studying perception and cognition.

EXPLANATIONS OF CHANGE BLINDNESS

There are several types of explanations for the failure to detect image changes. First, the critical prechange information might never have been attended to, or it might have been forgotten afterwards. Alternatively, after the change, the critical information might not be attended to. Finally, the information both before and after the change might have been attended to but the discrepancy between them might not be noticed, indicating a lack of integration of information acquired at different times. Thus, researchers try to determine the extent to which change blindness in a given situation results from attentional selectivity (information from before or after the change is not attended and stored), forgetting, or failure to integrate stored information. Explanations of instances of change blindness are given below.

Spatial or Object-based Inattention

Selective visual attention is critical in change blindness. Factors that draw attention to an object increase the likelihood of detecting changes to it,

Figure 2. A real-world example of change blindness. (a) An experimenter stops someone (an unwitting 'subject') on the street and asks for directions. (b) In the middle of their interaction, two men rudely pass between them carrying a door; during this brief interval, the original experimenter is replaced by a second experimenter. After the door passes, the second experimenter continues the conversation with the subject as if nothing had happened (c). About half the time, subjects fail to notice that they are now talking to a different person, even though the two experimenters differ in height, build, hair style, and clothing (d). From Simons and Levin (1998), with permission.

while reducing the detection of changes elsewhere. If a verbal cue indicates the identity of a change before its occurrence, or a visual cue draws attention to the changed object, detection is greatly facilitated (Rensink *et al*., 1997; Scholl, 2000). Having more objects in the display delays detection of a change in one object due to increased attentional scanning (Zelinsky, 2001), and when several objects change location, people usually detect the movement of only one (McConkie and Loschky, 2000). People who have a wider attentional breadth, measured by their ability to detect briefly presented targets in peripheral vision, are better at detecting changes under flicker conditions (Pringle, 2000). Changes occurring in central vision, the region most likely to be attended to during a fixation, are better detected than changes in the visual periphery. Finally, changes to objects of greater interest in a picture are detected faster than changes to objects of lesser interest (Rensink *et al*., 1997). All these phenomena argue for the importance of selective attention, though attending to an object does not necessarily result in detection of a change to it.

Temporal Inattention

During reading, there is evidence of attention to words at only selected times during fixations (Blanchard *et al*., 1984). In one study, at the beginning of each fixation the text being read contained one letter at a specified location. After a short period the text was briefly masked, and then reappeared but with the critical letter being changed, for example changing the word 'leaks' to 'leans'. Thus, one word was present at that location at the beginning of each fixation, and a different word during the latter part of each fixation. Readers were usually unaware of this change, reporting having read only one of the words: the perceived word was sometimes the earlier word and sometimes the later. This suggests temporal inattention. Whether this inattention to a word only occurs because attention is being given to a different word is not known.

Memory

The initial information that will be changed must be retained if the change is to be noticed. Pringle

(2000) found a strong relationship between people's composite scores on a battery of visuospatial working memory (VSWM) tests and their ability to detect changes, providing evidence for the role of memory in change detection. In fact, the VSWM measure predicted people's detection ability better than a test of attentional breadth did.

Expectations

Viewer's expectations and world knowledge also play a part. Changes of task-related aspects of a display (color of a traffic light for a driver) are detected more quickly than changes of unrelated aspects (location of a light pole) (Pringle, 2000). Changes to objects inappropriate in their context are detected faster than when they are appropriate (Hollingworth and Henderson, 2000).

Stimulus Characteristics

The more objects or parts of an object that change, the greater is the likelihood that a change will be detected (McConkie and Loschky, 2000; Williams and Simons, 2000). On the other hand, some features of the stimuli to which the gaze is directed can be changed during a saccade without detection. For example, size changes are often not detected (Grimes, 1996; McConkie and Currie, 1996). When reading text printed in AlTeRnAtInG cAsE (every other letter in upper case), the case of every letter can be changed during a saccade, thus changing the shape of every letter and word, without the readers' awareness or any effect on their eye movements. This indicates that letter and word shapes are not preserved across saccades during reading. Just directing the gaze toward an object does not guarantee that changing it will be detected: there are cases in which the viewer makes two successive eye fixations on an object in a picture, with the object changing substantially between those fixations, with no detection of the change (Grimes, 1996). These examples are all consistent with the proposal that the visual system retains only a limited set of the features of an attended object.

Coordinating Perception Across Saccades

A different mechanism, related to basic processes involved in coordinating perception across saccades, has been proposed for detecting intrasaccadic shifts, or displacements, of the stimulus (McConkie and Currie, 1996). It is proposed that, prior to making a saccade, the visual system chooses a target to send the eyes to (the 'saccade target object') and stores some identifying features (the 'locating features'). On the next fixation, the first task is to search for the locating features within the region of central vision (the 'search region'), to find the retinal location of the saccade target object. Locating that object establishes a mapping function between current retinal information and information obtained during prior fixations, enabling further perceptual activities to occur. If an intrasaccadic displacement of the stimulus moves the saccade target object out of the search region, this disrupts further processing and produces a conscious awareness of the image displacement, or change detection. Similarly, if the locating features are changed, this will interfere with the finding of the saccade target object.

The importance of the saccade target object in perception is confirmed by the fact that spatially displacing only that object is far more detectable than is displacing everything else in a picture except the saccade target (Currie *et al*., 2000). This work suggests that intrasaccadic display changes can be detected on different bases. Changes may be detected by early visual processes that are involved in locating the saccade target at the beginning of a fixation, or later as information acquired in the fixation is recognized as conflicting with information retained from earlier fixations.

CONSCIOUSNESS AND CHANGE BLINDNESS

An important limitation of current research is that it has depended almost exclusively on conscious report: did the viewer detect the change? However, it is possible that image changes produce effects on processing even if not consciously perceived. Studies are needed to search for effects of undetected display change on implicit measures of processing, such as eye movements or brain waves. Results from such studies could challenge current conclusions about the sparsity of information retained from brief stimulus exposures.

CONCLUSION

Although change blindness is an intriguing phenomenon, in some sense it is only incidentally a topic of study. Rather, it is a research paradigm that can be used to study issues regarding the selection, acquisition, retention and integration of information. Its primary contribution has been to call attention to how little information is retained from eye fixations and other brief exposures to

complex stimulus patterns such as photographs or real-world scenes, and how sparse our mental representations actually are.

Choice Selection

Intermediate article

John W Payne, Duke University, Durham, North Carolina, USA
James R Bettman, Duke University, Durham, North Carolina, USA

CONTENTS

Choice selection involves a set of alternatives, each described by some attributes or consequences for the decision-maker's goals. Decision-makers choose among such options using a variety of different psychological strategies.

INTRODUCTION

Multiattribute Choice Problems

Decision-making is a fundamental cognitive behavior which depends on a person's values and beliefs and can range from mundane problems (such as selection of a menu item for lunch) to more substantial and infrequent decisions (such as which automobile to purchase), and life-or-death decisions (such as a choice between alternative medical treatments). At the heart of the decision-making process is choice or selection among alternative courses of action. A simplified automobile choice task is illustrated in Table 1. Each choice option i (alternative) is described by a vector of attribute values (x_{i1}, x_{i2}, …, x_{in}), reflecting the extent to which each option meets the objectives (goals) of the decision-maker.

A key feature of almost all choice problems is the presence of conflict, since no single alternative is best (most preferred) on all attributes. Conflict is a major source of decision difficulty; negative emotions can arise from the need to accept less of one valued attribute (e.g., safety) in order to achieve more of another valued attribute (e.g., cost savings). The presence of conflict and the fact that a rule for resolving the conflict often cannot be drawn from memory are reasons that even simple choice tasks can lead to tentativeness and the use of novice problem-solving methods rather than the kind of pattern recognition methods that are typically associated with expertise in various domains.

Choice Among Risky Options

Another key feature of choice problems is the degree of certainty of the consequences associated with an attribute value. For example, one might (or might not) be certain about the level of reliability for a particular car in Table 1. Another example of uncertainty and choice is selecting between two gambles, one of which offers a higher probability of winning a lower amount of money while the other offers a lower probability of winning a larger amount of money. A real-world example of a risky choice problem with such trade-offs is selecting among investment options (gambles) such as bonds versus computer stocks for the next year when one is uncertain whether the state of the economy will improve or worsen.

CHOICE MODELS

The study of decision processes has long been of interest to psychologists, economists, and researchers in many other fields. How do people make preferential choice decisions of the types described above? The rational choice view is that people solve all (most) decision problems by obtaining all the relevant information about the decision problem, incorporating uncertainties into their reasoning, making trade-offs where necessary, and eventually selecting the alternative that maximizes their values. That is, people are presumed to be exquisitely rational beings who have, if not perfect, at least clear and voluminous information, who are able and willing to make trade-offs, and who always select the best course of action (Simon, 1955). The view that people are generally rational decision-makers means that one can start by trying to work out the best way a decision problem should be solved, assume that people try to do the best and are capable of calculating the best option, and therefore that the same model that provides a

Table 1. An example of a choice task

Car	Reliability	Price	Safety	Horsepower
A	Worst	Best	Good	Very poor
B	Best	Worst	Worst	Good
C	Poor	Very good	Average	Average
D	Average	Poor	Best	Worst
E	Worst	Very poor	Good	Best

Attributes are scored on seven-point scales ranging from 'best' (the most desirable value for the attribute) to 'worst' (the least desirable value).

normative definition of rational choice also provides a reasonable model of actual decision behavior.

Mathematical (Rational) Decision Models

Two classic rational choice models of decision behavior are the weighted additive value model (WADD) and the subjective expected utility model. The WADD model is often used to represent in a mathematical form the trading-off process in decision-making. A measure of the relative importance (weight) of an attribute is multiplied by the attribute's value for a particular alternative and the products are summed over all attributes to obtain an overall value for that alternative, WADD(X):

$$\text{WADD}(X) = \Sigma\, W_i V(X_i) \text{ for } i = 1 \text{ to } n \qquad (1)$$

where W_i is the weight given to attribute i, $V(X_i)$ is the value of option X on attribute i, and n is the total number of relevant attributes. The WADD model represents a normative procedure for dealing with multiattribute decision problems (see Keeney and Raiffa, 1976) in that it uses all the relevant information, explicitly resolves conflicting values, and selects the option with the highest overall evaluation. Note that it also assumes that the effects of the attributes are independent (i.e., there are no interactions), which may not always be appropriate. The WADD model underlies many of the techniques used by economists, market researchers, and others to assess preferences.

A model for making choices under risk and uncertainty is the subjective expected utility (SEU) model. The subjective expected utility of a risky option (gamble) is given by

$$\text{SEU}(X) = \Sigma\, S(P_i)U(X_i) \text{ for } i = 1 \text{ to } n \qquad (2)$$

where $S(P_i)$ is the subjective probability of occurrence for outcome X_i, and $U(X_i)$ is the utility to the individual of receiving amount X_i, e.g., an amount of money. Note that the SEU model is similar in structure to the WADD model, weighting each possible outcome by its probability of occurrence, summing those products over all possible outcomes, and then selecting the gamble with the highest SEU.

Cognitive Limitations and Heuristic Decision Processes

Although people sometimes make decisions in ways consistent with the WADD and SEU models, it has become obvious over years of decision research that people often make decisions using simpler decision processes (heuristics), more consistent with the idea that people are, at best, only boundedly rational. The bounded rationality view of decision-making emphasizes a decision-maker's limited information processing capabilities and the interaction of those computational limits with the complexity of task environments: 'human rational behavior is shaped by a scissors whose two blades are the structure of task environments and the computational capabilities of the actor' (Simon, 1990: p. 7).

In part because of limitations in information processing capacity, preferences for objects are often constructed at the time people are asked to make choices. That is, people may construct preferences on the spot when needed rather than simply retrieving well-defined values for objects when they are asked to make a choice (March, 1978). In addition, because of limited processing capacity and the need to be adaptive to task demands, decisions are often made not by using some invariant rule such as SEU, but rather by using a variety of decision strategies contingent upon the demands of the task environment (Payne *et al*., 1993). Such contingency upon a variety of task and context factors is consistent with and implied by the constructive nature of preferences. Finally, although the concept of bounded rationality does not mean that people are poor decision-makers, the combination of limited cognitive capabilities and difficult decision problems means that people sometimes make systematic errors when facing choice problems. For example, people will sometimes say that they prefer option A to option B, B to option C, and C to A (Tversky, 1969), or that they prefer A to B but would be willing to pay more for B than for A (Tversky *et al*., 1988).

Several commonly used decision-making heuristics have been identified. If a lexicographic strategy (LEX) is used, the alternative with the best value on the most important attribute is simply selected (assuming that there are no ties on this attribute); for example, if a decision-maker faced with the choice problem in Table 1 thought that reliability was the most important attribute for cars, he or she could use a lexicographic strategy, examine reliability (and no other information) for all five cars, and choose car B. If two alternatives have tied values, the second most important attribute is considered, and so on until the tie is broken. The LEX strategy is a choice heuristic, consistent with the bounded rationality notion that limited capacity for processing information implies that people generally cannot process all of the available information in a particular situation and must therefore be selective in what information is used. Even when the amount of available information is within the bounds of processing capacity, the processing of that information imposes cognitive costs. Thus, selective processing of information is generally necessary, and the information that is selected for processing will have a major impact on choice. Under some task conditions, for instance, the LEX choice heuristic can be almost as accurate a decision rule as more information-intensive strategies like WADD (Payne *et al*., 1993). Finally, the LEX strategy is a good example of a conflict-avoiding decision strategy that may minimize the emotional aspects of making a decision, because the focus is on only a single attribute at a time. The LEX strategy is a form of 'one reason' decision-making emphasized by Gigerenzer *et al*. (2001).

Satisficing (SAT) is another classic strategy for coping with bounded rationality. With a satisficing strategy, alternatives are considered sequentially, in the order in which they occur in the choice set. The value of each attribute for the option currently under consideration is compared to a predetermined cutoff level for that attribute. If any attribute fails to meet the cutoff level, the option is rejected and the next option is considered. For example, car A might be eliminated rapidly because it has the worst level of reliability. The first option passing the cutoffs for all attributes is selected. If no option passes all the cutoffs, the levels can be relaxed and the process repeated. Like the LEX strategy, satisficing does not involve explicitly considering tradeoffs and is therefore a noncompensatory model of decision-making – that is, a good value on one attribute cannot compensate for a below cutoff (poor) value on another attribute. One of the key differences across choice processes is the extent to which a compensatory (e.g., WADD) or noncompensatory decision process is utilized. Another property of the SAT strategy is that the option chosen will be a function of the order in which the options are processed. Thus, one can potentially influence choice by structuring the order in which options are considered.

Elimination by aspects (EBA) is a commonly used choice heuristic combining elements of both the LEX and SAT strategies. It eliminates options that do not meet a minimum cutoff value for the most important attribute. This elimination process is repeated for the second most important attribute, with processing continuing until a single option remains (Tversky, 1972). In our car example, suppose that the decision-maker's two most important attributes were reliability and safety, in that order, and that the cutoff for each was an average value. This individual would first process reliability, eliminating any car with a below-average value (cars A, C, and E). Then the person would consider safety for cars B and D, eliminating car B. Hence, car D would be selected. Elimination by aspects focuses on the attributes as the basis for processing information, is noncompensatory, reflects rationality in the ordered use of the attributes, and does not use all potentially relevant information. The extensiveness and selectivity of processing will vary when using EBA depending upon the exact pattern of elimination of options. As a general rule, the preferences expressed when using choice heuristics like LEX, satisficing, and EBA are subject to potentially 'irrelevant' task variables such as the order in which options and/or attributes are considered.

Decision-makers also use combinations of choice strategies. A typical combined strategy has an initial phase in which some alternatives are eliminated, and a second phase where the remaining options are analyzed in more detail. One frequently observed combination is an initial use of EBA to reduce the choice set to two or three options, followed by a compensatory strategy such as weighted adding to select among those. An important implication of the use of combined strategies is that the 'properties' of the choice task itself may change as the result of using a particular strategy first. For example, the use of a process for eliminating dominated alternatives from a choice set, an often advocated procedure, will make the conflict among attribute values more extreme, perhaps then triggering the application of a new strategy on the reduced set of options.

TASK AND CONTEXT EFFECTS

Constructed Preferences

Research supports the idea that people use choice heuristics and the more general constructive view of preferences. For example, people use a variety of different strategies to solve choice problems contingent upon the nature of the task, e.g. how many options are available, and the context of the choice problem, e.g. is the choice among a set of generally good or generally poor options. Task factors are general characteristics of a decision problem, such as number of alternatives available, response mode (e.g. choice or judgment), time pressure, or information format, that do not depend on the particular values of the alternatives. One well-replicated and important task effect is that people use compensatory (trade-off based) types of decision strategies (e.g. WADD) when faced with a decision problem involving only two or three alternatives. However, when faced with a more complex (multialternative) decision task, people tend to use noncompensatory strategies such as EBA. People also tend to use more noncompensatory strategies when asked to make choices rather than judgments, and when choosing under time pressure.

Context factors, such as the similarity of alternatives, are associated with the particular values of the alternatives in a choice set and the relationships among those values. Context variables affect both how decisions are made and which option is chosen from a set of alternatives. For example, the more negative the correlations among the attribute values (i.e., the more one has to give up something on one attribute to obtain more of another attribute), the more likely it is that people will use a WADD (expected value) strategy when choosing among gambles. Interestingly, when the attributes are more emotional, such as safety, greater conflict among attribute values tends to lead to greater use of strategies like the LEX rule (Luce *et al*., 2001).

A context effect that shows how the nature of the choice set can influence which option is chosen is illustrated by the problem in Table 2. Comparing options A and B, one is faced with a trade-off between ride quality (better with A) and fuel consumption (better with B). A basic principle of most choice models, regularity, states that adding a new option to the choice set containing A and B cannot increase the probability of choosing one of the original options. However, imagine that you are faced with the choice of A, B, or C rather than just A or B. Note that C is 'dominated' by option B: B is better than C on one attribute (ride quality) and at least equal to C on the other attribute (fuel economy). Option C is not dominated by A, so that in comparing options A and C there would still be a trade-off to be considered. Thus, there is an asymmetric dominance relationship among the three options A, B, and C. Given that C is dominated by B, it is highly unlikely that a person would select C. However, does the presence of C influence the choice between A and B? The answer is yes. Adding option C to the original choice set of A and B tends to increase the probability of selecting B (Huber *et al*., 1982). This increase in the probability of choosing the dominating option B with the addition of C violates the principle of regularity. Such a context effect indicates that 'people do not maximize a precomputed preference order, but construct their choices in the light of available options' (Tversky, 1996: p. 17).

Reason-based Choice

A number of explanations have been offered for the asymmetric dominance effect. One that has received support is that people use the relations among options as reasons for justifying their choices; that is, one can easily see that B is better than C, and this relationship provides a good reason for choosing B and not A. The size of the asymmetric dominance effect increases when people are asked to explicitly justify their choices (Simonson, 1989). Bettman *et al*. (1998) speculated that the fact that option B dominates option C is a good reason for choosing option B at an outcome level of explanation (it is clearly a better outcome than C). There is no need to refer to a process-level explanation (e.g. I chose B over A because of the trade-offs I prefer between ride quality and fuel economy). Outcomes are likely to be more salient than process in the wake of a decision, so arguments based on outcomes may provide better reasons.

Using easily detected relationships among the options in a choice set as a reason for choice allows a person to avoid cognitively and emotionally difficult trade-offs. For example, selecting the option in a set of three that is between the more extreme

Table 2. An example of an asymmetric dominance task

Car	*Ride quality*	*Fuel consumption (miles per gallon)*
A	83	24
B	73	33
C	70	33

options can be justified as a 'compromise' choice without having to explicitly consider trade-offs. For more on a reason-based view of choice processes, see Shafir *et al*. (1993).

CONCLUSION

The study of choice processes has been a subject of long-standing interest for psychologists, economists, and researchers in many other fields. How people make choices frequently departs from a purely rational decision process, reflecting the interplay of cognitive processing limits and task demands. People use a variety of simplifying choice heuristics and search for easy-to-justify reasons for preferring one option over another. As a consequence, the option people choose can be influenced by a variety of predictable task and context factors. More generally, in many situations the preferences people exhibit are constructed at the time of choice rather than reflecting pre-computed values.

While much has been learned about choice behavior, there is still much to be learned about how decisions are made and how decision-making can be improved.

Cognitive Development, Computational Models of

Intermediate article

Denis Mareschal, Birkbeck College, London, UK

CONTENTS

Computational models of cognitive development are formal models of the information processing, and changes in information processing, that take place during cognitive development. They are generally implemented as running computer simulations. They are tools for exploring mechanisms of transition (development) from one level of competence to the next during the course of cognitive development.

COGNITIVE DEVELOPMENT AND THE COGNITIVE SCIENCES

Jean Piaget, the father of cognitive development research, saw himself as an empirical philosopher. His goal was to answer the fundamental questions of epistemology through rigorous experimentation. He asked how knowledge (especially abstract conceptual knowledge and logic-based reasoning) could emerge from a child's interactions with the world. Piaget produced a vast body of work exploring the development of cognitive components such as the concepts of Space, Time, Number, and Causality. He is generally recognized as having identified the key questions that have set the agenda for cognitive development research since the 1950s.

Piaget was greatly influenced by the philosophies of Kant and Bergson, and by the Cybernetics movement of the early twentieth century. He believed that children constructed an understanding of the world through active engagement with the world and that feedback played a crucial role in learning and development. Unfortunately, he failed to ground many of his proposals because he lacked an appropriate vocabulary with which to express his dynamic and mechanistic ideas. The advent of cognitive science has provided powerful conceptual tools for addressing many of Piaget's original queries.

Contemporary theories of cognitive development lie along two distinct – albeit related – dimensions. One of these is the Nativist vs. Empiricist dimension (i.e. the nature vs. nurture debate). Radical Nativists believe that all knowledge is available to the infant prior to any learning experiences. Radical Empiricists believe that the infant is born with no prior knowledge, and that all knowledge is acquired through some form of experience with the world. Although no developmentalist will admit to holding either of these extreme views, the field is nevertheless polarized into two camps with strong, sometimes extreme, biases towards one or the other of these poles.

A second, more recent, dimension is the symbolic vs. subsymbolic dimension. Those in the symbolic camp believe that cognition is best characterized as a rule-governed physical symbol system. In this view, cognitive development consists in the modification rules. Those in the subsymbolic camp see cognition as a highly interactive dynamic system (e.g. an artificial neural network) that does not operate as a symbol processing system. In this view development consists in the continuous tuning of the underlying parameters of the cognitive system.

The rest of this article presents a number of models that illustrate the different developmental domains in which modeling has been undertaken. It also illustrates fundamental differences in the developmental mechanisms proposed. As will become apparent in this review, most symbolic models have emphasized the tractability of the knowledge representations involved in cognitive development at the expense of implementing explicit transition mechanisms. In contrast most subsymbolic models have emphasized the specification of a developmental mechanism at the expense of the tractability of the knowledge representations.

WHY BUILD COMPUTATIONAL MODELS OF COGNITIVE DEVELOPMENT

The Computer Modeling Methodology

Computer models complement experimental data gathering by placing constraints on the direction of future empirical investigations. First, developing a computer model forces the user to specify precisely what is meant by the terms in his or her underlying theory. Terms such as representations, symbols, and variables must have an exact definition to be implemented within a computer model. The degree of precision required to construct a working computer model avoids the possibility of arguments arising from the misunderstanding of imprecise verbal theories.

Secondly, building a model that implements a theory provides a means of testing the internal self-consistency of the theory. A theory that is in any way inconsistent or incomplete will become immediately obvious when trying to implement it as a computer program. The inconsistencies will lead to conflict situations in which the computer program will not be able to function. Such failures point to a need to reassess the situation and re-evaluate the theory.

A positive corollary of these two points is that the model can be used to work out unexpected implications of a complex theory. Because the world is highly complex with a multitude of information sources constantly interacting, even a simple process theory can lead to uninterpretable behaviors. Here again, the model provides a tool for teasing apart the nature of these interactions and corroborating or falsifying the theory.

Perhaps the main contribution made by computational models of cognitive development is to provide an account of the representations that underlie performance on a task that also incorporates a mechanism for representational change. One of the greatest unanswered questions of cognitive development is the nature of the transition mechanisms that can account for how one level of performance is transformed into the next level of performance at a later age. This is a difficult question because it involves observing how representations evolve over time and tracking the complex interactions between the developing components of a complex cognitive system. Building a model and observing how it evolves over time provides a tangible means of doing this.

Formulating development in computational terms forces the theoretician to be explicit about the mechanisms that underlie information processing. Piaget's own mechanistic theory provides an excellent example of why this is necessary. He described cognitive development in terms of assimilation, accommodation, and equilibration. Assimilation consisted in adapting or filtering incoming information to make it more compatible with existing knowledge representations. In contrast, accommodation consisted in adapting one's knowledge representations to make them more consistent with novel information. Equilibration was the process by which assimilation and accommodation interacted to cause cognitive development. While assimilation and accommodation capture intuitive notions of what might be involved in cognitive development, they are too loosely defined to be of any explanatory value. Some connectionist computational models of cognitive development have tried to solve this problem by providing computational implementations of assimilation and accommodation in terms of activation flow and weight updates respectively.

MODELS OF DEVELOPMENT IN INFANCY

Infancy is an ideal age range to begin modeling because infant behaviors are not complicated by the presence of language and sophisticated metacognitive strategies. Infant abilities are closely tied to their developing sensorimotor skills.

Object-Directed Behaviors

Kant identified objects as a fundamental category of cognition. The ability to represent hidden objects liberates infants from the tyranny of direct perception. It is the first step towards representational thought. Piaget suggested that infants progressed through six stages on the way towards an adult level of understanding of object permanence at the age of two. While many of Piaget's original findings have been replicated, changes in methodology (e.g. relying on visual attention measures rather than manual retrieval measures) have suggested that infants have a far more precocious understanding of hidden objects. These studies have all focused on infant competence at different ages but not on the mechanisms of development from one level of competence to the next.

There are relatively few computational models of infant object-directed behaviors (Mareschal, 2000). Early models took a strong cognitivist stance on behavior and were thus implemented in rule-based production systems (e.g. Luger *et al*., 1983).

Unfortunately, they were basically competence models that described infant behaviors but did not provide a mechanistic account of development. They proposed different sets of rules to describe behavior at different ages but did not explain how new rules could be acquired or how one set of rules was transformed into another set of rules. More recent (cognitivist) models have turned to attention-based accounts of object processing in an attempt to explain infant behaviors (Simon, 1998). Unfortunately, these models still fail (by and large) to implement any account of *how* development might occur.

One mechanistic learning model has implemented a parallel processing version of Piaget's sensorimotor theory of infant development. Drescher (1991) tried to show how the coordination of intra- and intermodal perceptual motor schemas could lead to a single unified representation of an object. Perceptual motor schemas were encoded as 'context-action-result' rules and implemented in a parallel processing machine. Learning consisted in using marginal probabilities to fill in context and results slots in appropriate perceptual motor schemas. Although this system developed an intricate network of intra- and intermodal schemas that mimic the infant's sensorimotor integration, it did not develop according to the pattern described by Piaget.

A number of connectionist models have also been proposed. In one family of models, a partially recurrent autoencoder network learns to predict the reappearance of a stationary object from behind a moving screen that temporarily occludes the object (Munakata *et al*., 1997). Network performance is measured by taking the difference in response of the nodes coding the location of the hidden object when an object should be revealed and subtracting it from the response of the nodes when an object should not be revealed. An increase in this difference is interpreted as increased knowledge of hidden objects. What this model shows is that object representations that guide action can be graded and arise though interactions within an environment.

Mareschal *et al*. (1999) describe an alternative connectionist model that is more closely tied to the neuropsychological finding that visual object information is processed down two separate routes. This model uses a combination of modules to implement dual route processing. One route learns to process spatial-temporal information while the other route learns to process feature information. Finally, a response module recruits and coordinates the representations developed by the other modules as and when required by a response task. The route specializations emerge as a result of the different associative mechanism in each module.

Perceptual Categorization

Because categorization lies at the heart of cognition it is not surprising to find that great effort has been exerted in trying to understand the early roots of category formation. Many infant categorization tasks rely on preferential looking or habituation techniques, based on the finding that infants direct more attention to unfamiliar or unexpected stimuli (Mareschal and Quinn, 2001). Connectionist autoencoder networks have been used to model the relation between sustained attention and representation construction (Mareschal *et al*., 2000). The successive cycles of training in the autoencoder are an iterative process by which a reliable internal representation of the input is developed. This approach assumes that infant looking times are positively correlated with the network error. The greater the error, the longer the looking time, because it takes more training cycles to reduce the error.

The perceptual categories formed by infants are not always the same as the corresponding adult categories. For example, when shown a series of cat photographs three- to four-month-olds will form a category of CAT that includes novel cats and excludes dogs (as will adults). However, when shown a series of dog photographs, the same infants will form a category of DOG that includes novel dogs but also includes cats (in contrast to adults). Many aspects of early infant perceptual categorizations (including the asymmetric exclusivity of CAT and DOG categories) are captured by the connectionist autoencoder model. In contrast to adults who apply top-down schemas when recognizing photographs of cats and dogs, three- to four-month-olds, like the autoencoder networks, simply process the bottom-up information in these images. Hence, their internal category representations are yoked to the distributional properties of features in the images. The model demonstrates that categorical representations can self-organize in a neural system as a result of exposure to the familiarization exemplars encountered within the test session itself.

Early Word Learning

Categorization is equally important in early language acquisition, both in terms of learning which sounds in the environment are relevant to speech

and in terms of learning the domain of applicability of a new word.

Infants are better at discriminating phonemes that do not belong to their linguistic environment at seven months than at 14 months. This has been interpreted as evidence for a shift in lexical processing between these age groups. The suggestion is that seven-month-olds are processing the sounds of the stimuli whereas the 14-month-olds are processing the stimuli as words. The process of word learning itself changes the way the stimuli are processed. In contrast, Schafer and Mareschal (2001) present a connectionist autoencoder model suggesting that these behaviors reflect two stages of the same processing mechanism. The model learns to associate sound representations with image representations (i.e. simple word learning). Early in training, the model is not committed to any meaningful internal representations for sound and is therefore better able to learn novel speech sounds in testing than later in training when it has firmly committed to representations tailored to its native linguistic environment. This model illustrates how discontinuities in behavior can emerge by the slow tuning of continuous parameters.

Once infants have segmented the sound stream into word units, there is the further problem of identifying the extension of the category referred to by the word (the Symbol Grounding Problem). One early model (Schyns, 1991) used a combination of self-organizing (kohonen feature maps) and supervised (backpropagation) connectionist networks to model the interactive process of identifying the category underlying the word, and then associating it with an appropriate label. This model showed many of the same developmental effects as young children learning novel words. In particular, the categories showed prototype effects and mutual exclusivity constraints. It demonstrated how the acquisition of a new word arose as an interaction of bottom-up and top-down effects. A more recent (autoencoder) model (Plunkett *et al*., 1992) shows how over extension and under extension errors, typical of children's early vocabulary, can arise through simple associative mechanisms in a system with shared sound and image internal representations.

MODELS OF DEVELOPMENT IN CHILDHOOD

Language acquisition marks the end of infancy and the beginning of childhood. Reasoning and conceptual development are the hallmark of cognitive development in childhood. The models in this section all focus on some aspect of reasoning development. We begin by reviewing models that have explicitly tried to implement Piagetian ideas. This is followed by a review of work that breaks away from the Piagetian tradition.

Modeling Piagetian Stage Development

There have been several attempts to explain the apparent stage-like growth of competence in children in terms of self-organization in dynamic systems, competition between cognitive growers, and bifurcation theory (e.g. van Geert, 1998). However such accounts have tended to rely only on mathematical descriptions that are either not implemented in running computer models or grounded in measurable information processing components.

As early as the 1960s an effort was made to use neural networks to operationalize the Piagetian notions of assimilation and accommodation. Several interpretations of connectionist learning in terms of assimilation and accommodation have been proposed. One such interpretation suggests that weight changes constitute a form of accommodation whereas the transformation (by the network weights) of input patterns into internal patterns of activation constitutes assimilation (McClelland, 1995). Another interpretation suggests that the adaptation of a network architecture constitutes a form of accommodation whereas the adaptation of weights is a form of assimilative learning (Shultz *et al*., 1995).

Models that try to implement Piagetian notions of development have attempted to model children's performance on key tasks (e.g. conservation: Klahr and Wallace, 1976; Shultz, 1998). One such task is the seriation (or sorting) task. Piaget found that children's ability to order a set of sticks developed through a number of stages. In a first stage, children were unable to sort the sticks. In a second stage, they were able to apply local ordering relations but could not extend the order to the set as a whole. In the third stage, they were able to sort the set of sticks, but only by applying a costly trial and error strategy. Finally, in the fourth stage children were able to sort the set quickly and efficiently by applying a systematic selection strategy.

Young (1976) approached this task from an information processing perspective. He carried out detailed analyses of the actions children carried out at different ages when sorting blocks. Based on the results of protocol analyses, he developed a rule-based production system that captured children's performance at each stage of development.

Progress from one stage to the next was modeled by the (hypothesized) modification of the rules. Although this model provided a good fit to children's behavior at individual stages, it fails to provide a working account of how those rules are modified. A recent connectionist model of the seriation task suggests how development could occur (Mareschal and Shultz, 1999). This model argues that development consists in the gradual tuning of connection weights, and the gradual extension of knowledge about small sets to larger sets. The model not only captures the stage progression described by Piaget, but it also captures the variability in sorting behaviors observed both within and between subjects.

Beyond Piaget: The Balance Scale Task

A recent benchmark of cognitive development, first developed by Inhelder and Piaget and later significantly extended by Robert Siegler, is the balance scale task. Siegler explored children's developing abilities to reason about balance scales. In these problems, children were presented with a symmetric balance scale with five equally spaced pegs on either side of the fulcrum. Weights were then placed on pegs to the left and the right of the fulcrum and children were asked to predict whether the balance scale would tip to the left, to the right, or remain balanced.

Seigler used a rule assessment methodology to infer the rules that govern children's performance. He found that rule one children relied only on a dominant dimension (weight) to predict which side the balance scale would tip. They predicted that the side with the most weights would be the side that the balance scale would tip. Rule two children applied the same rule as the preceding children, but had an additional rule stating that if the number of weights was equal on both sides, the side with the greatest distance would predict the side to which the balance scale would tip. Rule three children behaved like the rule two children with the exception that if the weight and distance cues provided conflicting answers they would guess which side went down. Finally, rule four children had a set of rules that effectively computed the torque on both sides of the balance scale and chose the side with the greatest torque. Seigler suggested that this knowledge was represented in the form of a growing decision tree. Klahr (1992) pointed out the equivalence of this representation to that of an increasing rule; a representation consistent with production system models of cognitive development.

Both connectionist (McClelland, 1995; Shultz *et al*., 1994) and decision tree models (Schmidt and Ling, 1996) of development on the balance scale task have been proposed. The connectionist models construe the problem as one of integrating information from two sources. They capture stage development in terms of microgenetic weight changes and hidden unit recruitment. An assumption of these models is that children have greater experience with weight comparisons than distance comparisons. The decision tree model uses the C4.5 tree-inducing algorithm. Children were hypothesized to have an increasing memory capacity and to care increasingly about the detail of correctness of their answers. While this latter model captures the main features of children's performance, the decision trees developed did not map onto those proposed by Siegler to reflect children's knowledge at different ages.

Modeling of the Development of Reasoning

Many of the successful developmental models described above are connectionist models. Such models process information based on the surface similarity between different exemplars. However, there are cases when children's (and adults') reasoning does not follow surface similarity. Analogical reasoning requires the child to distance his or herself from the surface similarity between the target and vehicle domains. Indeed between six and nine years of age children move from basing their analogies on surface similarity (such as color) between the two domains to structural similarity (such as the function of an object) between the two domains. This reliance on structural similarity is very difficult for connectionist systems to capture.

Gentner has suggested that adults and children solve analogical problems by comparing mental representations via a structure-mapping process of alignment of conceptual representations. A structurally consistent match conforms to a one-to-one mapping constraint between the domains. The process is implemented in the Structural Mapping Engine (SME) model. The SME is used to model the relational shift in children's analogical reasoning in terms of increased domain knowledge. As their knowledge of domain relations increases, children's relation representations within a domain become richer and deeper, increasing the likelihood that their comparisons will focus on matching relations. Thus, what develops between six and nine years is only knowledge and not processing.

Siegler and Shipley present a model of strategy choice. The intention is to provide some account of the range and variability of strategies observed in young children's problem solving. Their model is based on the strategies used by children when adding integers. The strategies are explicitly represented in terms of rules. Strategy choice is probabilistic. The probability of retrieving and executing a strategy depends on the previous association of that strategy with an outcome in conjunction with considerations of cost and efficiency. The strategy pool evolves according to a Darwinian procedure in which infrequently used strategies die off and new strategies enter the pool via random perturbations of existing strategies.

CHALLENGES TO CURRENT MODELS OF COGNITIVE DEVELOPMENT

The 'poverty of the stimulus' argument was most effectively put forward by Chomsky in response to Skinner's account of language acquisition. It is not possible for an unconstrained inductive learner to acquire a particular target grammar within a reasonable time. This argument has been wielded against connectionist models of language and cognitive development in general. However, it is important to understand that the 'poverty of the stimulus' argument holds for all inductive learning systems and in all domains (its application is not unique to connectionism). This is why most contemporary scholars of learning (whether studying learning in children or machines) believe that the key to understanding cognitive development is to identify the nature of the constraints on the learner that will allow knowledge to emerge.

Fodor's paradox claims that an inductive learner can never acquire any truly novel concept (Fodor, 1980). Indeed, in order to test the domain of applicability of a concept, the inductive learner must be able to represent that concept prior to having identified it. Hence, any learning simply involves the recombination of existing representational tokens in a system. While this may be true of inductive learning systems, it is not true of systems that increase their representational power in response to environmental pressures. Such systems include neural networks that construct their own architecture as part of learning and development (Mareschal and Shultz, 1996).

Finally, while computer models allow us to formulate questions about what can possibly cause cognitive development (e.g. processing capacity, processing speed, knowledge, and strategy choice) more constraints are required to identify the actual mechanisms involved in children's cognitive development. Recent advances in neuroimaging techniques have allowed us to place greater constraints on how information is processed in the brain. Many of the models above make little use of these constraints and, in the future, such constraints should be incorporated in any functional models of development. Furthermore, cognitive development does not occur in a social vacuum. Vygotsky has emphasized the role of social interactions in cognitive development. Society provides a kind of cognitive scaffolding that nurtures and aids the child's cognitive development by actively selecting and filtering the type of problems the child is faced with at any age. Future models will need to consider these constraints to reflect the child's learning environment more accurately.

Cognitive Science: Experimental methods

Introductory article

Raymond S Nickerson, Tufts University, Medford, Massachusetts, USA

CONTENTS

Cognitive activity can be studied in a variety of ways, including observation, simulation by computer modeling, and controlled experimentation.

INTRODUCTION

Cognitive science is a broad topic. It encompasses cognitive – or cognitive-like – activity wherever it is found, in humans, animals or machines. It is studied in a variety of ways, including observation, simulation (notably by efforts to give computers the ability to do things that when done by people are considered cognitive), and controlled experimentation.

PURPOSES OF EXPERIMENTATION

Scientific experimentation involves the investigation of how the controlled manipulation of one or more (independent) variables affects one or more other (dependent) variables.

Experiments are performed for several purposes, including testing hypotheses, establishing the values of parameters of process models, comparing the predictive power of competing theoretical accounts of specific phenomena, and evaluating the effectiveness of operational devices or procedures in realizing the intents of their designers. Sometimes experiments are done for such purposes as investigating hunches that are not sufficiently precise to be treated as testable hypotheses, looking for relationships or regularities that are worthy of more focused study, checking the adequacy of experimental designs, or fine-tuning setups of experimental equipment in anticipation of their use for more formal purposes. Experiments of these types are sometimes referred to as exploratory, pilot or calibration studies, and they are less likely than more formal studies to be reported in scientific journals – but they are experiments nonetheless. Experiments are also sometimes done to demonstrate already known relationships among variables; although these may replicate the conditions of experiments that have already been conducted for purposes of discovery, their purpose is strictly educational.

All these distinctions pertain to experimentation on cognition as well as to experimentation in other fields.

COMPARISON OF METHODS

Laboratory Versus Field Methods

Most studies of cognition take place in university laboratories or classrooms, or in the research facilities of industrial or government organizations. Some, however, are done in the field. An example of laboratory research is an experiment designed to investigate the effects of the spacing of rehearsal on the memorization and recall of verbal material. An example of field research is a study of the effects of a secondary task, such as carrying on a telephone conversation, on how well an automobile driver performs the driving task.

The choice of laboratory or field research in any particular case is likely to involve consideration of a trade-off between control and realism: between precision and applicability to real-world contexts. Generally speaking, it is possible to exercise much greater control over variables – both those whose effects the investigator is interested in studying, and those that are better thought of as nuisance factors – in a laboratory setting than in the field. However, this greater degree of control is usually bought at the price of making the situation so artificial that generalization of the findings from the laboratory to the real world may be difficult or impossible.

For these reasons it is desirable when possible to verify the generalizability of findings obtained in the laboratory to the real-world situations to which

they are believed to apply before drawing firm conclusions about their applicability. The laboratory findings can serve as tentative conclusions that need to be confirmed in the real-world situation of interest. This approach is illustrated by efforts to determine whether what students have learned in a laboratory context designed to teach specific aspects of flying an airplane transfer to performance in an actual flight situation.

Cross-sectional Versus Longitudinal Studies

Most experiments in psychology involve comparisons between measurements that are made at approximately the same time. To determine the immediate effects on hearing of short-term exposure to noise, for example, one might simply determine the ability of people to detect weak auditory stimuli after exposure to noise of different intensities. Sometimes, however, the interest is in how people's abilities (attitudes, values, beliefs) change over long periods.

One experimental approach to the study of such changes is to investigate people of different ages; another is to study the same group of people over many years. The advantage of the first (cross-sectional) approach is that the study can be done quickly; a disadvantage is that people in the different groups are likely to differ in ways other than age (they were born and grew up in different times), which can complicate the interpretation of results. The advantage of the second (longitudinal) approach is the opportunity to see how people change with respect to abilities and other characteristics of interest with the passing of time; a disadvantage is that such studies take many years to perform, during which participants may leave the study, funding may be lost, and so on.

Both cross-sectional and longitudinal studies have proved useful in the study of aging, the findings of the one type complementing those of the other.

Single-case Studies Versus Averaging Over Multicase Samples

The vast majority of experiments on cognition involve the averaging of experimental data over a group of participants. Case studies, however, can sometimes provide extensive and in-depth information about individuals that is generally not available in data from multicase samples. Often case studies are opportunistic in the sense that they capitalize on the occurrence of a unique event or the chance discovery of an individual with an unusual ability. The highly publicized case of Phineas Gage, the railroad worker who in 1848 suffered a horrendous but nonfatal injury when an iron bar used for tamping explosive powder was propelled by an accidental explosion completely through his head, illustrates the first situation. Gage's experience was unusual, if not unique, and documentation of the long-term cognitive and affective effects of his injury contributed to a better understanding of how certain functions depend on specific parts of the brain.

There are many published examples of case studies of individuals with unusual memories. John Dean's recorded recollection of events as given in testimony before the Watergate committee of the US Senate in 1973 provided the basis for one such study; discovery of a man (Hideaki Tomoyori) who was able to recite from memory the first 40 000 digits of pi provided another. Experiments with Tomoyori showed his ability to recall the details of narrative stories to be quite ordinary.

Comparing and Evaluating Models with Empirical Evidence

As in all experimental sciences, the acid test of the tenability of a theory in cognitive science is its ability to predict the results that would be obtained in carefully controlled experiments. In practice, progress occurs in a cyclic fashion. Predictions are derived from a theory. The predictions are tested by experimentation. Depending on the outcomes of experiments, theories may be strengthened and made more precise, or they may be shown to be false or in need of modification. Sometimes experimental results match theoretically derived predictions closely, in which case the theories from which the predictions were derived are considered to have been corroborated – not to have been proved, but to have gained greater credibility. Sometimes the results match the predictions only marginally or not at all. In such a case, if the experiment has been carefully done, the theory from which the prediction was derived might have to be modified or replaced.

A type of theorizing that has been used to great advantage in science involves the building of models of processes of interest. Attempting to build a working model of a process – an artifact that behaves in the same way as the process of interest – is an especially fruitful way to develop an understanding of that process. It has often been pointed out that centuries of observing birds in flight were not nearly as effective a means of

learning about aerodynamics as attempts to build machines that could fly. Efforts to give computers the ability to do things that human beings do with apparent ease has revealed the hidden complexity underlying many human capabilities. The point is illustrated by the history of efforts to give computers the ability to understand natural language. Despite decades of intensive work on this problem, it remains unsolved in any general sense. It is now clear that the complexity of the problem was grossly underestimated when the quest was first engaged, but the effort has revealed much about human language comprehension, answering many questions while raising others that no one knew enough to ask before the effort was made.

The case for computational modeling has been articulated by several psychologists and cognitive scientists. Mathematical and computer models of human performance have been applied to great advantage to the design and study of complex systems in which humans function as hands-on operators or as supervisors of largely automated processes. Modeling typically involves an iterated series of steps: a model is developed that will accommodate experimental data that have already been collected, that model is then used as a basis for making predictions about the outcomes of additional experiments, and the actual outcomes of those experiments are used to modify the model or adjust its parameters so as to increase its predictive power or accuracy. This process of testing and refining can be continued indefinitely, or at least until the model is capable of predicting outcomes with a desired degree of accuracy or it becomes clear that it should be discarded for a qualitatively different one.

CONVERGING METHODOLOGIES

Many factors are relevant to the selection of an experimental methodology: the nature of the phenomenon of interest; the availability of resources (equipment, experimental participants, time); the practicalities of controlling the variables that must be controlled; the types of measurements that are feasible (brain potentials, skin conductance, pupil size, eye fixation, motor response times, verbal responses); the options one has for analyzing experimental data; the kinds of inferences one wishes to draw; and the nature of the population to which one wants to generalize the results. Often it is necessary to make trade-offs, gaining control, for example, at the expense of limited generalizability. Similarly, it typically is much easier for academic researchers to conduct experiments with students as participants than to conduct them with samples that are more representative of the general population, or of nonstudent populations to which they may wish to generalize results.

In general, experimenters tend to think of variance in data, other than that produced by intentional manipulation of the independent variables involved, as 'noise' that must be treated statistically in order to determine the effects of the experimental manipulations. However, one of the ways of limiting this noise (of controlling within-condition variability) is to use relatively homogeneous samples of participants; although this increases the chances of obtaining statistically significant results, it can also preclude the generalizability of the findings to populations that are less homogeneous than the sample studied.

For these and other reasons, it is good that experimentation can be done in a variety of ways. Generally, advances are made when insights into relationships are confirmed by experimental evidence of more than one type. Seldom, if ever, is any question of more than trivial importance, theoretical or practical, settled decisively with a single experiment. The general rule is one of gradual increase in understanding of phenomena of interest resulting from the convergence of evidence from a variety of sources.

CONTENTS

The psychology of color perception concerns color appearance and the visual processing of light spectral information. Researchers in this area seek to determine the relationships among visual stimuli, activity in the human nervous system and the conscious representation of color.

INTRODUCTION

Color is the psychological representation of light spectral properties. Normal human color vision is served by three classes of retinal photoreceptor, which differ in their abilities to respond to photons of varying wavelength. Comparing the responses of the three kinds of photoreceptor to a light provides an estimate of the light's spectral properties: how its energy varies with wavelength. Color depends also on the perceived cause of light reaching the eye, such as emission by a light source or reflection by a surface. Color thus helps to identify objects and their material properties, to the extent that object color remains constant under varying conditions of viewing and that color is handled appropriately by memory and other cognitive systems.

PHOTORECEPTORAL RESPONSES TO LIGHT

The transduction of light energy into neural responses is accomplished by the approximately 5 million cones and 100 million rods arrayed across the retina. Found primarily within the central 10° of the visual field, cones serve photopic vision under viewing conditions when colors are visible. Color vision depends on the responses of more than one spectral class of cone. The spectral sensitivity of a class of cones is determined by the photopigment molecule responsible for photon absorption. Knowledge of cone spectral sensitivities lets one predict the initial chromatic response of the visual system to a light.

Trichromatic Color Matching

That normal human color vision is served by a system with three spectral classes of sensors may be inferred from the results of color-matching experiments. A prototypical experiment uses quasi-monochromatic lights, each possessing energy in just a narrow band of visible wavelengths. The visible spectrum ranges in wavelength from about 400 nm (blue, with ultraviolet lights at shorter wavelengths) to about 700 nm (red, with infrared lights at longer wavelengths). Results show that a single monochromatic test light can be matched in appearance by combining additively three primary lights R, G and B, of appropriate intensity. It is sometimes necessary for one of the primaries to be added to the test light rather than to the other primaries. By varying the wavelength of the test light, one generates three color-matching functions $\bar{r}(\lambda)$, $\bar{g}(\lambda)$ and $\bar{b}(\lambda)$, which describe the intensity of each primary required to match the test of a particular wavelength (Figure 1a). The dependence of such color-matching functions on the arbitrary choice of primary wavelengths led to the development in 1931 by the Commission Internationale de l'Eclairage (CIE) of the XYZ colorimetric system. The $\bar{x}(\lambda)$, $\bar{y}(\lambda)$ and $\bar{z}(\lambda)$ color-matching functions in this system have no negative values, and the $\bar{y}(\lambda)$ function is identical to the photopic luminosity function $V(\lambda)$, which describes the relative brightness of monochromatic lights presented at photopic intensity levels (Figure 1b).

Cone Spectral Sensitivities

The three physiological response systems underlying normal color matching are the long (L), medium (M) and short (S) wavelength-sensitive cones, each class with a different photopigment. Their spectral sensitivities, taken in combination with knowledge of the spectral absorption characteristics of the eye's lens and macular pigment,

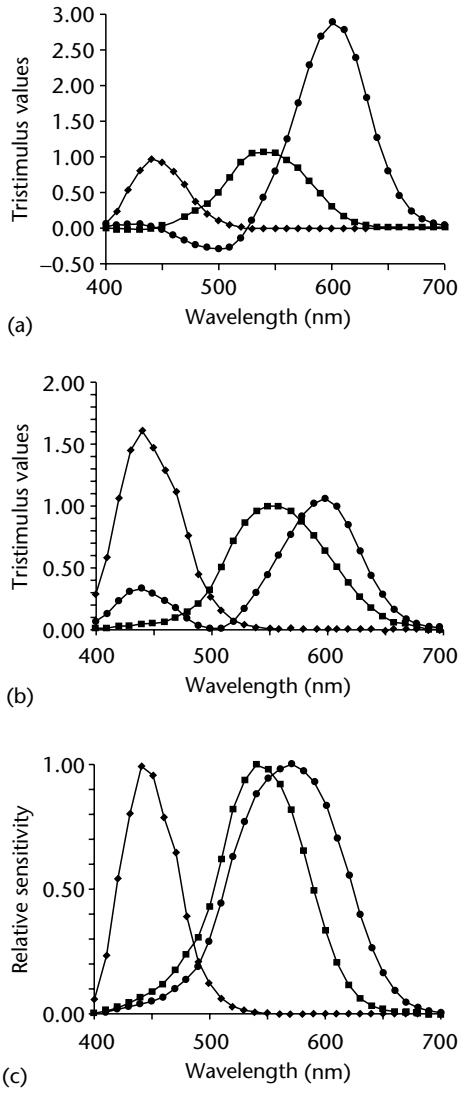

Figure 1. Trichromatic spectral sensitivity. (a) Values of the Stiles 2° color-matching functions $\bar{r}(\lambda)$ (●), $\bar{g}(\lambda)$ (■) and $\bar{b}(\lambda)$ (♦) with monochromatic primaries at 645.2 nm, 526.3 nm and 444.4 nm, plotted at 10 nm intervals. (b) The color-matching functions $\bar{x}(\lambda)$ (●), $\bar{y}(\lambda)$ (■) and $\bar{z}(\lambda)$ (♦) of the Judd-modified CIE 1931 standard 2° observer *XYZ* system. (c) The Stockman and Sharpe (2000) 2° cone fundamentals $L(\lambda)$ (●), $M(\lambda)$ (■) and $S(\lambda)$ (♦). The L and M cones have similar spectral sensitivities; S cones are almost completely insensitive to lights at wavelengths longer than 570 nm.

provide color-matching functions that determine the initial response of the visual system to spectral variation in lights. Rods possess a fourth photopigment, rhodopsin, which differs from those of the three classes of cones, and so potentially support a tetrachromatic response to lights of mesopic intensity.

The first accurate estimates of the cone spectral sensitivities were provided by an analysis of color matching by dichromatic observers (Smith and Pokorny, 1975). A dichromat can match in appearance any light by combining additively just two primaries. A dichromat confuses lights that are distinguishable to trichromatic observers in one of three ways, depending on whether the dichromat lacks L cones (a protanope), M cones (deuteranope) or S cones (tritanope). The color-matching confusions made by the three classes of dichromat let one derive a linear transformation relating cone spectral sensitivities to the CIE system. The psychophysical estimates were soon confirmed by the results of physiological experiments using microspectrophotometric and electrophysiological techniques. Refinements of these estimates based on molecular genetic considerations (Figure 1c) have now been introduced (Stockman and Sharpe, 2000).

Variation Among Individuals

Differences among individuals in chromatic sensitivity can be traced to five primary factors. The first is the pigmentation of the eye's lens, which tends to become more yellow (absorb more light at shorter wavelengths) as one ages and with exposure to ultraviolet light. The second is the amount of macular pigment in an eye. This yellow pigment covers the region of the retina serving central (foveal) vision and varies in density from one person to the next. The third is the numerosity of each class of cone. Anatomical measurements show that S cones form about 7% of the cone population; there are none in the very center of the fovea. There is some controversy about the average ratio of L cones to M cones, which may be about 1.5–2; however, this ratio varies considerably from person to person, and is thought to influence both photopic luminosity, to which S-cone signals do not contribute, and estimates of unique yellow. The fourth factor is photopigment optical density, which influences absolute photoreceptor responsivity. The fifth factor influencing individual chromatic sensitivity is photoreceptor relative spectral sensitivity. There are polymorphisms in the genes lying on the X chromosome which code for the L and M cone opsins (Sharpe *et al*., 1999). There are also hybrid genes which underlie anomalous trichromacy, evident when one of the L or M cone pigments has an abnormal spectral sensitivity. Dichromacy is exhibited when there is only one X-chromosome-linked cone photopigment (that of either the normal L or M cone, or of a hybrid), or when there are polymorphic versions of a single gene. Estimates of the peak spectral sensitivity of the M cone pigment lie in the range 528–532 nm, and

those for the two primary L cone polymorphisms in the ranges 553–558 nm and 557–563 nm. Hybrid genes lead to anomalous M cone peak sensitivities, estimated to lie in the range 529–538 nm and, for anomalous L cones, in the range 545–559 nm. In males of European descent, the behavioral expression of red–green color deficiencies occurs at about a rate of 7.4%; for males of Asian and African descent, the rates are 4.2% and 2.6%, respectively. Owing to the X chromosome placement of the genes for the L and M cones, behavioral expression of red–green color deficiency is much less common among females (about 0.5%).

Models of color perception by dichromats as reduced forms of normal trichromatic perception have been validated by reports of observers who are born with one normal and one color-deficient eye. Rather than perceiving the hues of the visible spectrum in the sequence red, orange, yellow, green, blue, indigo and violet, in passing from long to short wavelengths, both protanopes (1% incidence in males of European descent) and deuteranopes (1.3%) see the sequence yellow, blue, with the transition occurring at a wavelength just shorter than 500 nm. They are able to distinguish lights normally perceived as red and green only in terms of saturation and brightness variations. Tritanopes perceive the sequence red, blue–green, with the transition at about 560 nm; they are unable to discriminate lights at short and middle wavelengths. Inherited tritan defects are rare, because the gene sequence for the opsin component of the S cone photopigment molecule resides on chromosome 7. Acquired defects are more common, because S cone function deteriorates in a variety of medical conditions.

Chromatic Response

The first step in photoreceptoral transduction is the absorption of a photon by a photopigment molecule, which causes a change in the molecule's shape, leading in turn to a change in membrane potential. The likelihood that a photopigment molecule will absorb a photon, as a function of photon wavelength, corresponds to the receptor's spectral sensitivity. The principle of univariance holds that equal numbers of absorbed photons, no matter what their wavelength, generate identical receptoral responses. Univariance underlies the computation of a receptor's response to a light with photons at many wavelengths. In discrete form, one sums over wavelength the product of a photoreceptor's spectral sensitivity $P[\lambda]$ and light energy $E[\lambda]$ to compute the response p:

$$p = \sum_{i=1}^{n} P[\lambda_i]E[\lambda_i] \tag{1}$$

where n is the number of wavelengths at which the light possesses energy. In continuous form, one integrates over wavelength the product of the photoreceptoral spectral sensitivity function $P(\lambda)$ and the function $E(\lambda)$ describing light energy:

$$p = \int P(\lambda)E(\lambda)\mathrm{d}\lambda \tag{2}$$

One often works with spectral sensitivity functions that are tabulated at discrete intervals, for instance, from 400 nm to 700 nm in steps of 10 nm. The 31 numbers describing such a function can be thought of as comprising a 31-dimensional vector $\mathbf{p}$. By describing the light energy in a similar fashion to provide a vector $\mathbf{e}$, one finds that the response p is given by the dot product of the two vectors:

$$p = \mathbf{p}\cdot\mathbf{e} \tag{3}$$

The response of a trichromatic system to a light is represented by three numbers. For instance, one can use the L, M and S cone spectral sensitivities in place of the spectral sensitivity P above to determine the responses l, m and s, respectively. One consequence of the three-dimensionality of trichromatic visual response is that lights that differ physically may produce the same response. Such different but indistinguishable lights are known as metamers, and exist in consequence of the fact that a three-dimensional representation of lights cannot possibly represent accurately variation in the high-dimensional space of lights.

A light's chromaticity describes its chromatic properties independently of its intensive properties. For instance, if X, Y and Z are the responses to a light determined using the CIE $\bar{x}(\lambda)$, $\bar{y}(\lambda)$ and $\bar{z}(\lambda)$ functions, then the light's chromaticity (x, y) and its luminance L are given by the following formulae:

$$x = X/(X + Y + Z) \tag{4}$$

$$y = Y/(X + Y + Z) \tag{5}$$

$$L = Y \tag{6}$$

Perceived hue and saturation vary in the two-dimensional color space described by chromaticity; equiluminant lights vary in chromaticity alone.

COLOR OPPONENCY

The Young–Helmholtz theory that the responses of the L, M and S cone systems are tied directly

to the perception of red, green and blue, respectively, is of historical interest alone. Subsequent work has substantiated Hering's idea that color appearance is due to the activity of opponent mechanisms that compare photoreceptoral system responses. Color-opponent processing commences in the retina, as is evident in the responses of bipolar cells and ganglion cells, and continues in the lateral geniculate nucleus (LGN) and in visual cortex. The mismatch between psychologically determined color-opponent functions and physiological opponent-mechanism sensitivities is of current research interest. Higher-order color-opponent mechanisms, although implicated in the results of chromatic detection experiments and organized in a manner consistent with physiological studies of visual cortex, have yet to be linked to appearance.

Standard Mechanisms of Color Appearance

Color-opponent theory is based on the analysis of hue. Under simple viewing conditions, one cannot perceive a light that appears both reddish and greenish, or one that appears both bluish and yellowish. This suggests that the responses of two opponent mechanisms underlie color appearance. The first is a red–green mechanism, the response of which can generate red or green, but not both simultaneously; the second is a similarly organized blue–yellow mechanism. A second critical observation concerns the existence of lights with unique hues: unique red and unique green appear neither yellowish nor bluish, while unique yellow and unique blue appear neither reddish nor greenish. All other hues appear to combine two of the primary hues. For instance, orange appears both reddish and yellowish. One can integrate the observation of unique hues into the opponent model as follows: first, unique red and unique green are seen when the red–green mechanism responds red or green, respectively, and when the response of the blue–yellow mechanism is zero (signals neither blue nor yellow); and second, unique blue and unique yellow are seen when the blue–yellow mechanism responds blue or yellow, respectively, and when the response of the red–green mechanism is zero. Graded responses by the mechanisms can account for perceived color saturation (chroma). For instance, a highly saturated red will be seen if the red–green mechanism produces a strong red response; less-saturated reds correspond to weaker responses.

Hurvich and Jameson used a hue-cancellation technique to derive spectral sensitivities for the two opponent mechanisms (Hurvich and Jameson, 1957). For instance, the relative amounts of red in monochromatic lights of equal energy can be measured by adding a green light of fixed wavelength and varying its intensity to produce a unique yellow light, which appears neither reddish nor greenish. The intensity of the green light needed to cancel the redness found in lights of long and short wavelength provides a measure of the red half of the red–green mechanism's spectral sensitivity function. Similar procedures provide the green half of the red–green mechanism's sensitivity, and the blue and yellow halves of the blue–yellow mechanism's sensitivity (Figure 2a).

Opponent-mechanism sensitivities can be described in terms of cone responses by combining cone spectral sensitivity functions to provide the best fit to the opponent functions. Such fits suggest, first, that the responses of L and S cones are opposed to those of the M cones by the red–green mechanism, and second, the responses of S cones are opposed to those of L and M cones by the blue–yellow mechanism. The contribution by L and S cones to red causes not only lights at long wavelengths to appear red but also lights at very short wavelengths, a feature required to account for the redness in the violet lights at short wavelengths. The L and M cones combine in the blue–yellow mechanism to produce a yellow response that is opposed to the S cone's blue.

The opposition of cone responses results in color-opponent sensitivities that take on both positive and negative values. For instance, if the L and S cones are taken to excite and the M cones to inhibit the red–green mechanism, then the 'red' portion of the red–green spectral sensitivity will take on positive values while the 'green' portion will take on negative values. A positive response by such a mechanism would cause red to be perceived, and a negative response green.

A common emendation to the standard model, consistent with physiological evidence, uses rectification to produce separate red, green, yellow and blue mechanisms (as well as black and white) (Figure 2b). Nonlinear combination of cone inputs by such mechanisms can account for the spectral nonlinearity in blue–yellow processing; stated simply, too much of the spectrum appears blue and too little yellow to be consistent with linear combination of cone responses.

Chromatic Sensitivity

Chromatic sensitivity depends on adaptation by the visual system to viewing conditions. Absolute

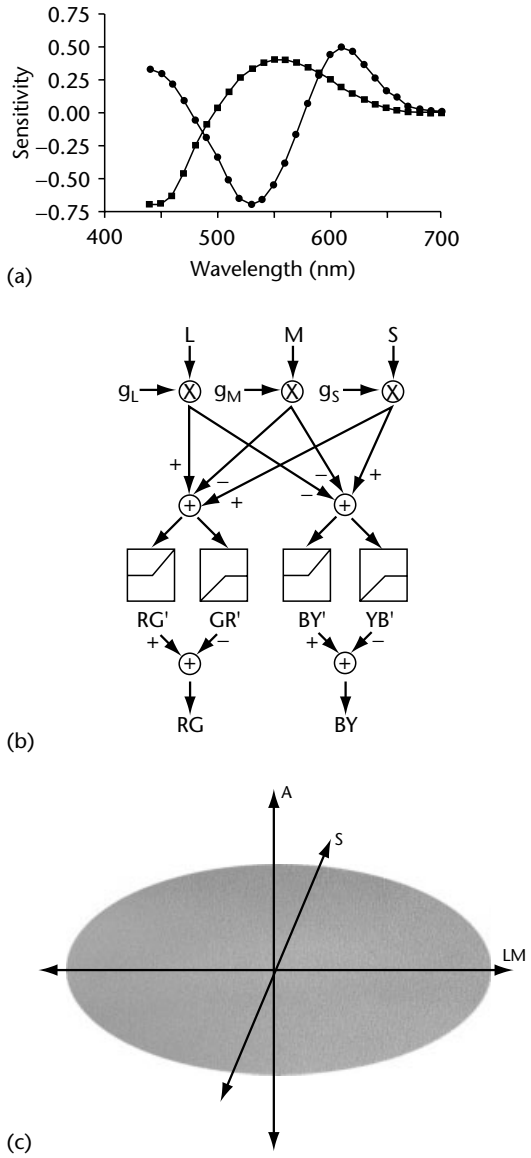

Figure 2. [*Figure is also reproduced in color section.*] Color-opponent transformation of photoreceptoral signals. (a) Hurvich and Jameson hue-cancellation functions. The red–green function (●) codes redness through positive values and greenness through negative values, while the yellow–blue function (■) codes yellowness through positive values and blueness through negative values. (b) Wiring diagram for color-opponent mechanisms. Signals from L, M and S cone photoreceptors with multiplicative gain controls are combined by half-wave-rectified opponent mechanisms to produce mechanisms that signal red (RG′), green (GR′), blue (BY′) and yellow (YB′) which are then combined to form RG and BY opponent channels. (c) Equiluminant colors in a plane defined by LM and S axes. Modulation among lights along LM and S axes changes only L and M cone signals and only S cone signals, respectively. These axes correspond to the peak chromatic sensitivities of the retinogeniculate pathways.

sensitivity to changes in light level about some reference light declines as the intensity of the reference light increases. This change occurs, in part, through the action of multiplicative gain controls within individual cone photoreceptors, although such adaptation of cones is significantly less than that predicted by psychophysical measurements. Chromatic adaptation to a steady background light also occurs at color-opponent sites in the visual pathways and is thought to involve both multiplicative and additive components.

The sensitivity of color-opponent mechanisms to modulations about a steady background light is high. The red–green mechanism supports the detection of red signals with L cone contrasts as small as 0.1%, a sensitivity more than five times greater than that found with stimuli of varying intensity (e.g. black–white). Equiluminant stimuli (Figure 2c) are generally used to probe the sensitivity of chromatic processing, because chromatic mechanisms are more likely to detect equiluminant stimuli than are mechanisms sensitive specifically to variation in light intensity. Equiluminant stimuli provide poor inputs to visual subsystems that handle motion, stereopsis, Vernier acuity and the interpretation of shadows. This is thought to be due, in part, to the strong coloration possible with very small contrast signals.

Chromatic sensitivity depends also on the spatiotemporal pattern of light modulation about a steady background light. For instance, prolonged viewing of a red–green temporal modulation reduces red–green sensitivity but leaves blue–yellow sensitivity relatively unscathed, and vice versa. Such long-term habituation to chromatic modulation is complemented by the activity of rapidly acting gain controls which operate on the spatial pattern of color-opponent contrast signals. Both habituation and color contrast gain control are thought to have a cortical locus.

Higher-order Mechanisms

Two spectral classes of color-opponent neuron are found in macaque retina and LGN. The first opposes L and M cone inputs linearly. Such a neuron does not have the sensitivity of the standard red–green opponent mechanism, which requires S cone input to produce red at short wavelengths. The second opposes S cone inputs to those of L and M cones. This class of neuron is largely insensitive to lights that correspond to unique red, so bearing one of the characteristics of the standard blue–yellow mechanism, but typically

combines cone responses linearly in a steady state of adaptation.

The mismatch between retinogeniculate processing and the standard color-opponent model takes a different form in areas V1, V2 and V3 of the visual cortex. Color-sensitive neurons in cortex have spectral sensitivities which are scattered more uniformly in the color plane (Lennie *et al*., 1990). Many such neurons are most sensitive to hues lying along axes in the color plane that lie between the LM and S axes that characterize retinogeniculate processing (Figure 2). Psychophysical work with habituation, visual search and noise-masking paradigms suggests that these higher-order mechanisms operate in everyday visual detection tasks. For example, observers can deploy a violet-sensitive mechanism when looking for a violet signal rather than looking for simultaneous red and blue signals. How these mechanisms contribute to color appearance, if at all, is an open question.

COLOR CONSTANCY

The utility of color in object recognition depends on the stability of an object's color appearance under change in its viewing conditions. An important aspect of this is the stability of surface color under change in the spectral properties of illumination. Observers can discount illumination spectral change nearly completely under appropriate circumstances (Kraft and Brainard, 1999). Physics-based analyses have identified conditions under which this is possible, and have explored a variety of cues that a trichromatic visual system can use to find descriptors of an object's surface reflectance function from reflected lights (Maloney, 1999). Transparency provides a further avenue into the study of surface color appearance; observers assign colors to surfaces behind a filter in a manner consistent with filter-specific changes in color-opponent signals (D'Zmura *et al*., 2000). The parallel representation of filter and surface chromatic properties in perceived transparency suggests that low-level chromatic signals are shunted into parallel, layered representations of scene color.

Change in Illumination Spectral Properties

A white piece of paper reflects very different lights towards the eye when viewed outdoors under direct sunlight or under a yellow tungsten lightbulb (Figure 3a). Perfect color constancy entails identical colors for the white paper under the two viewing conditions. This is possible if the visual system represents directly the chromatic properties of the paper's surface. These are specified by a reflectance function $R(\lambda)$, which describes the fraction of light reflected by a surface as a function of wavelength (Figure 3b).

Principal components analysis of collections of surface reflectance functions shows that much of their variation (greater than 99% in sets such as the Munsell chips) can be captured by just three components; to a good approximation, surface reflectance functions lie in a three-dimensional space (Figure 3d). A particular surface reflectance is identified by three descriptors which tell how much each principal component contributes to the reflectance. A trichromatic visual system can thus represent surface reflectance properties directly through a linear transformation of cone responses, similar to that by the standard black–white and color-opponent mechanisms, which produces surface reflectance descriptors.

Nevertheless, reflected light confounds illumination and surface spectral properties. The reflected light $E(\lambda)$ is the product of the illumination spectral power distribution $D(\lambda)$ and the surface reflectance function $R(\lambda)$. The linear transformation of cone responses which provides surface reflectance descriptors must change in response to illumination change if color constancy is to be possible.

Principal components analysis of collections of daylight spectral power distributions (SPDs) shows that almost all of their variation can be captured by just three components (Figure 3c). For daylight, then, knowledge of an illuminant's chromaticity lets one reconstruct its SPD, up to a single scale factor.

Potential cues to the chromatic properties of scene illumination are numerous. If one assumes that the brightest surface in a scene is white, with a spectrally flat reflectance function, then the photoreceptoral responses to the white surface correspond to those of the illuminant itself. This knowledge can be used to adjust the linear transformation of photoreceptor responses to provide color-constant reflectance descriptors. This idea works more generally for reference surfaces with known reflectance properties. The gray-world assumption is similar; one assumes that the space-averaged surface reflectance in a scene corresponds to a spectrally neutral gray, so that illuminant chromatic properties can be inferred from the space-averaged photoreceptor responses. Specularity provides a further such cue; the lights from two or more surfaces with highlights provide sufficient information to infer illuminant chromatic

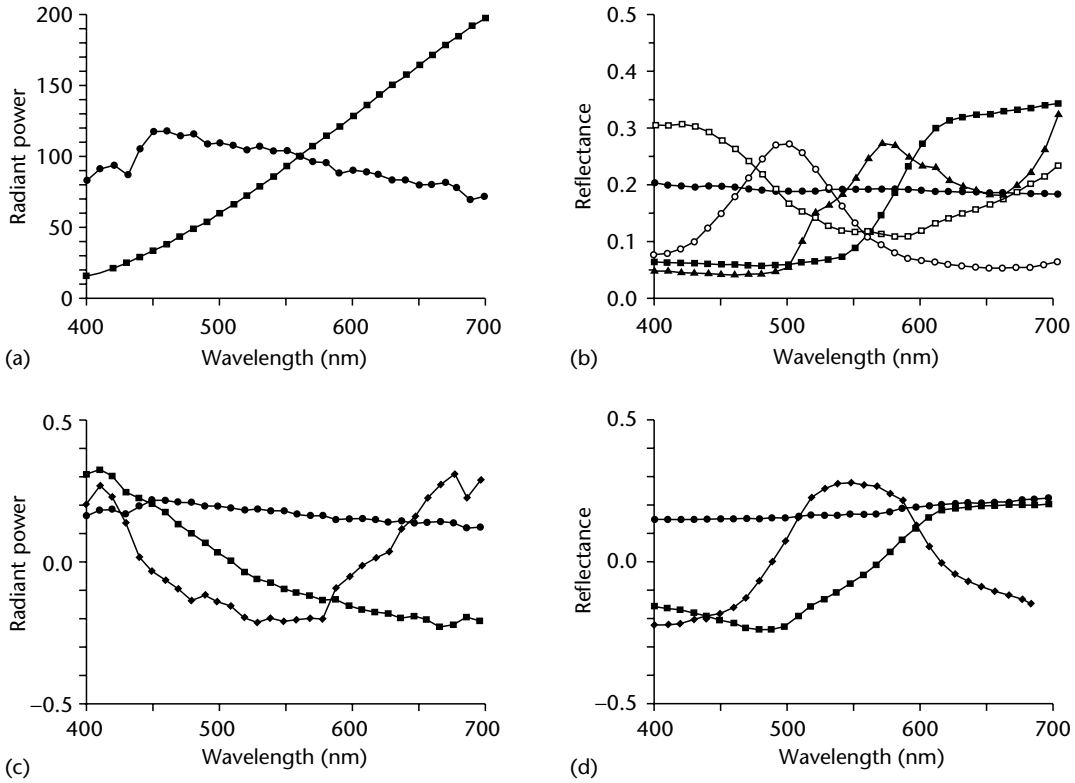

Figure 3. Finite-dimensional linear models for illuminant spectral power distributions (SPDs) and surface reflectance functions. (a) The SPDs of CIE illuminant D65 (●) and illuminant A (■), which match those of average daylight and a yellow tungsten light bulb, respectively. (b) Reflectance functions of five Munsell chips: N 5 (●), 10R 4/6 (■), Y 5/6 (▲), BG 4/6 (○) and 10PB 4/6 (□). (c) First three functions in the CIE daylight illumination model (Gram–Schmidt orthogonalized). The function $D_1(\lambda)$ (●) captures variation in the mean level of illumination; the function $D_2(\lambda)$ (■) captures 'blue–yellow' variation like that found between blue sky and the yellow solar disk, while the function $D_3(\lambda)$ (♦) captures minor 'red–green' variation. Daylight with SPD $D(\lambda)$ can be approximated accurately as a linear combination of these three functions: $D(\lambda) \approx d_1\ D_1(\lambda) + d_2\ D_2(\lambda) + d_3\ D_3(\lambda)$. (d) First three functions in the Cohen principal components analysis of Munsell chip reflectance functions (Gram–Schmidt orthogonalized). The function $R_1(\lambda)$ (●) captures variation in the mean level of reflectance; the function $R_2(\lambda)$ (■) captures 'red–green' variation, while the function $R_3(\lambda)$ (♦) captures 'blue–yellow' variation. A reflectance R can be approximated by a linear combination of these three functions: $R(\lambda) \approx r_1\ R_1(\lambda) + r_2\ R_2(\lambda) + r_3\ R_3(\lambda)$. The coefficients $\{r_1, r_2, r_3\}$ describe the reflectance function and do not vary with illumination, so that a visual system able to recover these descriptors can exhibit color constancy.

properties. Of these three cues, only the gray-world assumption is thought to have perceptual relevance; eye movements let mechanisms with sufficiently long integration times adjust their sensitivity to space-averaged inputs. The scaling of photoreceptoral responses by their average inputs, a form of von Kries adaptation, is considered an important influence on perceived surface color. Yet numerous examples show that von Kries adaptation is insufficient to account for surface color appearance.

The gray-world assumption is a statistical one that may be generalized to assumptions concerning the prior distributions of possible surface reflectances and illuminant SPDs in visual scenes. Bayesian algorithms for color constancy take as data the photoreceptoral responses from a set of surfaces and determine the illuminant and surface chromatic properties most likely to have given rise to the data.

Models of photoreceptor response that depend linearly on both surface reflectance and illumination spectral properties are bilinear models. Analysis of such bilinear models shows that viewing several surfaces under an unknown daylight illuminant does not provide enough information to find three reflectance descriptors per surface. Yet if the same surfaces are seen under first one illuminant and then another, so that two views of the surfaces are provided, sufficient information exists to determine both surface and illuminant chromatic properties. A key assumption in the use of multiple

views is that the visual system must know the correspondence between surfaces viewed under the first and second illuminants.

Transparency

Surface correspondence is readily determined in viewing situations involving transparent filters. Surfaces that lie along the edge of a filter are viewed both directly and through the filter. At the intersections of surface and filter edges are X junctions, where color changes are cues to surface and filter chromatic properties. Psychophysical studies show that a filter of uniform color properties is perceived best when surface chromatic changes are characterized by a single shift (translation) in color space and/or a single change in contrast. The shift in surface responses corresponds to filter color, while the change in contrast corresponds to filter cloudiness, which ranges from clear to opaque.

The perceived separation of a spatiochromatic pattern into surface and filter layers is an example of scission, the layered representation of the visual field. Standard color theory allows for a trichromatic representation of scene spectral properties at every point, and this is seemingly insufficient to account for our ability to perceive two (or more) colors simultaneously at the same point. One possibility is that mechanisms involved in scene segmentation feed back on standard representations to shunt trichromatic signals into multiple, concurrent color representations.

Color Coding

While color provides information about an object's material properties, it also serves as a flexible visual code well suited to investigations in visual attention, category learning, verbal production (e.g. the Stroop effect) and other cognitive tasks. Performance based on color coding depends on memory and language, which depend, in turn, on categorization. All major modern languages have equivalents for the achromatic color names white, gray and black; the primary color names red, yellow, green and blue; and the secondary color names pink, brown, orange and purple. These names correspond to volumes in three-dimensional color space that bound the chromatic stimuli that elicit the names. Stimuli in the center of such a volume typify the color category better than those close to a boundary. Studies of color memory suggest that remembered colors often tend to shift towards their prototypes, revealing perhaps the action of verbal encoding on color memory. Color coding has many important roles in society through semantic binding (e.g. the red, orange and green of traffic lights), perceived emotional content, and through esthetic considerations expressed in art and design.

CONCLUSION

The psychophysical study of color relies on careful distinctions among physical light stimuli, chromatic properties related to photoreceptoral and opponent mechanism responses, and perceived color. Relating perceived color to physical light stimuli is difficult, not only because of the intermediate chromatic mechanisms, but also because of philosophical issues in understanding color and comparing color among individuals. These difficulties notwithstanding, considerable progress has been made in characterizing chromatic processing and in identifying sources of individual differences in chromatic sensitivity.

Comparative Psychology

Introductory article

Edward A Wasserman, University of Iowa, Iowa City, Iowa, USA

CONTENTS

Comparative psychology explores the behaviors of different species of animals with a special interest in any similarities and differences that may reveal the evolutionary origins of those behaviors.

INTRODUCTION

Are animals intelligent? How can we learn about animal intelligence? Do different species differ in intelligence? How can we measure species differences in intelligence? Does animal intelligence resemble human intelligence? What would it mean if animals were indeed intelligent and if their intelligence approached, or even eclipsed, our own? (*See* **Intelligence**; **Animal Cognition**; **Animal Learning**)

Most people, young and old, have asked these intriguing questions. Answering them is the business of comparative psychology, a field that explores similarities and differences in the behavior of human and nonhuman animals. Comparative psychologists are interested in a wide range of behaviors: from mating to migrating, from feeding to fighting, from sleeping to scratching. These scientists have been especially interested in intelligent behaviors: those actions whose acquisition advances an animal's chances of surviving and reproducing in an environment that is fraught with danger and uncertainty.

Historical Foundations

The comparative psychology of intelligence is only a century or so old if we date the origin of the field as an exact experimental science with the 1898 publication of Edward L. Thorndike's pioneering monograph, *Animal Intelligence: An Experimental Study of the Associative Processes in Animals*.

But, weren't people interested in and didn't they know about animal intelligence for much more than the past century? Certainly. Ancient texts and drawings suggest that humans have trained animals for work and amusement for centuries; doing so meant that humans understood and exploited the modifiability of animal behavior. Nevertheless, a practical understanding of animal intelligence is decidedly different from a scientific understanding. Formulating precise laws of learning and developing effective technologies of teaching are crucial to determining the nature of intelligence and to exploring its generality throughout the animal kingdom. These critical additions to our knowledge of animal intelligence came only at the beginning of the twentieth century with the work of Thorndike and other trailblazers in the new science of comparative psychology. (*See* **Learning, Psychology of**)

Even before this modern experimental era, famous scholars had deemed animal intelligence to be central to comprehending the nature and origin of humankind. Two key points in the history of human thought place the study of animal behavior and learning at the very center of philosophical and scientific inquiry: (1) Descartes' distinction between humans and brutes, and (2) Darwin's hypothesis of mental continuity between human beings and nonhuman animals.

The seventeenth-century French philosopher René Descartes believed that human beings were profoundly different from brutes. Animals were mere machines; they had intricate bodily systems that controlled their physiology and behavior, but they lacked what humans alone possessed – a rational soul. The rational soul was divinely created, it was not made of matter, nor did it reside in the human body. (*See* **Descartes, René**)

The operation of the rational soul had two unique behavioral consequences: (1) it allowed us to communicate our private thoughts and feelings to other human beings, and (2) it permitted us to suitably tailor our behaviors to a vast variety of complex and ever-changing environmental situations. Descartes

believed that animals had no thoughts to communicate; they were thus forced to respond as their sensory and motor systems demanded, without the involvement of intelligence.

Against this backdrop of Cartesian thinking, the nineteenth-century English biologist Charles Darwin proposed that the nature and descent of human beings was not a matter for theology or philosophy, but biology. Scores of naturalistic and anecdotal observations convinced Darwin that humans and animals were not fundamentally different from one another, nor did they have different origins; all beings were the products of organic evolution. In contrast to Descartes, Darwin viewed both communication and intelligence from a natural scientific perspective; primitive or even highly advanced forms of each of these abilities were to be found throughout the animal kingdom, thus disclosing what Darwin called 'mental continuity' between human and nonhuman animals. (*See* **Evolutionary Psychology: Theoretical Foundations**)

Darwin's bold evolutionary ideas made the study of animal behavior crucial to understanding human behavior: if humans arose from lower forms of animals, then the study of animal intelligence is essential to elucidating the biological precursors of the human mind.

Thorndike's Contributions

When he began his research, Thorndike accepted Darwin's evolutionary perspective, but he was skeptical of Darwin's evidence of animal intelligence. Indeed, Thorndike devised his famous 'puzzle box' method in order to provide an objective and experimental antidote to the subjective and anecdotal accounts of animal intelligence that were in vogue during the final decades of the nineteenth century, and that Darwin used to make his case for mental continuity between human and nonhuman animals. These anecdotes were tall tales of animal genius that were spun by pet owners, zookeepers, and amateur naturalists. Most of these astounding and amusing anecdotes proved to be of dubious accuracy and reliability; but, they did provoke great interest and debate in popular and scientific circles.

In his innovative research, Thorndike placed animals into small boxes from which they could escape and receive food by solving a simple behavioral puzzle. For instance, a hungry cat might have to pull a loop of string; doing so opened a door through which the feline could exit the box and nibble a tasty titbit of fish. By measuring the time that it took the cat to claw the string after each placement into the box, Thorndike found that this time progressively fell with successive trials.

Thorndike had discovered a basic law of learning – the law of reinforcement. When a response is followed by a reward, an organism is more likely to make that response again in that situation. Further study by Thorndike and later comparative psychologists showed that this law of reinforcement is not limited to cats, to pulling loops of string, or to fish snacks. Pigeons more quickly peck a button when grains of seed ensue. Rats more rapidly rotate a wheel when draughts of water follow. And, human infants kick with added alacrity when a motorized mobile turns afterwards. Such learned behaviors need not continue indefinitely; if the reward is revoked following the response, then the behavior returns to its initial level – the law of extinction.

By 1911, Thorndike's own research and that conducted by several other investigators led him to conclude that most vertebrate animals learn in the same general way: stimulus–response associations are automatically strengthened by reward and weakened by extinction. (*See* **Reinforcement Learning: A Biological Perspective**)

Learning by consequence was positively Darwinian. Natural selection leads to the retention of fit organisms and to the elimination of unfit ones; the laws of reinforcement and extinction lead, respectively, to the retention of effective behaviors and to the elimination of ineffective ones.

Most relevant to the evolution of intelligence, Thorndike believed that species differences in learning are matters of degree, not kind: stimulus–response associations may increase in number, may be formed more quickly, may last longer, and may become more complex. Growth in the number, speed of formation, permanence, and complexity of associations reaches its high point in human beings. Thorndike also suggested that a parallel exists between individual development (ontogeny) and species evolution (phylogeny): the development of the infant's intelligence to the adult condition may be viewed as progressing from animal to human competence.

COMPARATIVE PSYCHOLOGY OF LEARNING

Thorndike's groundbreaking research and theorizing set the stage for the work of succeeding generations of comparative psychologists.

Critical to this later work was the crafting of advanced methods which could sensitively and reliably measure animals' learning of new behaviors. Most famous among these new methods was I. P. Pavlov's conditioned reflex procedure and B. F. Skinner's 'Skinner Box' procedure, a refinement of Thorndike's puzzle box procedure. These new methods have been creatively adapted to the unique behavioral repertoires of different species in the quest to uncover similarities and differences in their intelligence. (*See* **Pavlov, Ivan Petrovich**; **Skinner, Burrhus Frederic**; **Conditioning**)

Quantitative Differences in Learning

Despite the large amount of experimentation into quantitative differences among animal species that has been conducted since Thorndike's investigations, most reviewers have concluded that this line of research has not been productive. Quite simply, animal behavior is affected by so many other factors – differences in sensory and motor capabilities, variations in motivation and reward, differences in daily activity levels – that valid quantitative cross-species comparisons of intelligence have proven to be virtually impossible to document. (*See* **Motivation**)

Consider an illustrative example: is a cat smarter than a dog? To begin, we have to select some common behavioral technique that can properly measure intelligence in these two very different animals. But, which technique? The senses of cats and dogs are obviously not equally keen. Cats have excellent audition (hearing); dogs have excellent olfaction (sense of smell). By requiring the animals to use one sense or the other in the experimental task, we could stack the deck in favor of one species over the other. The two species' motor abilities also differ, with cats being outstanding jumpers and dogs being outstanding runners. Different response requirements could favor one species over the other. What about the reward? How much of which kinds of foods will equate the value of the rewards for the two species? What will be the effect of different levels of food deprivation in the two species? And, at what time of day should the animals be trained? Should we train in the day for the diurnal dog or in the night for the nocturnal cat?

These and many additional considerations make it abundantly clear that, however interesting and well-intentioned the original question may have been, it is practically impossible to say whether the cat or the dog is the more intelligent species of animal.

Does it therefore follow that there are no differences in intelligence among different species to be documented? Not necessarily. We may simply have to adopt a different experimental tactic in order to discover them.

Qualitative Differences in Learning

The comparative psychologist M. E. Bitterman has suggested that we investigate qualitative differences in learning among different species of animals. Bitterman's proposed plan of investigation has been to compare species according to their orderly responses to changes in the conditions of reinforcement.

For example, some species of animals may come to learn discrimination reversals faster than they learned the original problem, whereas others may not show such improvement. To illustrate: the choice of a white circle over a black one might initially lead to reward. Then, the discrimination is reversed: the choice of the black circle over the white one now leads to reward. Later, the discrimination is reversed over and over again from problem to problem. In fact, some species of animals improve in the speed of reversal learning, whereas others do not. Such a dramatic difference suggests that qualitatively different learning processes may be producing these effects.

As another example, some species may exclusively select the better response alternative ('maximizing'), whereas other species may match their choices to the reward probabilities ('matching'). So, if responses to one button produce food with a probability of 0.75, whereas responses to a second button do so with a probability of 0.25, then the receipt of reward will be maximized by choosing the first button 100 per cent of the time ($100(0.75) + 0(0.25) = 75.00$), but not by choosing the first button 75 per cent of the time and the second button 25 per cent of the time ($75(0.75) + 25(0.25) = 62.50$). These two patterns of choice responding may represent qualitatively different decision strategies: a potentially important species difference in learning and behavior. (*See* **Choice Selection**)

COMPARATIVE PSYCHOLOGY OF MEMORY

Beyond the comparative study of learning in animals, other advanced intellectual processes have attracted experimental attention, among them memory. Memory is obviously necessary for

learning to occur. If an organism in Thorndike's puzzle box were to forget what response it last performed in that situation, then there would be no way for food to strengthen that particular stimulus–response bond. (*See* **Memory**)

Given how central memory is to the acquisition of intelligent action, it should not be surprising that comparative psychologists have long been interested in the experimental investigation of memory. Furthermore, given Darwin's hypothesis of mental continuity and Thorndike's suggestion that species differences in learning are primarily quantitative and not qualitative in character, it should not be surprising that researchers have endeavored to determine if some species can remember prior acts and events for different lengths of time.

Delayed Response

The pioneer in the study of animal memory was W. S. Hunter, who in 1913 devised the delayed response paradigm. In this paradigm, an animal might see one of three potential sites baited with food or otherwise marked by a brief stimulus such as a light. Then, after a delay of a few or several seconds, the animal would be required to select the earlier baited or marked site. If the animal succeeded in choosing the correct site and in receiving the food that was to be found there, then this result might constitute evidence for memory of the baited location. The longer the delay over which the animal is able to respond correctly, the better is its memory.

But, a rival interpretation presents itself. Successful performance in the delayed response task might not be the result of some enduring cognitive or neural process; it might instead be due to the animal merely maintaining its bodily orientation to the baited site during the delay period. Postural mediation was an especially obvious possibility for one of Hunter's contingent of different experimental subjects – the dog, an animal that is well known for its pointing behavior.

Hunter and other memory researchers cleverly strove to eliminate this postural possibility by rotating the animal on a turntable or by removing the animal from the apparatus during the delay period. These measures did sometimes succeed in disrupting the animal's delayed discrimination performance, as they should if pointing were all that there was to accurate performance after a delay. But, these measures did not always disrupt the animal's performance. Clearly, then, there are at least some bona fide cases of memory in the delayed response paradigm that cannot be due to mere postural mediation.

Delayed Matching-to-Sample

More recent research has exploited an alternative testing method for measuring animal memory – delayed matching-to-sample. This method is not plagued by the problem of positional mediation; also, delayed matching-to-sample is much more versatile in its application to a wide variety of issues in animal memory and intelligence than is the delayed response paradigm. Further contributing to the popularity of delayed matching-to-sample has been its extremely successful application to the behavior of the pigeon, which – because of its long life, excellent vision, and ready adaptation to laboratory captivity – has become a favorite of experimental psychologists interested in animal cognition.

In this procedure for the pigeon, two simultaneously presented testing stimuli (for example, red and green lights) follow the presentation of the sample stimulus (randomly, a red or a green light on alternate trials). Only one testing stimulus (whose color matches the sample stimulus) is correct and leads to food if it is chosen; the other testing stimulus (whose color does not match the sample stimulus) is incorrect and does not lead to food if it is chosen. With a short delay between the sample and the testing stimuli, pigeons show a strong tendency to choose the correct (matching) testing stimulus. However, as the delay is lengthened, choice accuracy declines towards the indiscriminate selection of the correct (matching) and the incorrect (nonmatching) testing stimuli, thereby documenting the forgetting of the sample stimulus. Not only is there a decline in memory as the sample–test interval is lengthened; choice accuracy is also positively related to the duration of the sample stimulus and negatively related to the time between trials.

Because these simple temporal parameters of delayed matching-to-sample exert such a strong influence on memory performance within a species, any claims about memory differences between species are extremely difficult to prove. The parallel to the case of quantitative species differences in learning is obvious.

An important variant of the delayed matching-to-sample procedure involves sample and testing stimuli that are drawn from different pools of stimuli. For instance, pigeons might be shown different colors as sample stimuli and different forms as testing stimuli. No true matches are possible; only arbitrary or symbolic matches can hold. So, the selection of circle after red or the selection of square after green might be the correct responses,

whereas the selection of square after red or the selection of circle after green might be the incorrect responses. This so-called 'delayed symbolic matching-to-sample' procedure has afforded researchers special opportunities to expand the investigation of animal memory.

With true matching-to-sample procedures, it has been shown that pigeons can remember the color of a sample stimulus, its shape, its orientation, and its spatial location. With the symbolic matching-to-sample procedure, it has also been possible to show that the duration of a stimulus can be remembered. Thus, pigeons remember different durations of a red sample stimulus and report that memory during testing stimuli of differing line orientations.

Beyond the attributes of single sample stimuli, pigeons that have been given embellished versions of the symbolic matching-to-sample paradigm have also been shown to remember the temporal order (e.g. red–green) of two differently colored sample stimuli, the spatial order (e.g. left–right) of two identically colored sample stimuli, and the relative duration (e.g. short–long) of two differently colored sample stimuli. As well, pigeons and rats have successfully been trained to make one of two different responses depending on the number of prior visual or auditory stimuli (for example, two versus four).

Another way in which the memory of complex information has been studied has involved sample stimuli that comprise two or more elements. Pigeons were thus shown two-element sample stimuli that were composed of color (red or green) and line orientation (horizontal or vertical) elements. Tests with just color comparisons or just line comparisons each yielded highly accurate testing performance, indicating that the pigeons discriminated and remembered both the color and the line orientation of the compound sample stimuli. Significantly, however, accuracy on these compound sample (color and line) trials was lower than on other trials involving only single-element samples (color or line); this result suggests that the two sample elements on compound sample trials competed with one another for what in humans is commonly called *attention*. (*See* **Attention**; **Selective Attention**)

All of this evidence shows that animals are amazingly sensitive to the richness and subtlety of their environment. That sensitivity is also enduring, as witnessed by the fact that stimuli can be retained for substantial periods of time, sometimes for durations as long as half a minute.

Rehearsal

Many theorists of human memory have proposed the operation of control processes: means by which memories are changed in accord with the needs of the individual or the demands of the task. One key control process is *rehearsal*: a covert activity that helps to sustain the memory of a prior event. Engaging in rehearsal should aid in retaining earlier information, whereas terminating rehearsal should impair retention.

In order to investigate the role of rehearsal in human memory, researchers have devised the directed-forgetting paradigm. In one version of the directed-forgetting paradigm, people are given one of two cues (e.g. red or green colors) either to remember or to forget a previously presented stimulus. When the remember cue is given the memory test is presented afterwards; when the forget cue is given the memory test is not presented afterwards.

Finally, a trick is played on the individual; a forget cue is given and is followed by a retention test. When these unexpected retention tests are given, researchers generally find that memory performance is worse on forget-cued trials than on remember-cued trials; this result implies that the post-stimulus cues were affecting the rehearsal process and thereby modulating memory.

Researchers have further found that postponing the forget cue in a delay interval of fixed duration leads to a loss in its effectiveness; memory performance for earlier information improves the later into the delay interval the forget cue is given. This result suggests that the spontaneous or uncued rehearsal that occurs prior to the forget cue effectively protects memory from the decremental effect of the forget cue.

Several workers in the area of animal memory have attempted to see whether directed forgetting is uniquely human. Research with both pigeons and monkeys has adapted the delayed matching-to-sample paradigm to this objective by adding brief post-sample cues during the delay interval in order to signal that a test for sample memory either would or would not be given. As in the case of human memory, animal memory proved to be much lower on forget-cued trials than on remember-cued trials. In addition, memory was more markedly reduced if the post-sample forget cue was presented early than if it was presented late in the delay interval.

These results suggest that animals may indeed have active control over memory processing.

Rehearsal may not be uniquely human nor necessarily verbal.

COMPARATIVE PSYCHOLOGY OF CONCEPTUALIZATION

Human beings and other animals are incessantly bombarded by an extraordinarily complex array of external stimuli; yet, they somehow make sense of these varied and varying stimuli. One way to reduce the demands on an organism's sensory and information-processing systems is for it to treat similar stimuli as members of a single class; by doing so, considerable behavioral economy can be achieved, thus freeing its adaptive machinery to deal with other competing demands of survival. In addition, categorical processing permits an organism to identify novel stimuli as members of a particular class and to generalize knowledge about that category to these new members. So, an organism need not be bound to respond only to those stimuli with which it has had prior experience, further enhancing its ability to cope with a continually changing world. (*See* **Generalization**)

Theorists often trumpet these adaptive virtues of categorization and conceptualization; yet, we remain far from understanding precisely how organisms partition the world into classes of related objects and events. Indeed, theorists have historically doubted whether nonhuman animals are even capable of conceptual behavior. More than a century ago, the famous English comparative psychologist C. Lloyd Morgan denied animals the ability to behave conceptually. Morgan believed that only adult humans, and not even children, are capable of conceptualization. Recent research is changing that opinion. (*See* **Categorical Perception**)

Object Concepts

One familiar case of conceptual behavior involves the kinds of open-ended categorization responses that we make when we label different natural (e.g. cat) and artificial (e.g. car) objects with different nouns. Such verbal behaviors are occasioned by specific instances of wide variability and individuality. Indeed, accurate classification even extends to categorical exemplars that we have never seen before. Is it at all possible for nonhuman animals lacking language to engage in this form of conceptual or classificatory behavior?

In order to answer this question, a new technique was devised to train pigeons concurrently to discriminate stimuli from several human language categories. The specific method parallels the technique that parents often use in order to teach their children to label objects in a picture book. When the page is turned, the child is first asked to look at the object and then she is requested to name it. If she is correct, then she is praised. If she is incorrect, then she is told 'no' and is encouraged to try again. If self-correction fails, then she is provided with the correct name. (*See* **Concept Learning**)

In order to implement this method with pigeons, a color snapshot was displayed on a small screen and the pigeon was required to peck a clear plastic key covering the screen in order to guarantee that it was looking at the snapshot. Then, four differently colored keys were illuminated just beyond the corners of the screen. A single choice response was permitted. If the response was to the correct key for reporting the stimulus on the viewing screen, then the pigeon was fed grain; if the response was to any of the three incorrect report keys, then no grain was given and the pigeon had to repeat that trial until it made the correct response. The slides that were shown in each daily session depicted several different examples of cats, flowers, cars, and chairs. The pictures contained one or more instances of the critical stimulus object; the objects were indoors or outdoors, near or far away, centered or off-center, and in different colors, orientations, and backgrounds.

In a representative experiment, pigeons attained a level of discriminative performance that averaged about 75 percent correct at the end of a month of training, after beginning the investigation near the chance level of 25 percent correct. Most important were the results of two later days of testing performance with the original training slides and with brand-new slides of cats, flowers, cars, and chairs. Accuracy to the old slides averaged about 80 percent and accuracy to the new slides averaged about 65 percent.

These results suggest that the pigeons had learned general object concepts that permitted them to categorize both old and new stimuli from four human language classes. Although the pigeons' testing performance was highly discriminative to both old and new stimuli, accuracy was reliably higher to the old pictures than to the new ones, perhaps because the birds memorized some or all of the old slides. (*See* **Concept Learning and Categorization: Models**)

In another project, three groups of different pigeons were also trained to categorize photographic slides. The three groups were given 48 daily training trials comprising: 12 copies of one

example from the categories cat, flower, car, and chair (group 1); three copies of four examples from the same categories (group 4); or one copy of 12 examples from the same categories (group 12). The rate of learning was a negative function of the number of examples per category. Of additional importance were the results of a generalization test with 32 novel stimuli: eight from each category. Now, accuracy was a positive function of the number of training examples.

Although increasing the difficulty of original learning, greater numbers of training examples per category enhanced the accuracy of generalization performance, perhaps because of the increased likelihood that any given test stimulus resembled one or more of the remembered training stimuli. These data are not only orderly, but they neatly correspond with a large body of research on categorization in human adults and children. Empirical parallels like these are unlikely to be coincidental; rather, they suggest a basic behavioral similarity. Whether there are other correspondences in conceptualization by humans and animals is a topic of current research.

Abstract Concepts

One of the empirical hallmarks of conceptualization is that discriminative responding is independent of the specific details of the prevailing stimuli. Note that it was imperative in research on object concepts to show that the discriminative responding that was established to a familiar set of training stimuli also extended to a novel set of testing stimuli. To have conceptualized 'chairs' requires that new chairs occasion the same response as old ones. (*See* **Representations, Abstract and Concrete**)

An even more advanced level of conceptualization may be achieved when organisms respond 'same' or 'different' to several simultaneously or successively presented stimuli. Again, the critical test comes when novel stimuli are given, in order to see whether the organism appropriately responds to them.

Here, too, great doubt has historically been expressed that animals can learn abstract concepts. The seventeenth-century English philosopher John Locke, in particular, believed that abstract conceptualization represented the key intellectual divide between humans and animals.

Despite his firm conviction that nonhuman animals were incapable of abstraction and conceptualization, Locke may have been premature in his assessment. Mounting behavioral evidence suggests that nonhuman animals – even pigeons – can form abstract concepts.

In this research, pigeons received food reward for pecking one button (for example, red) when they were shown any displays that pictured 16 copies of the same computer icon, and for pecking a second button (for example, green) when they were shown any other displays that pictured one copy of 16 different computer icons. Incorrect responses led to nonreward.

After the pigeons had reached a high level of discrimination accuracy (exceeding 80 percent correct choices when the chance score was 50 percent correct), in testing sessions the birds were shown brand-new Same displays and brand-new Different displays that pictured icons that they had never seen before. In various experiments, discrimination accuracy averaged from 83 to 93 percent correct to the Same displays and to the Different displays from the training set; accuracy averaged from 71 to 79 percent correct to the Same displays and to the Different displays from the testing set. These high levels of discrimination accuracy to both familiar and novel displays are consistent with the pigeons' having learned an abstract same–different concept.

Not only has same–different conceptualization been demonstrated for pigeons that were given simultaneous displays of visual items, but also for pigeons that were given successive lists of visual items. In the latter case, the 16-list icons were presented one at a time, thereby requiring the memory of prior items in order to decide whether the just-presented list comprised identical or nonidentical items.

Despite this important procedural change, discrimination accuracy averaged 94 percent correct to the Same lists and to the Different lists from the set of training icons; further, accuracy averaged 72 percent correct to the Same lists and to the Different lists from the set of testing icons. Abstract conceptualization may thus be within the ken of even the pigeon.

DIFFERENT APPROACHES TO COMPARATIVE INTELLIGENCE

The foregoing has described a sampling of investigations whose results suggest that advanced intellectual processes – including learning, memory, and conceptualization – can be comparatively studied. The results of these investigations disclose many salient similarities in the behavior of human and nonhuman animals.

Should we thus agree with Thorndike that intelligence is pretty much the same throughout the

animal kingdom? Perhaps not. But the many similarities that have been uncovered so far are simply too provocative not to merit further investigation. However, although they are surprisingly few in number, species differences in intelligence have been found and many more may ultimately surface if we assiduously seek them.

The Process Approach

Despite the prominence of the above line of research, some authors have questioned the value of the comparative study of such distantly related species as pigeons, rats, cats, dogs, monkeys, and humans. These critics have insisted that any comparisons among species that are not close evolutionary relatives of one another are capricious and of doubtful biological significance.

These critics have also argued that the seemingly expedient selection of distantly related species is an anthropocentric or human-centered strategy that springs directly from Darwin's hypothesis of mental continuity. Indeed, to such anthropocentric theorists, the true vision of comparative psychology is as a distinctly human psychology whose prime purpose is to understand and to specify the rules of human psychological functioning, as well as their degree of zoological generality.

A different and perhaps more accurate picture of this line of research in the comparative psychology of intelligence focuses on the matter of process. Thus, we are interested in establishing whether some intellectual process is involved in human and nonhuman behavior and the degree to which that process reflects common behavioral and biological mechanisms.

For example, the comparative study of the laws of reinforcement and extinction could speak to the nature and generality of these adaptive processes. If these behavioral processes are indeed general, then animal models and subsequent neuroanatomical and neurophysiological research might shed great light on their underlying biology.

Furthermore, if most extant species of animals similarly obey the laws of reinforcement and extinction, then there is good reason to believe that a common ancestor of all of these species must also have been subject to the same behavioral laws, perhaps because of common selection pressures. It would not make much sense for each species to have independently devised the same evolutionary solution to a common survival problem.

The Phylogenetic Approach

It is also possible more directly to develop the comparative psychology of intelligence from a phylogenetic perspective. In this approach, researchers study the behavior of more strategically selected species in order to elucidate the natural and evolutionary histories of the chosen animals. Adopting this more ethological and ecological approach means that one may compare either closely related species that face divergent survival demands or unrelated species that face similar survival demands. Such phylogenetic study may not only help to identify the selection pressures for complex behavior and intelligence, but it might also help to identify any specialized behavioral or intellectual adaptations. (*See* **Learning and Memory, the Ecology of**)

Take, for example, the spatial memory of animals that do not always eat the food that they find while they are foraging; rather, these animals may store the food in small reserves to which they can return for later meals. Such a food-storing strategy makes especially good sense when food is abundant at some times of the year, but scarce at other times.

One famous food-storing animal is Clark's nutcracker, a bird that lives in high mountainous regions of the Southwestern United States. These nutcrackers collect pine seeds in a small pouch under their tongue; the birds later drive those seeds into the soil with their beak. Field observations indicate that the nutcrackers return to small feeding caches many months later in order to retrieve those seeds, even under snow cover; in autumn, 33,000 seeds may be stored in 2500 caches for later recovery in winter and spring.

This is truly a remarkable feat of spatial memory. But what does it imply about the general memory ability of this particular species? In order to find out, laboratory experiments were conducted with this species and with three other bird species that are not proficient at storing and recovering food. Two general types of memory tasks were devised that were variants of delayed matching-to-sample: one task required memory for the location of a prior stimulus and the other task required memory for the color of a prior stimulus.

Clark's nutcrackers easily won the contest for spatial memory; but, they were in the middle of the pack in the contest for color memory. These data suggest that Clark's nutcrackers do not have generally exceptional memory ability; rather, they possess a more highly advanced spatial memory that may be a very special adaptation to their

particular evolutionary niche. Other special intellectual adaptations may include the pigeon's homing ability, the rat's rapid learning of taste–illness associations, and the human's propensity to learn language.

Reconciliation

These two different approaches to the comparative study of intelligence may seem to be at odds with one another. But, there really is no inherent conflict because the two programs ask different questions about animal intelligence. The process approach concentrates on a few taxonomically distant 'focus' animals in order to understand the general processes that are shared among species, whereas the phylogenetic approach concentrates on more closely related species in order to elucidate the intellectual mechanisms of specific adaptive behaviors and their ecological determinants. Together, the parallel use of both strategies should make for a powerful and complementary alliance for the future study of animal intelligence.

CONCLUSION

This brief review of research in the comparative psychology of intelligence suggests that we have merely scratched the surface in our quest to understand the nature of animal intelligence. Are animals capable of even greater cognitive feats? Can intelligence be demonstrated in animals without backbones? Are the same behavioral results the product of common brain mechanisms? (*See* **Learning in Simple Organisms**)

These questions are among the most important for the science of comparative psychology as it embarks upon its second century. Answering them will help us to tackle the most challenging question of all: how did intelligence evolve? This question was famously posed by Darwin, who hypothesized that humans and animals not only share common natural origins, but that they share common emotions and intelligence. Answering these questions with hard scientific evidence, not with beguiling anecdotes, is the business of our field.

Of course, the more we learn about the intelligence of animals, the more similar to us they seem to be. Such similarity often gives rise to empathy, leading some individuals to question whether animals should ever be the objects of scientific investigation. But, continued scientific inquiry is not only critical to answering key theoretical questions, it is also crucial to solving vexing practical problems.

Basic research into behavioral principles is vital to remedying such maladies as obesity, drug abuse, and AIDS – all the result of human behavior. That research may as well help us to contend with other serious societal woes such as crime, pollution, and overpopulation – also the products of human action.

Animals too may profit by such study, as we try to preserve and to expand their natural habitats. Knowledge of animal behavior and intelligence may also enable us to protect natural animal populations or even to increase them through repopulation efforts coordinated through zoos and animal sanctuaries.

Concept Learning

Introductory article

Bradley C Love, University of Texas, Austin, Texas, USA

CONTENTS

Concept learning is the process of acquiring knowledge structures that enable an agent to make predictive inferences.

INTRODUCTION

The human species evolves to meet challenges in the environment. Unfortunately, evolution is a slow 'learning' process. Evolution can only help us address aspects of our environment that are not very variable and that are stable over a long period of time. Of course, many aspects of our environment are constantly undergoing change. Accordingly, many concepts have to be learned *de novo* by each individual. For example, a radiologist is not born knowing how to interpret x-ray images. It is hard to imagine how that particular skill could evolve.

Concept learning is integral to the survival of any agent (e.g. a human, an animal, a robot, etc.) operating in a complex and changing environment. A concept is a mental representation that is often derived from experiences with specific instances. We often develop concepts of categories (i.e. collections of objects) in the world. Without acquired concepts, we would be unable to make sense of the world around us. Every new object encountered would appear completely novel and we would not know how to interact with it. For example, the first time a child encounters a hot stove he may get burned. When the child visits a friend's house and encounters another stove, it is unlikely the child will touch it, even though the new stove may differ in a number of ways from the original stove (e.g. size, color, design, etc.). If the child did not generalize from his experiences and form a concept of stoves, he would go through life with burned hands. (*See* **Categorization, Development of**; **Generalization**)

One basic question is how do we learn new concepts? Philosophers, psychologists, and computer scientists have all pondered this question. In the following sections, three basic views (i.e. models) of concept learning and concept representation (i.e. what is stored as a consequence of learning) will be examined. The first account posits that concepts consist of rules. A more recent account holds that concepts are represented as prototypes. A prototype can be thought of as the average example of a concept. A third account of concepts is the exemplar view. The exemplar view holds that concepts are nothing more than a collection of stored exemplars (i.e. examples of the concept). We will evaluate the relative merits of each of these accounts of human concept learning. All three accounts correctly characterize some aspects of human concept learning. After evaluating these three accounts, we will discuss more modern neural network models of concept learning. Neural network models embody some of the characteristics of rule, prototype, and exemplar approaches. (*See* **Concept Learning and Categorization: Models**; **Classifier Systems**; **Concepts, Philosophical Issues about**; **Conceptual Representations in Psychology**)

RULES

The classical view of concepts holds that categories are defined by logical rules. In Figure 1, any item that is a square is a member of category A. This simple rule determines category membership. According to the rule view, our concept of category A can be represented by this simple rule. Discovering this rule would involve a rational hypothesis-testing procedure. This procedure attempts to discover a rule that is satisfied by all of the positive examples of a concept, but none of the negative examples of the concept (i.e. items that are members of other categories). In trying to come up with such a rule for category A, one might first try the rule 'if dark, then in category A'. After rejecting this rule (because there are counterexamples), other rules would be tested (starting with simple rules

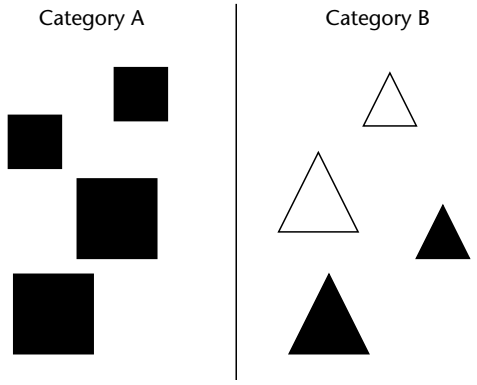

Figure 1. Examples of category A and category B.

and progressing towards more complex rules) until the correct rule is eventually discovered. For example, in learning about birds, one might first try the rule 'if it flies, then it is a bird.' This rule works pretty well, but not perfectly (penguins do not fly and bats do). Another simple rule like 'if it has feathers, then it is a bird' would not work either because a pillow filled with feathers is not a bird. Eventually, a more complex rule might be discovered like 'if it has feathers and lays eggs, then it is a bird'.

Although rules can in principle provide a concise representation of a concept, often more elaborate representations would serve us better. Concept representation needs to be richer than a simple rule because we use concepts for much more than simply classifying objects we encounter. For instance, we often use concepts to support inference (e.g. a child infers members of the category stove can be dangerously hot). Using categories to make inferences is a very important use of concepts. Knowing something is an example of a concept tells us a great deal about the item. For example, if you can classify a politician from the USA as a Republican, you can readily infer the politician's position on a number of issues. The point is that our representations of concepts need to include information beyond what is needed to classify items as examples of the concept. For example, the rule 'if square, then in category A' correctly classifies all members of category A in Figure 1, but it does not capture the knowledge that all category A members are dark. One problem with rule representations of concepts is that potentially useful information is discarded.

The biggest problem with the rule approach to concepts is that most of our everyday categories do not seem to be describable by a tractable rule. To demonstrate this point, Wittgenstein noted that the concept game lacks a defining property. Most games are fun, but Russian roulette is not fun. Most games are competitive, but ring around the roses is not competitive. While most games have characteristics in common, there is not a rule that unifies them all. Rather, we can think of the members of the category game as being organized around a *family resemblance* structure (analogous to how members of your family resemble one another).

A related weakness of the rule account of concepts is that examples of a concept differ in their *typicality*. If all a concept consisted of was a rule that determined membership, then all examples should have equal status. According to the rule account, all that should matter is whether an item satisfies the rule. Our concepts do not seem to have this definitive flavor. For example, some games are better examples of the category game than others. Basketball is a very typical example of the category game. Children play basketball in a playground, it is competitive, there are two teams, each team consists of multiple players, you score points, etc.

Basketball is a typical example of the category of games because it has many characteristics in common with other games. On the other hand, Russian roulette is not a very typical game – it requires a gun and one of the two players dies. Russian roulette does not have many properties in common with other games. In terms of family resemblance structure, we can think of basketball as having a central position and Russian roulette being a distant cousin to the other family members. These findings extend to categories in which a simple classification rule exists. For example, people judge the number three to be a more typical odd number than the number forty-seven even though membership in the category 'odd number' can be defined by a simple rule.

The fact that category membership follows a gradient as opposed to being all or none affords us flexibility in how we apply our concepts. Of course, this flexibility can lead to ambiguity. Consider the concept mother. It is a concept that we are all familiar with that seems straightforward – a mother is a woman who becomes pregnant and gives birth to a child. But what about a woman who adopts a neglected infant and raises it in a nurturing environment? Is the birth mother who neglected the infant a mother? What if a woman is implanted with an embryo from another woman? Court cases over maternity arise because the concept of motherhood is ambiguous. The concept exhibits greater flexibility and productivity than is even indicated above.

For example, is it proper to refer to an architect as the mother of a building? All the above examples of the concept mother share a family resemblance structure (i.e. they are organized around some commonalities), but the concept is not rule based. Some examples of the concept mother are better than others.

PROTOTYPES

The prototype approach to concept learning and representation was developed by Rosch and colleagues to address some of the shortcomings of the rule approach. Prototype models represent information about all the possible properties (i.e. *stimulus dimensions*), instead of focusing on only a few properties like rule models do. The prototype of a category is a summary of all of its members. Mathematically, the prototype is the average or central tendency of all category members. Figure 2 displays the prototypes for two categories, simply named categories A and B. Notice that all the items differ in size and luminance (i.e. there are two stimulus dimensions) and that the prototype is located amidst all of its category members. The prototype for each category has the average value of both the stimulus dimensions of size and luminance for the members of its category. (*See* **Prototype Representations**)

The prototype of a category is used to represent the category. According to the prototype model, a novel item is classified as a member of the category whose prototype it is most similar to. For example, a large bright item would be classified as a member of category B because category B's prototype is large and bright (see Figure 2). The position of the prototype is updated when new examples of the category are encountered. For example, if one encountered a very small and dark item that is a member of category A, then category A's prototype would move slightly towards the bottom left corner in Figure 2. As an outcome of learning, the position of the prototype shifts towards the newest category member in order to take it into account. A prototype can be very useful for determining category membership in domains where there are many stimulus dimensions that each provide information useful for determining category membership, but no dimension is definitive. For example, members of a family may tend to be tall, have large noses, a medium complexion, brown eyes, and good muscle tone, but no family member possesses all of these traits. Matching on some subset of these traits would provide evidence for being a family member. (*See* **Multidimensional Scaling**; **Similarity**)

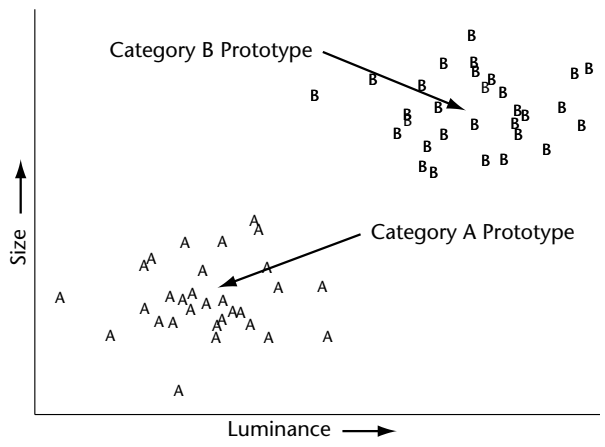

Figure 2. Two categories and their prototypes.

Notice the economy of the prototype approach. Each cloud of examples in Figure 2 can be represented by just the prototype. The prototype is intended to capture the critical structure in the environment without having to encode every detail or example. It is also fairly simple to determine which category a novel item belongs to by determining which category prototype is most similar to the item.

Unlike the rule approach, the prototype model can account for typicality effects. According to the prototype model, the more typical category members should be those members that are most similar to the prototype. In Figure 2, similarity can be viewed in geometric terms – the closer items are together in the plot, the more similar they are. Thus, the most typical items for categories A and B are those that are closest to the appropriate prototype. Accordingly, the prototype approach can explain why robins are more typical birds than penguins. The bird prototype represents the average bird: has wings, has feathers, can fly, can sing, lives in trees, lays eggs, etc. Robins share all of these properties with the prototype, whereas penguins differ in a number of ways (e.g. penguins cannot fly, but do swim). Extending this line of reasoning, the best example of a category should be the prototype, even if the actual prototype has never been viewed (or does not even exist). Indeed, numerous learning studies support this conjecture. After viewing a series of examples of a category, human participants are more likely to categorize the prototype as a category member (even though they never actually viewed the prototype) than they are to categorize an item they have seen before as a category member.

Because the prototype approach does not represent concepts in terms of a logical rule that is either satisfied or not, it can explain how category membership has a graded structure that is not all or none. Some examples of a category are simply better examples than other examples. Also, categories do not need to be defined in terms of logical rules, but are rather defined in terms of family resemblance to the prototype. In other words, members of a category need not share a common defining thread, but rather can have many characteristic threads in common with one another.

The prototype approach, while preferable to the rule approach for the reasons just discussed, does fail to account for important aspects of human concept learning. The main problem with the prototype model is that it does not retain enough information about examples encountered in learning. For instance, prototypes do not store any information about the frequency of each category, yet people are sensitive to frequency information. If an item was about equally similar to the prototype of two different categories and one category was one hundred times larger than the other, people would be more likely to assign the item to the more common category (under most circumstances).

People are also sensitive to the variability along stimulus dimensions. To use Rips' example, a circular object with a 10 cm diameter may be more similar to a US quarter (which is about 2.5 cm in diameter) than to a pizza (which is much larger). Nevertheless, the novel object is more likely to be classified as a pizza than a quarter because quarters display very little variability in their diameters whereas pizzas can vary in size.

Finally, prototypes are not sensitive to the correlations and substructure within a category. For example, a prototype model would not be able to represent that spoons tend to be large and made of wood or small and made of steel. These two subgroups would simply be averaged together into one prototype. This averaging makes some categories unlearnable with a prototype model. One example of such a category structure is shown in Figure 3. Each category consists of two subgroups. Members of category A are either small and dark or they are large and light, whereas members of category B are either large and dark or they are small and light. The prototypes for the two categories are both in the centre of the stimulus space (i.e. medium size and medium luminance). Items cannot be classified correctly by which prototype they are most similar to because the prototypes provide little guidance.

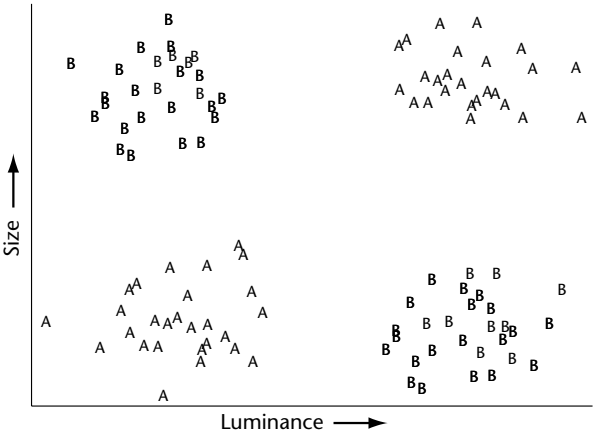

Figure 3. Two categories, each containing two subgroups.

In general, prototype models can only be used to learn category structures that are *linearly separable*. A learning problem involving two categories is linearly separable when a line or plane can be drawn that separates all the members of the two categories. The category structure shown in Figure 2 is linearly separable because a diagonal line can be drawn that separates the category A and B members (i.e. the category A members fall on one side of the line and the category B members fall on the other side of the line). Thus, this category structure can be learned with a prototype model. The category structure illustrated in Figure 3 is nonlinear – no single line can be drawn to segregate the category A and B members. Mathematically, a category structure is linearly separable when there exists a weighting of the feature dimensions that yields an additive rule that correctly indicates one category when the sum is below a chosen threshold and the other category when the sum is above the threshold.

The inability of the prototype model to learn nonlinear category structures detracts from its worth as a model of human concept learning because people are not biased against learning nonlinear category structures. Some nonlinear category structures are actually easier to acquire than linear category structures. For example, it seems quite natural that small birds sing, whereas large birds do not sing. Many categories have subtypes within them that we naturally pick out. One way for the prototype model to address this learnability problem is to include complex features that represent the presence of multiple simple features (e.g. large and blue). Unfortunately, this approach quickly becomes unwieldy as the number of stimulus dimensions increases.

EXEMPLARS

Exemplar models address many of the shortcomings of the prototype model. Exemplar models store every training example in memory instead of just the prototype (i.e. the summary) of each category. By retaining all of the information from training, exemplar models are sensitive to the frequency, the variability, and the correlations among items. For the learning problem illustrated in Figure 2, an exemplar model would store every training example. New items are classified by how similar they are to all items in memory (not just the prototype). For the category structure illustrated in Figure 2, the pairwise similarity of a novel item and every stored item would be calculated. If the novel item tended to be more similar to the category A members (i.e. the item was small and dark) than the category B members, then the novel item would be classified as a member of category A.

One aspect of exemplar models that seems counterintuitive is their lack of any abstraction in category representation. It seems that humans do learn something more abstract about categories than a list of examples. Surprisingly, exemplar models are capable of displaying abstraction. For instance, exemplar models can correctly predict that humans more strongly endorse the underlying prototype (even if it has not been seen) than an actual item that has been studied (a piece of evidence previously cited in favor of the prototype model). How could this be possible without the prototype actually being stored? It would be impossible if exemplar models simply functioned by retrieving the exemplar in memory that was most similar to the current item and classified the current item in the same category as the retrieved exemplar (this is essentially how processing works in a prototype model, except that a prototype is stored in memory instead of a bunch of exemplars).

Instead, exemplar models engage in more sophisticated processing and calculate the similarity between the current item (the item that is to be classified) and every item in memory. Some exemplars in memory will be very similar to the current item, whereas others will not be very similar. The current item is classified in the category in which the sum of its similarities to all the exemplars is greatest. When a previously unseen prototype is presented to an exemplar model it can be endorsed as a category member more strongly than a previously seen item. The prototype (which is the central tendency of the category) will tend to be somewhat similar to every item in the category, whereas any given non-prototype item will tend to be very similar to some items (especially itself!) in memory, but not so similar to other items. Overall, the prototypical item can display an advantage over an item that has actually been studied. Abstraction in an exemplar model is indirect and results from processing (i.e. calculating and summing pairwise similarities), whereas abstraction in a prototype model is rather direct (i.e. prototypes are stored).

The exemplar model does seem to make some questionable assumptions. For example, exemplar models store every training example which seems excessive. Also, every exemplar is retrieved from memory every time an item is classified. In addition to these assumptions, one worries that the exemplar model does not make strong enough theoretical commitments because it retains all information about training and contains a great deal of flexibility in how it processes information. These issues are currently being resolved by researchers. On the whole, exemplar models seem to be a more viable approach to understanding human concept learning than existing prototype or rule-based approaches, but there is still room for further work. (*See* **Computational Models of Cognition: Constraining**)

NEURAL NETWORK MODELS

Neural network models are intended to learn in a manner analogous to how the brain learns. A neural network consists of layers of neuron-like units that connect to units in other layers. Units can excite and inhibit one another across these connections. An item is represented at the input layer (the first layer) and passes activity to more advanced layers in the network until it reaches the output layer which determines the category the item is a member of (e.g. if the unit in the output layer representing category B is the most activated, then the item is classified as a member of category B). Each unit integrates all the activity originating from the layer below via its connections and passes this summed activity through a transfer function to generate its own output which is passed on to the next layer. Figure 4 illustrates a feedforward neural network with an input, hidden, and output layer. (*See* **Connectionism**)

The connections between units are altered as a result of learning in order to minimize the prediction error (i.e. the weights are altered in order to correctly classify items). Sophisticated learning algorithms dictate how the weights should be altered as a result of learning. Neural networks with only an input and output layer share many of

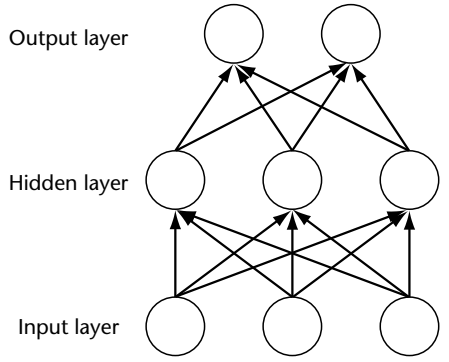

Figure 4. A typical feedforward neural network.

the limitations of the prototype model – they can only learn linearly separable functions (i.e. simple category structures). More complicated neural networks with a hidden layer (and nonlinear transfer functions) can learn just about any category structure. However, neural networks of this variety are not very good models of human concept learning because they tend to learn problems quickly that people learn slowly and vice versa.

Neural network models that are conceptually related to rule, prototype, and exemplar models have been successful as models of human concept learning. For example, the ALCOVE model replaces the hidden layer in Figure 4 with encoded exemplars. In other words, units in the hidden layer are added as exemplars are encountered. This exemplar neural network model, which combines an exemplar representation of concepts with the powerful learning algorithms of neural networks, does a good job of accounting for aspects of human concept learning. The SUSTAIN model is a neural network model that combines aspects of both exemplar and prototype models. SUSTAIN initially begins like a prototype model, but it can store exemplars (which themselves can later evolve into prototypes) when prediction errors occur. For the problem illustrated in Figure 3, SUSTAIN would form four prototypes that correspond to the four clusters of items. The ability to store multiple prototypes per category allows SUSTAIN to avoid the problems that plague prototype models. Both ALCOVE and SUSTAIN also incorporate rule-like dynamics. These models learn to attend to the most relevant stimulus dimensions and neglect the less meaningful dimensions, much like how rule models tend to focus on a limited number of stimulus dimensions (e.g. if it is *large*, then it is in category A).

CONCLUSIONS AND FUTURE DIRECTIONS

From this brief review of concept learning models we saw that the progression from rule models to prototype models to exemplar models was marked by a shift towards more concrete representations (i.e. more information about the training examples is retained), greater fluidity (i.e. category boundaries are not seen as rigid), and more sophisticated processing at decision time (exemplar models are the quintessential case – all abstraction is done after the training examples are encoded). Although all three approaches have their shortcomings, they all reflect some aspects of human concept learning. The successful neural network models of concept learning retain characteristics of all three approaches. Like the rule approach, these neural network models acknowledge the utility of strategically focusing on a subset of stimulus dimensions. If a stimulus dimension is irrelevant to a learning problem, the models will ignore the dimension and not be distracted by it. Like prototype models, some of these neural network models form abstractions which can assist generalization and reduce storage requirements. Like exemplar models, these neural network models are quite fluid, can encode individual exemplars, and engage in sophisticated processing at decision time.

One important aspect of concept learning that these models do not address is the influence of prior knowledge. Our prior knowledge exhibits strong influences on what we learn from a series of examples. For example, even if all the blue cars on a mechanic's lot have transmission problems and none of the red cars do, the mechanic would never predict that blue cars in general have transmission problems. Certainly, the mechanic would not paint a car red in the hope of repairing it. The mechanic's prior knowledge and theories of how cars function preclude this association. Instead, the mechanic is oriented towards more fruitful solutions. One important challenge for concept learning models is to illuminate how prior knowledge affects our interpretation of examples. Conversely, more work is needed in understanding how examples we encounter affect our theories of the world.

Conceptual Change

Intermediate article

Paul Thagard, University of Waterloo, Waterloo, Ontario, Canada

CONTENTS

Conceptual change is the creation and alteration of mental representations that correspond to words. It is an important part of learning in science and everyday life.

INTRODUCTION

Concepts are mental representations corresponding to words. For example, the concept 'dog' is a mental structure that corresponds to the word 'dog' and refers to dogs in the world. Conceptual change is produced by mental processes that create and alter such mental representations. Explaining how conceptual change works is important for understanding the growth of scientific knowledge, the development of children's thinking, and the education of students in fields such as science and mathematics. In each of these kinds of learning, a theory of conceptual change is needed that can answer such questions as the following. What is the nature of the concepts that are learned? What kinds of changes do concepts undergo? What are the mental processes that produce different kinds of conceptual change? It is also interesting to inquire whether the processes of conceptual change in scientists, young children, and students are similar or different.

TYPES OF CONCEPTUAL CHANGE

The simplest type of conceptual change is when people learn a new concept. A more challenging type occurs when existing concepts must be adjusted and reorganized to accommodate new information: in such cases, the meaning of concepts changes in relation to other concepts and the world. In radical conceptual change, the development of knowledge involves a shift in which a collection of important concepts undergo alterations in meaning. In such cases, learning is not simply a matter of accumulating new concepts and beliefs; it also requires substantial revision and restructuring of mental representations.

CONCEPTUAL CHANGE IN SCIENTISTS

The problem of conceptual change in science was first highlighted in Thomas Kuhn's famous book, *The Structure of Scientific Revolutions* (Kuhn, 1962). He challenged the prevailing view that scientific knowledge grows cumulatively by progressively adding to the stock of available theories and concepts. Instead, Kuhn proposed that the development of science often involves revolutionary changes in which one theory or paradigm is replaced by a radically different one. For example, the acceptance of the Copernican theory that the earth revolves around the sun required the rejection of the Ptolemaic theory that the sun revolved around the earth. Replacement was not merely a matter of one theory being substituted for another, but also involved shifts in meaning of the concepts used in the theories. In the Copernican revolution, for example, the concept 'planet' shifted to include the earth and exclude the sun and moon. According to Kuhn, radical differences between theories make it difficult to establish rationally that one is better than another.

Kuhn distinguished between normal science, in which a dominant paradigm is taken for granted, and revolutionary science, in which the dominant paradigm is replaced by a radically new one. The main activity in normal science is puzzle solving, which deals with problems within the scope and constraints of the dominant way of thinking. Scientists pursue normal science until there is an accumulation of anomalies, which are problems that the paradigm fails to solve. For example, in the eighteenth century the prevailing theory of combustion based on phlogiston, a substance supposed to be given off by burning objects, encountered the anomaly that objects gain rather than lose weight

during combustion. Scientists attempt to deal with individual anomalies as puzzles to be solved with the tools provided by the paradigm they accept, but the accumulation of anomalies produces a state of crisis in which scientists begin to consider the need for new theories. When a new paradigm is conceived that can solve the problems that were anomalous for the old one, a scientific revolution occurs and a new theory becomes accepted. Kuhn's favorite examples of scientific revolutions include the Copernican revolution, the chemical revolution in which Lavoisier's oxygen theory of combustion replaced the phlogiston theory, and the revolution in physics in which relativity theory was adopted.

Before Kuhn, science was generally viewed as a cumulative process in which new theories built on the successes of previous ones. Kuhn insisted that scientific revolutions are noncumulative episodes in which an older paradigm is replaced by an incompatible new one. He even suggested that the new and old theories are incommensurable with each other, that is, there may be no logical means for objectively choosing between them. A major source of incommensurability is the use by the different paradigms of very different concepts. For example, it might seem that the Newtonian physics and relativity theory both use the concept of mass, but Einsteinian mass can be converted into energy whereas Newtonian mass is conserved. Thus for Kuhn a major aspect of scientific revolutions was radical conceptual change.

In *Conceptual Revolutions*, Thagard (1992) offered a comprehensive account of the kinds of conceptual changes that have occurred in the major revolutions in the history of science. Most scientific revolutions involve the introduction of new concepts, such as Newton's gravitational force, Lavoisier's oxygen, Darwin's natural selection, and Wegener's continental drift. In addition, revolutions usually involve reclassification in which a concept changes its place in the hierarchy of kinds, just as Copernicus reclassified earth as a planet, Darwin reclassified humans as a kind of animal, and the cognitive revolution in psychology reclassified thinking as a kind of computation. Even more radically, the principle of classification sometimes changes, as when Darwin argued that species should be organized into kinds on the basis of evolutionary history rather than similarity. Like many other philosophers of science, Thagard argued that Kuhn had overestimated the conceptual differences between theories, so that conceptual change did not prevent one theory from being rationally preferred to another on the basis of its explanatory power. Nevertheless, he accepted Kuhn's basic contention that new theories often have very different conceptual systems from the ones they replace.

Philosophers and psychologists have discussed the cognitive mechanisms by which new conceptual systems in science are constructed. These include conceptual combination, in which a concept such as 'sound wave' is constructed out of the previously existing concepts 'sound' and 'wave'. New concepts are rarely derived directly from experience, but instead are built up from previously existing concepts. A concept produced by conceptual combination need not be a simple sum of the original concepts, but instead can involve emergent properties. For example, the concept 'blind lawyer' has characteristics not found in either 'blind' or 'lawyer': people use causal reasoning to conclude that a blind lawyer must be courageous.

Another creative mechanism is analogy, in which new scientific concepts are formed by adapting and transforming previous concepts. For example, Darwin's concept of natural selection was based in part on his familiarity with artificial selection practiced by breeders who produced new varieties of plants and animals. Maxwell developed concepts of electromagnetism using mechanical analogies (Nersessian, 1992), and Kepler extensively used analogies to develop new concepts concerning light and motion (Gentner *et al*., 1997).

Once a new conceptual system has been constructed by mechanisms such as combination and analogy, it becomes a contender to replace an existing conceptual system. The major cognitive mechanism for such large-scale conceptual change is explanatory coherence: scientists adopt a new theory along with its conceptual system because it provides a better explanation of the evidence and is more coherent with other beliefs (Thagard, 1992). Of course, most conceptual change in science does not involve such large-scale shifts in which conceptual systems are substantially altered, but rather the introduction of new concepts that fit in with existing conceptual schemes and theories.

CONCEPTUAL CHANGE IN YOUNG CHILDREN

Young children acquire a wealth of new concepts as their knowledge of language and the world increases. The average high-school graduate in the USA knows around 60 000 root words, which must have been acquired at a rate better than 10 per day. Presumably, children have concepts that are mental representations corresponding to all these words, so how can we account for their acquisition in such large numbers? Much conceptual change is

straightforwardly cumulative, as children simply add new concepts such as 'dog' and 'ice cream' to their mental systems. However, some developmental psychologists have argued that conceptual development in children is like conceptual change in science, in that it sometimes requires substantial revisions of existing conceptual schemes.

Susan Carey argued that children's acquisition of biological knowledge between the ages of 4–10 years involves considerable conceptual reorganization (Carey, 1985). In particular, the concepts 'alive' and 'animal' undergo substantial change during those years. Many 4-year-olds have difficulty naming any objects that are not alive, and take objects such as tables and clocks as being alive because they have activities or motions associated with them. By the age of 10 years, however, most children have acquired the adult concept of 'living thing'. Similarly, children under 7 years old often do not count people and insects as animals. According to Carey, children undergo a complete reorganization of knowledge of functions such as eating and sleeping and of organs such as the stomach and heart as the domain of biological knowledge becomes differentiated from the domain of knowledge of human activities. It is not just that the concepts of a 10-year-old have different relations among them than those of a 4-year-old, but more that the concepts themselves have changed as the result of additional biological knowledge. The concepts 'animal' and 'plant' coalesce into the concept 'living thing' by virtue of recognition that they are fundamentally alike. At the same time, children learn to differentiate 'dead' from 'inanimate' as two different senses of 'not alive'. Just as scientists had to learn to differentiate between heat and temperature, so children have to learn to differentiate weight from size and density. Like scientists, children have theory-like conceptual structures, and learning consists in radical alteration of such structures, not just additions to them.

Frank Keil reached similar conclusions from his studies of the development of children's concepts of biological kinds (Keil, 1989). As children gain an increasing appreciation of the biological principles that organize adults' intuitive theories of biology, they increasingly appeal to origins and internal parts in their biological classifications, reducing the impact of visible features. For example, older children are more likely to judge that a pear covered with apple skin is still a pear. In contrast, there was no similar shift for artefacts such as cup and nail, indicating that conceptual change was specific to biological kinds. Keil argues that concepts are part of coherent belief systems, so that conceptual change is closely tied in with theory change in children.

Gopnik and Meltzoff (1997) are even more emphatic in tying conceptual change to theory change. They advocate the 'theory theory', according to which the process of cognitive development in children is similar to and perhaps even identical to the process of theory development in scientists. They describe changes in understanding of objects in infants, who are born assuming a world of three-dimensional objects that have visual, auditory, and tactile features. By 6 months, infants have gained systematic, coherent knowledge about the movements of objects, but they still lack understanding of hidden objects, which develops around 9 months. Later, at around 18 months, infants acquire the ability to represent invisible movements. Gopnik and Meltzoff contend that these shifts are like theory change in science, and that there is a certain incommensurability between the concepts of the old and new theories held by the infants.

These and other studies of learning in children strongly suggest that conceptual development is not simply a matter of accumulating new concepts but also involves important changes in concepts and conceptual systems. However, the evidence is still limited for claims that children's conceptual systems are like those of scientists and that the cognitive mechanisms of change in children are like those that take place in the minds of scientists. It is possible that children's knowledge is much more fragmented than the conceptual systems that make up scientific theories such as relativity and evolution by natural selection. Scientific theories consist of hypotheses that provide unifying explanations of diverse empirical phenomena, but no one knows whether children's beliefs involve the same kind of explanatory hypotheses. Moreover, the process by which scientists come to realize that one theory is better than and should replace a previous one involves a systematic comparison of the explanatory coherence of the two theories. Belief change in children may be much more piecemeal, as isolated fragments of a new theory of objects and kinds are acquired from experience and teaching. It is possible that new ways of looking at things supplant previous ones by a process of gradual build-up of new concepts and progressive disuse of old ones, rather than by a dramatic replacement of the old theories by new ones. The view that conceptual change in children is similar to theory change in scientists has been heuristically useful in stimulating research on children's learning, but much more empirical research is needed before the analogy between children and

scientists can be accepted as showing a common set of cognitive processes.

CONCEPTUAL CHANGE IN STUDENTS

Suppose it is true that learning in children and scientists involves radical conceptual change rather than mere accumulation of new concepts and beliefs; then teaching students cannot be understood as merely providing new material to mesh with what students already know. Rather, education in science and other subjects may require a much more challenging process of dealing with the prior concepts and hypotheses that guide students' thinking. If teachers are not aware that students come to science classes with misconceptions about living things and physical processes, the teachers will not understand many of the difficulties that the students have in learning. From the perspective of conceptual change, teaching requires an active approach in which children must be engaged in building explanations that challenge concepts and beliefs that they previously held. Effective teaching may require the use of the kinds of analogical models and thought experiments that have often facilitated conceptual change in the history of science.

Chi (1992) argues that physics education is often difficult because it requires conceptual change across fundamental ontological categories such as matter, events, and abstractions. For example, naive students start with concepts of force, light, heat and current that class them as kinds of material substances, but physics students must learn to reconceptualize them as fields, which are a complex kind of event. Vosniadou and Brewer (1992) studied the development of children's knowledge of astronomy and found that children have difficulty reconciling the teaching that the earth is round with their other beliefs and observations. Children develop models that reconcile their observation-based belief that the earth is flat with what they are taught about the earth being round. For example, first-graders often believe that there are two earths – a flat one on which we live and a round one up in the sky. Other children think that the earth is a sphere, but we live inside it rather than on top of it. Thus, teaching children that the earth is round is not just a matter of telling them an additional fact, but requires them to revise their basic beliefs about the nature of the earth and other planets.

Science education is thus in part a cognitive process involving conceptual change, but it is also being increasingly recognized as a social, contextual, and emotional process (Guzzetti and Hynd, 1998). Conceptual change is a kind of mental change, but this may come about because of social interactions that students have with teachers and each other, as well as with the physical world. Motivation and emotion can greatly influence conceptual change when students acquire the intention and enthusiasm to adopt new concepts and hypotheses rather than to remain entrenched in their previous frames of mind. Future research on conceptual change will have to find ways to integrate cognitive processes with social and emotional processes that interact with them continuously.

The last section raised the question of whether conceptual change in children is like that found in scientists undergoing major theoretical changes. It is also an open question whether students need to undergo conceptual revolutions, or whether instead they can learn by a more gentle process in which new conceptual systems come to predominate over previous ones without the explanatory conflicts that occur in science. More research is needed to determine whether the cognitive mechanisms of conceptual change and theory evaluation that operate in scientists are also responsible for educational progress in science students.

Conceptual Representations in Psychology

Introductory article

Arthur B Markman, University of Texas, Austin, Texas, USA

CONTENTS

Conceptual representation refers to the way that information about categories is stored and organized.

INTRODUCTION

Concepts are mental representations that are used to divide the world into groups that will be treated as equivalent for some purpose. Concepts may refer to objects, events, or ideas. Concepts may be used for reasoning, prediction, and communication. Some researchers have distinguished between concepts, which are the mental representations of information, and categories, which are sets of objects in the world that are grouped together. Often, however, these terms are used interchangeably.

Psychologists have explored concept representations in detail. This work has examined both within-category representation and between-category structure. Within-category representation refers to the information that describes a particular category such as 'dog'. Between-category structure refers to the relationships among different categories such as that between the categories 'dog', 'cat', and 'animal'.

WITHIN-CATEGORY REPRESENTATION

The central question about within-category representation involves the way people store information about particular concepts that enables them to classify new items (exemplars) as members of a category. Some work has looked at other uses of categories such as making predictive inferences, causal reasoning, and communication, but this discussion will focus on classification. Three broad types of within-category representation are rule-based models, similarity-based models, and theory-based models.

Rule-based Models

The classical approach to concept representation has been to seek a rule that specifies the necessary and sufficient conditions for something to be a member of a category. A property is a necessary condition for being in a category if all members of that category possess the property. A set of necessary conditions is sufficient to specify a category if all exemplars that have that set of properties are members of the category, and no exemplars that have that set of properties are members of any other category. For example, an object is a triangle if it is a three-sided closed figure. This set of features is necessary and sufficient, because all triangles are three-sided and closed. No object that has these properties can be anything but a triangle.

Unfortunately, outside formal domains like geometry, it is difficult (or perhaps impossible) to find a set of necessary and sufficient conditions that specify the members of a category. For example, it might seem at first glance that a bachelor is an unmarried adult man. While this rule correctly classifies most bachelors, there are many dubious cases. For example, Catholic priests and widowers are both unmarried adult men, but one might be hesitant to classify them as bachelors. While it is possible to continue to refine this definition, it is likely that exceptions could be found to any rule that was generated.

One approach that has been tried to save rule-based approaches has been to assume that people generate fairly simple rules that are good for classifying most exemplars, and then store exceptions to the rules separately. In the example above, the rule 'unmarried adult man' would be used to classify

most bachelors, but exceptions such as priests and widowers would be considered separately.

Similarity-based Models

Intuitively, it seems that a new exemplar is classified based on its similarity to the category. For example, an object might be classified as a bird, because it looks like a bird. This intuition has been captured by similarity-based models, which assume that people classify a new exemplar based on its similarity to some stored category representation. Similarity-based models differ from each other primarily in their assumptions about the nature of the stored category representation.

Prototype models assume that people store some average representation of an object. The average need not be identical to any actual exemplar, but rather contains the features most frequently associated with that category. For example, the typical bird might be a small animal that flies, sings, and has feathers. Not all birds have this entire set of properties (e.g. penguins do not fly), but the more of these features an exemplar possesses, the more likely it is to be a bird.

One result often taken as evidence for prototype models is that categories have a graded typicality structure: that is, people have strong intuitions about which members of a category are typical members of that category and which members are atypical. For example, robins and sparrows are generally thought to be typical birds, while chickens and emus are thought to be atypical birds. Generally, the typicality of an exemplar is related to its similarity to the prototype of the category.

A second prominent similarity-based model is the exemplar model, which posits that people store representations of each category member rather than creating a prototype. New exemplars are then classified by comparing them with all of the known exemplars. The more similar a new exemplar is to the known exemplars of a particular category, the more likely it is that the exemplar will be classified as a member of that category. Exemplar models are also able to account for graded typicality structure, because typical exemplars are similar to many members of a category, but atypical exemplars are similar to only a few members of a category.

Theory-based Models

Despite the success of similarity-based models in predicting how people classify new items, there are situations in which people classify items in a manner that violates similarity. For example, at a party, a person might be classified as drunk if he or she dives headfirst into a cake. This person is not being classified on the basis of any similarity to known exemplars of drunk people; rather, common beliefs about drunken behavior are sufficient to classify the person as drunk.

There seems to be a developmental change in people's ability to use theory-based information. When children first learn categories, they often classify on the basis of surface characteristics. For example, if told about a black cat that has a white stripe painted on its back, and a bag of smelly stuff surgically placed inside it, young children will classify it as a skunk. Older children and adults, however, will classify it as a cat, suggesting that they are able to use a theory about biological categories to classify this (rather strange) exemplar.

Which Type of Model is Right?

Of the three types of models, the rule-based models are least often used in conceptual processing. There are some situations in which people must make repeated classifications that involve a rule and exception process. However, empirical studies suggest that even when people are asked to form rules, their ability to apply the rule is influenced by the similarity of a new exemplar to those seen before.

Both similarity-based and theory-based processes are often used in categorization. There are times when people must be able to identify a new item on the basis of the similarity of its properties to those of items seen in the past. In addition, there are cases in which people's theories about a domain influence categorization. Current research is focusing on how to integrate similarity-based and theory-based approaches.

BETWEEN-CATEGORY STRUCTURE

A second important aspect of category representation involves the relationships among categories. In this section, two aspects of between-category structure are examined. First, much research has examined the hierarchical organization of categories. This work is concerned with understanding how people may categorize objects at different levels of abstraction. A second area that has received attention is people's ability to generate categories based on goals. This study of goal-derived categories also provides a window into conceptual processing.

Hierarchical Organization of Categories

If you see a small, curly-haired, four-legged living creature being walked on a leash down the street, you can classify this thing as a poodle, a dog, or an animal. That is, for any given object, there are a variety of categories to which it belongs. Many of these categories differ from each other in their degree of abstraction: 'dog' is a more abstract category than 'poodle', because all poodles are dogs, but not all dogs are poodles. Similarly, 'animal' is a more abstract category than either 'dog' or 'poodle'.

A striking aspect of this category structure is that if you show people a picture of some object, they are most likely to identify it using a category at a middle level of abstraction. For example, shown a picture of the item described in the previous paragraph, people are likely to identify it first as a dog rather than as a poodle or as an animal. This tendency has led psychologists to refer to this middle level of abstraction as the basic level. Categories more abstract than those at the basic level (e.g. animal) are called superordinate categories, and categories more specific than those at the basic level are called subordinate categories (e.g. poodle).

Basic level categories have been shown to have a number of characteristics. First, they tend to be the most abstract categories whose members have a common shape, and whose shape differs from other contrasting basic level categories. For example, dogs tend to be shaped similarly to each other and differently from other animals; in contrast, animals come in many different shapes. Second, basic level categories tend to have shorter labels than either subordinate or superordinate categories; for example, 'car' is the label for a basic level category, and the labels 'vehicle' (for the superordinate) and 'sports car' (for a typical subordinate category) are both longer than the basic level label. Basic level categories are also the most abstract level for which the category members share the same set of parts: cars all have wheels, brakes, and engines, whereas there are many other vehicles (e.g. helicopters and boats) that do not share these parts. Finally, children tend to learn basic level labels for objects before learning the labels for categories at other levels of abstraction. The factors that characterize basic level categories can be summarized as follows:

- Objects are identified first at the basic level.
- Objects are classified fastest at the basic level.
- The basic level is the most abstract level at which the members tend to have the same shape.
- The basic level is the most abstract level at which the members tend to share parts.
- The basic level is the most abstract level at which people interact with the members using similar motor movements.
- The basic level is the most abstract level at which the category members tend to be similar.
- The basic level is the most abstract level at which category members tend to be dissimilar from members of contrasting categories.
- Children often learn basic level labels before labels at other levels of abstraction.
- Basic level labels are shorter than labels for categories at other levels of abstraction.

The hierarchical organization of categories seems to be strongest for object categories. Some research has been done on the between-category structure of abstract concepts such as events and ideas. People also have categories at different levels of abstraction for these concepts, but the basic level does not have as much of an advantage relative to subordinate and superordinate categories.

Goal-derived Categories

The previous section suggested that an object might belong to many different categories, and that these categories generally differ in their level of abstraction. There are some categories, however, that are organized around people's goals rather than around the overall shape and parts of objects. Some of these categories are ones that we use all the time, and their labels have become words. For example, a 'pet' is a domesticated animal that is kept as a companion. Thus, membership in this category is determined by whether an object serves a particular goal.

An important observation is that people can also generate goal-derived categories as they are needed. For example, you may never have considered the category 'Things to take out of a house in the event of a fire'. Now that this category has been suggested, however, it is easy to generate members of the category (e.g. children, jewellery, photographs).

Novel goal-derived categories are called *ad hoc* categories. A striking finding is that, although they are being generated on the fly, they share many characteristics with categories that were previously learned. For example, like regular categories, *ad hoc* categories exhibit a graded typicality structure: that is, people find it easy to determine which members of an *ad hoc* category are typical or atypical. For example, people might agree that old photographs

of family members are good examples of things to take out of the house in the event of a fire, but that an old sofa is a poor example.

One key difference between regular categories and goal-derived categories is in the way that typicality is assessed. For regular categories, an object is typical to the extent that it is similar to the average member (or prototype) of the category. In contrast, for goal-derived categories there is often an ideal member, and items are more typical to the extent they are similar to the ideal. For example, someone might create the goal-derived category 'diet foods'. The ideal member of this category tastes great and has no energy content. A new object will be typical of a category to the extent that it is similar to its ideal.

CONCLUSION

Psychologists have explored the internal (within-category) representation and external (between-category) structure of category representations. Research on within-category representation has focused on the role of rules, similarity, and theory in determining category representation. Research on between-category structure has focused both on relationships among categories at different levels of abstraction and on goal-derived categories.

Conditioning

Introductory article

Frances K McSweeney, Washington State University, Pullman, Washington, USA

CONTENTS

Classical and operant conditioning are procedures for changing behavior. Behavior changes when a previously neutral stimulus predicts an important stimulus (classical conditioning). Behavior also changes when a response produces a particular consequence (operant conditioning).

INTRODUCTION

Classical and operant conditioning provide powerful techniques for understanding and controlling behavior. In classical conditioning, the behavior towards a previously neutral stimulus changes when that stimulus predicts the occurrence of a stimulus that already evokes a response. In operant conditioning, the frequency of, or the time spent making, a response is changed by consequences (reinforcers or punishers) that follow that response.

CLASSICAL CONDITIONING

The discovery of classical conditioning is usually attributed to Ivan Pavlov, a Russian physiologist. Pavlov briefly turned on a metronome and then presented food to a dog. After several exposures to the metronome followed by food, the dog salivated when the metronome was presented alone. That is, the dog's behavior toward the metronome changed when the dog learned that the sound of the metronome was followed by food.

In Pavlov's procedure, the metronome or tone is usually referred to as the 'conditioned stimulus' (CS). The CS is originally neutral to the animal in the sense that it does not automatically evoke the response of interest (salivation). The food is referred to as the 'unconditioned stimulus' or US. It is a stimulus that already evokes a response. The response that is evoked by the US is called the 'unconditioned response' (UR). The response that occurs to the CS, as a result of its pairing with the US, is called the 'conditioned response' (CR).

The classical conditioning procedure presented above might be described by saying that when a CS is followed by a US several times, the CS comes to evoke a CR that resembles the UR. Even stated this way, classical conditioning is of some practical interest. For example, it may explain the acquisition of a fear or phobia (CR) when a stimulus (CS, e.g. a snake) precedes a frightening event (US: e.g. someone screams). It may play a part in the development of preferences for or aversions to food, and it may facilitate digestion because stimuli that precede food intake may help to prepare the body. Since the time of Pavlov, however, our understanding of classical conditioning has changed in ways that have greatly increased its practical usefulness.

The Form of the CR

Voluntary behaviors as CRs

Pavlov studied the reflexive response of salivation while his animals were immobilized by suspending them in a hammock. Reflexive responses are behaviors that are automatically evoked by a stimulus (e.g. you blink your eye in response to a threat). Reflexive responses are often distinguished from voluntary behaviors that are emitted rather than evoked by a particular external stimulus (e.g. you read this article). Pavlov's study of reflexive behaviors in restrained animals may have limited peoples interest in classical conditioning. Most people are more interested in the voluntary behavior of freely moving animals, including people.

The principle of 'sign tracking' suggests that classical conditioning does apply to the voluntary behavior of freely moving animals. Sign tracking states that animals approach and contact the stimulus that is the best predictor of a US, and withdraw from stimuli that signal the absence of a US. According to this idea, when a CS predicts a US, the behavior that is learned is movement (approach or withdrawal), not just reflexive behavior (e.g. salivation). For example, I once visited a wildlife park in Australia where a vending machine sold kangaroo chow. The machine made a loud noise

when it operated and that sound (CS) predicted the availability of food (US). As expected from sign tracking, a stampede of kangaroos approached (CR) the food machine as soon as it operated (CS), an undesirable event for those standing by the machine. (Technically, without further tests, this behavior cannot be conclusively identified as classically conditioned. It might also be a discriminated operant, as described later.)

CRs may differ from URs

In Pavlov's experiment, similar responses served as the CR and UR. That is, dogs salivated when food was presented (UR) and they learned to salivate to the sound of a metronome that preceded food (CR). If the CR must be identical to the UR, then classical conditioning cannot be used to train a response unless a US can be found that automatically evokes that response. This is difficult in many cases (e.g. teaching someone to play the piano).

We now know that the CR may differ from the UR. For example, when some types of drugs are used as a US, the CR may be the opposite of the UR. To give one example, morphine is a painkiller (UR), but animals become hypersensitive to pain (CR) in the presence of an arbitrary stimulus (CS), e.g. the sight of a needle, that predicts a morphine injection (US). This means that classical conditioning may contribute to the build-up of tolerance for drugs and to the withdrawal symptoms that are observed when drugs are not available. Think of the UR to morphine as a 'high' (a pleasant state) and the CR to morphine as a 'low' (an unpleasant state). Classically conditioned responses gradually become stronger with each successive pairing of the CS and US. If a conditioned 'low' becomes stronger with each morphine injection, then more and more of the drug will be needed to overcome it – that is, tolerance will develop. If the conditioned stimuli that accompany a drug injection (e.g. time of day, sight of the needle) occur without the drug, then the animal will experience only the low (CR) without the high (UR) produced by the US. This low may contribute to withdrawal symptoms. Although classical conditioning may play a role in drug tolerance and withdrawal, it is undoubtedly only one of many contributors.

Information versus Temporal Contiguity

In the earlier description, classical conditioning occurred when a CS was followed by a US. More recently, it has been argued that a CS must provide information about, or predict, the occurrence of the US for conditioned responding to occur. Consider the following experiment. One group of animals receives a CS followed by a US 10 times. A second group receives the same 10 CS–US pairings, but also receives 10 extra unconditioned stimuli that are interspersed among the CS–US pairings. If conditioned responding develops when a CS is followed by a US, then conditioned responding should be strong in both groups. They both experience the CS followed by the US 10 times. If conditioned responding occurs when the CS provides information about the US, then the first group should respond more than the second group. In the first group, the CS is a perfect predictor of the US; in the second group, it is not. The evidence supports the information view.

Cue Competition Effects

The strength of conditioned responding to a CS depends on how well that CS predicts the US. It also depends on the strength of conditioning to other conditioned stimuli that also predict the US. Because the presence of other predictive conditioned stimuli usually weakens conditioned responding to any one of them, cues are said to compete for conditioning. Overshadowing and blocking are examples of cue competition.

Overshadowing

In most cases, more conditioned responding occurs to CS1 (e.g. a light) when CS1 alone predicts the US (CS1 $\rightarrow$ US) than when CS1 and CS2 (e.g. a light plus a tone) together predict the US (CS1 + CS2 $\rightarrow$ US). The stimulus CS2 is said to 'overshadow', and therefore to reduce conditioned responding to, CS1. Although overshadowing is the usual finding, the opposite, potentiation, is occasionally reported, especially when the stimuli are tastes and odors. Potentiation refers to greater conditioned responding to CS1 when it predicts the US in compound with CS2 than when CS1 predicts the US alone.

Blocking

If an animal learns that CS1 predicts a US (CS1 $\rightarrow$ US), then the animal will not later perform a CR to a second CS (CS2) that also predicts the US when presented in compound with CS1 (CS1 + CS2 $\rightarrow$ US). The prior conditioning to CS1 is said to block conditioned responding to CS2. The occurrence of blocking provides further support for the idea that conditioned responding develops only when a CS provides information about a US. Presumably, a CR does not occur to CS2 because it provides

no information about the US beyond that already provided by CS1.

Again, blocking is the usual finding, but the opposite result of augmentation is sometimes reported. Augmentation refers to a situation in which prior conditioning to CS1 strengthens, rather than weakens, conditioned responding to a redundant CS2. Augmentation, as potentiation, is particularly likely when tastes and odors serve as CSs.

Cue to Consequence Effect

Some combinations of CSs and USs yield stronger CRs than others. For example, a strong CR of aversion will develop when a taste (CS) predicts illness (US), as well as when a light (CS) predicts an electric shock (US). Weaker or no aversion will result when a light (CS) predicts illness (US) and when a taste (CS) predicts an electric shock (US). Although it is not known why this occurs, some have argued that evolution favors animals that quickly learn to avoid foods whose tastes predict illness. Such animals are less likely to die of poisoning.

Significance of Classical Conditioning

Classical conditioning was once described in ways that made it appear to be a simple mechanical transfer of behavior from one stimulus to another. This view was challenged by many findings, including that the CR need not resemble the UR and that blocking may occur. More recently, classical conditioning has been seen as a mechanism through which the predictive relations among stimuli in the environment alter behavior. In many cases, receiving an early warning from an arbitrary stimulus may help an animal deal with a potentially harmful stimulus (e.g. a drug) to come.

OPERANT CONDITIONING

Operant conditioning is a change in behavior that occurs as a result of the consequences of that behavior. Its most prominent student was B. F. Skinner. Because of the power of operant techniques, they form the basis for behavior therapies that are effective in correcting many human behavioral problems. They are used to train nonhuman animals for performances in films or circuses. They are also often used in scientific studies to establish a baseline for assessing the effect of other manipulations (e.g. drug injections, physiological interventions). Operant techniques are useful as baselines because they provide stable and replicable control over behavior.

Positive Reinforcement

The most frequently studied form of operant conditioning is positive reinforcement. According to the principle of positive reinforcement, a response that is followed by a reinforcer will increase in frequency. For example, if lever pressing (response) yields food (reinforcer) for a hungry rat, the rat will press the lever more frequently in the future. Some behaviors are more easily measured in terms of the time devoted to them than in terms of their frequency (e.g. reading). In that case, following the response by a reinforcer will increase the amount of time spent making the response. For example, if practicing the piano (response) yields the opportunity to watch a favorite television program (reinforcer), then the time spent practicing will increase.

Notice that a response cannot be strengthened by reinforcement unless a reinforcer can be found. Over the years, many definitions for the term 'reinforcer' have been rejected. For example, reinforcers were once thought of as substances that are physiologically needed (e.g. food, water), but there are many reinforcers that are not physiologically needed (e.g. watching television, going to the cinema). Reinforcers were once defined as stimuli that reduce tension (e.g. sexual behavior), but many stimuli that increase tension also serve as reinforcers (e.g. watching a scary film, riding a roller coaster).

Because of these failures, a reinforcer is technically defined as any stimulus that increases the frequency of a response that it follows. This is an undesirable definition because it makes the principle of positive reinforcement circular. That is, the principle now states that a response followed by any stimulus that increases the frequency of the response that it follows will increase in frequency. This definition has been accepted because scientists can identify a stimulus as a reinforcer in one situation (e.g. they can show that the stimulus will increase the frequency of one response that it follows); they can then test the principle of positive reinforcement in another situation (e.g. they can ask whether that reinforcer also increases the frequency of other responses that it follows).

Some stimuli will serve as reinforcers for both human and nonhuman animals (e.g. food, water, access to conspecifics for herd animals). Other reinforcers will be more effective with people than with other animals (e.g. praise, money, the opportunity to watch television). Different items will serve as reinforcers for different people, and the

Premack principle provides a way to identify effective reinforcers. The Premack principle states that the opportunity to perform any higher probability response can serve as a reinforcer for any lower probability response. The probability of a response is measured by examining what the animal does when it has free time. According to the Premack principle, if a child often plays electronic games, then the opportunity to play such a game will serve as a reinforcer for less probable behaviors, such as doing homework.

Eliciting the first response

A response cannot be reinforced until that response occurs. When working with people, verbal instructions may be used to elicit the first response (e.g. 'please practice the piano'). For complex responses, such as a golf swing, physical guidance known as 'prompting' may also be needed. Shaping by successive approximations may be useful when dealing with nonhuman animals or with a nonverbal person such as a baby. During shaping, closer and closer approximations to the desired response are reinforced. For example, if you want to teach your dog to sit up, you could begin by following any movement by a reinforcer. Then you might reinforce only movements that involve some transfer of the dog's weight to its back paws. Then you might reinforce only movements that involve weight transfer to the back paws plus lifting the forepaws off the ground. By carefully choosing which behaviors to reinforce and when to alter the reinforced response, you should quickly have your dog sitting up.

The Four Basic Conditioning Procedures

Operant conditioning can be used to either increase (reinforcement) or decrease (punishment) the frequency of a response. The frequency of a response may change when the response produces something (positive) or when it escapes or avoids something (negative). It is called 'positive reinforcement' when a response increases in frequency because it produced something (e.g. you work because you have been paid for working). Negative reinforcement occurs when a response increases because it escaped or avoided something (e.g. you drive safely because safe driving has prevented accidents). Positive punishment occurs when a response decreases in frequency because it produced something (e.g. your cat no longer scratches the furniture because you squirted it with water whenever it scratched). Negative punishment occurs when a response decreases in frequency because it prevented or removed something (e.g. your child stops hitting his little brother because you took away his allowance or confined him to his room when he did so).

Technically, a stimulus is classified as a reinforcer or punisher depending on its effect on behavior. Reinforcers increase behaviors that they follow; punishers decrease behaviors. Terms related to pleasure and pain do not appear in these definitions. Nevertheless, stimuli that serve as positive reinforcers when they are delivered and as negative punishers when they are removed are usually described as pleasant. Stimuli that serve as negative reinforcers when they are removed and positive punishers when they are presented are usually described as aversive or painful.

Schedules of Reinforcement

Reinforcers are delivered according to schedules of reinforcement, which are rules specifying which response will be followed by a reinforcer. During a continuous reinforcement (CRF) procedure, every occurrence of a particular response is followed by a reinforcer. For example, in a perfect world, depositing an appropriate amount of money into a soft-drink machine (response) would yield a soft drink (reinforcer) each time that you did it. Continuous reinforcement procedures have drawbacks that reduce their usefulness. For example, the person administering a CRF procedure must be alert enough to identify and to reinforce every instance of the behavior when it occurs. Therefore, CRF is often used to initially teach a response but it is usually replaced by partial reinforcement as the response becomes stronger.

During partial reinforcement (PRF), some instances of a response do not yield the reinforcer. There are four basic schedules of partial reinforcement. In a fixed ratio schedule (FR x), a reinforcer is delivered after every x occurrences of a response. For example, in a piecework factory, you might be paid (reinforcer) every time you completed 10 widgets (10 responses). This would be an FR 10 schedule. In a variable ratio schedule (VR x), a reinforcer is delivered after every xth occurrence of the response on average. For example, a foraging pigeon probably does not find food (reinforcer) each time it pecks the ground (response), but it does find food after some variable number of pecks.

In a fixed interval (FI x min) schedule, a reinforcer follows the first response emitted after a fixed period of time since the last reinforcer. For

example, if the post is delivered at approximately the same time every day, then the response of checking your mailbox will be followed by the reinforcer of finding mail approximately 24 h after the last time that you received mail. In a variable interval (VI *x* min) schedule, a reinforcer follows the first response emitted after a variable period of time since the last reinforcer. For example, the response of getting through when dialing a telephone number that is busy is probably reinforced on a VI schedule. Notice that that response must be emitted or the reinforcer will not be delivered during FI and VI schedules. Notice also that only one response is required to produce the reinforcer. In spite of this, animals emit many more than one response per reinforcer when responding on these schedules.

Psychologists distinguish between these four basic schedules because the schedules control behavior in different ways. Animals respond at a relatively high and steady rate when responding on VR and VI schedules. In contrast, animals pause after reinforcement when responding on FR and FI schedules. When responding begins, it either continues at a steady rate after the pause (FR schedules) or gradually accelerates to a peak rate just before the next reinforcer is delivered (FI schedule). The length of the pause following reinforcement is directly proportional to the size of the schedule requirement. For example, animals may pause for approximately 30 s when responding on an FI 1 min schedule that makes reinforcers available once per min. They may pause for approximately 5 min when responding on an FI 10 min schedule that makes reinforcers available only once every 10 min. If the requirement becomes too large, the animal may stop responding entirely. This is called 'ratio strain'. Ratio strain can be reversed by returning to a less difficult requirement for reinforcement.

CHARACTERISTICS OF CONDITIONED BEHAVIOR

Acquisition

Conditioned responses gradually gain strength as the reinforcer repeatedly follows the response or the CS repeatedly predicts the US. For example, the amount of saliva that Pavlov collected when he presented the CS (strength of the CR) would be greater after ten pairings of the CS with the US than it was after only two pairings. However, conditioned responses do not gain strength indefinitely. Eventually, a point is reached beyond which further pairings of the CS with the US or the response with the reinforcer do not further increase the strength of the conditioned behavior.

Extinction

The extinction of a classically conditioned response refers to the return of a CR to its baseline strength after the relation between the CS and US is broken. Baseline strength is the strength of the CR before conditioning. Extinction may be accomplished in either of two ways. The US may be removed entirely, or the CS and US may be presented randomly with respect to each other. In the earlier example, kangaroos approached (CR) a feeder because the sound of the feeder (CS) predicted that food (US) was available. Kangaroos would stop approaching the feeder (extinction) if either the feeder was empty so that the sound occurred with no food (US removal) or if the feeder was broken so that the sound occurred randomly with respect to the availability of food (random CS and US presentation).

The extinction of an operantly conditioned response refers to the return of that response to its baseline strength when the relation between the response and the reinforcer is broken. Again, this relation may be broken by removing the reinforcer or by presenting the reinforcer randomly with respect to the response. For example, if you work (response) because you have been paid for working (reinforcer), you would work less (extinction) if you were no longer paid (the reinforcer was removed) or if you won the lottery (received money regardless of whether you worked or not).

Generalization

Generalization of classical conditioning refers to the fact that a CR to one particular CS also occurs in response to other stimuli that resemble that CS. The greater the resemblance between the new stimulus and the CS that was actually paired with the US, the stronger the CR to the new stimulus. For example, if you are stung (US) by a bee (CS), you may learn to fear (CR) other insects, and your fear will be stronger the more closely the insect resembles a bee.

In operant conditioning, a response that has been reinforced in the presence of one stimulus will also occur in the presence of other stimuli that resemble the original stimulus. Again, the response to a new stimulus will be stronger, the more that stimulus resembles the stimulus in the presence of which the response was reinforced. For example, teachers do not have to teach appropriate classroom behavior

at the beginning of each school term. The new classroom resembles the students' classrooms of the previous year. Therefore, behaviors (e.g. sitting quietly) that were reinforced in the old classroom occur in the new one without training.

Discrimination

During a classical conditioning discrimination procedure, one stimulus (CS+) predicts the US and another stimulus (CS−) does not. The CR occurs to CS+ but not to CS−. In our kangaroo example, the kangaroos approach (CR) the sound of the food magazine (CS) because it predicts food (US). They do not approach the sound of the gate opening (CS−) because it does not predict food (US).

During an operant discrimination procedure, a response is reinforced in the presence of one stimulus (S+) and not in the presence of another (S−). The response occurs in the presence of S+, but not in the presence of S−. For example, if a child learns that whining (response) gets him anything that he wants (reinforcer) when his father is around (S+), but not when his mother is around (S−), the child will whine only when his father is present.

Discrimination procedures provide useful techniques for asking questions of nonhuman animals or nonverbal people (e.g. infants). You may have heard that dogs do not see colors and wondered how we know. Part of the answer comes from discrimination training. Suppose you reinforce sitting up by giving the dog a treat in the presence of anything red, but not in the presence of anything green. If the dog can see colors, then you will quickly have a dog that sits up when a red, but not a green, stimulus is presented. This experiment must be done carefully. For example, if red and green stimuli reflect different amounts of light, then the dog will solve the discrimination on the basis of the brightness of the stimuli rather than on the basis of their color. However, when this experiment is done properly, dogs have difficulty forming a discrimination between red and green. As a result of many discrimination experiments, a great deal is known about the sensory and conceptual worlds of infants and many species of nonhuman animals.

Higher-order Conditioning

Some stimuli innately serve as unconditioned stimuli or reinforcers without additional training. These stimuli are called 'primary reinforcers' (or primary US). They include biologically important stimuli, such as food and water. Other stimuli acquire their ability to act as reinforcers through experience. These stimuli are called 'secondary', 'conditioned' or 'higher-order' reinforcers (or secondary US). Money provides the most obvious example of a secondary reinforcer.

Stimuli acquire the ability to act as secondary reinforcers in many ways. Two examples illustrate this. First, secondary reinforcers called 'tokens' are stimuli that can be exchanged for primary reinforcers. For example, money acquires the ability to act as a reinforcer because it can be exchanged for food, drink and other primary reinforcers. Second, classical conditioning pairing of a stimulus with a primary US or reinforcer will produce a secondary reinforcer or US. Therefore, a bell that is used to summon animals for feeding will gain the ability to act as a reinforcer itself.

The ability of stimuli to act as secondary reinforcers will be extinguished if their relation to the primary reinforcer or US is broken. Therefore, money would gradually lose its ability to reinforce if it was no longer exchangeable for goods, and the bell would lose its ability to reinforce if it was presented often without food.

Constructivism

Intermediate article

Jacqueline Grennon Brooks, State University of New York, Stony Brook, New York, USA

CONTENTS

Constructivism is a learning theory based on the notion that learners generate meaning through iterative mental formulation and reformulation of theories that satisfy the search for understanding.

INTRODUCTION

Constructivism has roots in various research traditions. It asks the psychological question: how is learning self-regulated? It considers the epistemological query: what is knowledge? It poses the pedagogical problem: how can educators facilitate knowledge construction? It examines the philosophical dilemma: is there an objective truth that we struggle to know, or are their different truths dependent on perception? Amid an array of widely varied responses to these questions is the cohesive focus on the learner's active role in generating meaning.

ACTIVE PROCESSES OF MEANING MAKING

The cognitive processes involved in making meaning are active ones that require the learner to continually evaluate new information and experiences against the learner's current theories, rules or notions. This viewpoint stands in stark contrast to other assertions that the learner's mind is a clean slate ready for inscription through direct teaching. Constructivism states that the learner approaches new experiences with a set of pre-established beliefs and naive theories, and that the learner changes those beliefs and theories only when unable to reconcile new data with previously held conceptions. Often learners will dismiss data that do not fit their present thinking as irrelevant or unrelated, and will assimilate the new information into their previously established theories without any disequilibrium or cognitive conflict. When learners find new data compelling enough to reconsider old theories, however, they experience cognitive conflict. They conquer their disequilibrium by accommodating current theories to include adequate explanations of past and present data (Piaget, 1953, 1970a). Educational programs based on constructivist principles are premised on the idea that it is the learner's responsibility to construct meaning through reflection on experiences with objects, phenomena or people, and that it is the teacher's responsibility to scaffold learner reflection in a manner that may generate learner analysis, synthesis and insight. (*See* **Naive Theories, Development of**)

The Nature of Knowledge

When a learner can construct interrelationships among sets of factual information and apply those understandings of interrelationships in novel contexts, the learner has constructed knowledge. This knowledge is dependent on mental structures. If a learner does not have the precursor mental structures in place, for example, to understand proportions, no amount of repeating the statement 'density is a ratio of mass to volume' will help the learner establish the concept. The learner's search for relationships among variables is the mental activity critical for an understanding of density as a ratio and the comparison of densities as a proportion. The depth to which a learner can construct understandings is predicated not only on the precursor mental structures mentioned previously, but on the information to which the learner has access. For instance, with information about atomic structure, density can be further understood in terms of the degree and nature of the packing of atoms in crystalline form. Within the iterative process of cognitive growth, the learner can create new knowledge from an ever-expanding repertoire of information that gives rise to yet new mental structures and then possibly new mental stages. (*See* **Piagetian Theory, Development of Conceptual Structure**)

Mental Structures

One way of describing constructivism is through an analysis of mental structures.

> We may say that a structure is a system of transformations. Inasmuch as it is a system and not a mere collection of elements and their properties, these transformations involve laws. … In short, the notion of structure is comprised of three key ideas: the idea of wholeness, the idea of transformation, and the idea of self-regulation. (Piaget, 1970b: p. 5)

Wholeness refers to the learner's quest to map the relationships among parts of a set. For instance, knowing the meaning of each word in a sentence is different from knowing the meaning of the entire sentence. It is the learner's ability to derive meaning from the relationships among the words in a sentence that forms the basis of the learner's understanding of the sentence. Transformation refers to the notion that as the learner constructs deeper understandings of the world, a mathematical necessity for grouping those understandings emerges. Thus, fundamental transformations of undergirding logical structures gives rise to new, more inclusive structures. Piaget's own career history provides an example. As a biologist studying the appearance of new structures in plants, Piaget transformed his understanding of how the hereditary aspects of the plant are affected by conditions in the environment into a more inclusive relationship between previous structures and environmental conditions that he could apply in a variety of settings. In the immediate case, he applied this relationship in the realm of psychology. Self-regulation refers to the learner's ability to engage in assimilation and accommodation in order to either maintain cognitive equilibrium or resolve cognitive conflict and reestablish cognitive equilibrium.

Personal knowledge construction is a key element of the constructivist paradigm. The eighteenth-century philosopher Vico was one of the earliest writers to put forth the notion that human beings can only know what their cognitive structures allow them to know. This notion surfaces for teachers in terms of readiness for learning. How far a learner can progress is a function of what the learner currently understands, and what the learner currently understands is a function of the learner's existing mental structures. The teacher plays a part in facilitating the learner's development of new knowledge and new structures through the creation of settings in which the learner may detect discrepancies and in which the teacher fosters discrepancy resolution. This iterative process gives rise to ensuingly more rigorous theory building.

Cognitive Conflict

Logical structures and processes of transformation, wholeness and self-regulation are terms from the philosophical and psychological literature. Constructivism, when described by educators, is associated with another set of correlated terms. Ausubel (1963) explains learning through a process he calls 'subsumption', in which new, more specific knowledge is linked with previous, more inclusive knowledge. His term 'obliterative subsumption', describes a process highly related to the law of transformation set out by Piaget in which concepts are modified so dramatically over time that learners can lose access to some of the specifics of their own earlier thinking. These more robust concepts characterize the superordinate learning that is typically called 'meaningful' learning.

Prior Knowledge

What a learner already knows and how the teacher scaffolds the current learning environment are important determiners of the future understandings the learner will be able to construct. When a learner is investigating a new phenomenon, whether it be how shadows are cast, how an odd number of supplies can be shared among an even number of students, or how one locates an entry in an encyclopedia, the constructivist teacher negotiates the phenomenon or concept with the learner using a subtle yet observable set of practices. The teacher seeks to understand the learner's readiness to generate certain types of knowledge by determining the learner's present hunches, conceptions, beliefs, etc. The teacher then provides opportunities for the learner to confirm or refute those initial thoughts. Unless the confirmations or refutations come from the learner, the likelihood that the learner will generate understanding is compromised. Unveiling the prior knowledge of the learner is an important aspect of constructivist teaching because constructivist theory stresses the importance of the learner's transforming current mental structures. It is the constant replacement of understandings with richer and deeper ones that characterizes the processes of cognitive growth and learning.

ROLE OF SOCIAL INTERACTION IN MEANING MAKING

The theory of constructivism postulates that learners come to know their world by interacting

with it in ways that allow them to build the mental structures that 'explain' what is perceived. Ultimately, this process of meaning making is individually constructed, but it is an outgrowth of social interaction. The social interaction may be immediate, as in the case of discourse with others in a community, or may be contextual, as in the case of learners formulating ideas within historical and cultural moments. Some theorists view knowledge as the mechanism by which learners make sense of their experiences in their environment. Others view it as the outcome of learners making sense of their experiences in their environment; and yet others see knowledge as both a means and an end. Within these divergent views of knowledge, there is much debate as to the nature of the relative components of knowledge, and also over the merit of classifying particular knowledge as true or false (Philips, 1998). However, there is general agreement among constructivists that knowledge is socially constructed and a function of the culturally derived, community-sanctioned perspective of the knower. The goal of education is to foster the development of shared knowledge among community members. Peers play a powerful role in this shared knowledge construction.

Community of Learners

The theory of constructivism gives rise to a 'community of learners' model within educational settings, a model in which learners in search of understanding communicate current thinking with others by formulating and reformulating their thoughts based on peer and expert feedback and by reflecting on that feedback. This model presupposes a definition of knowledge as dynamic and socially constructed and rejects a definition of knowledge as static and 'passed on'. This model also requires a good deal of scaffolding on the part of the teacher to maximize the likelihood that meaningful learning will occur. Some level of dissonance must be established either through peers' sharing diverse perspectives or through teacher prompts to highlight sources of cognitive dissatisfaction. The task must be within the reach of the learners, more advanced than any individual within the group would be likely to complete independently, but not so far advanced that learning shuts down.

Zone of Proximal Development

What is the teacher's role in the community of learners model? As the 'expert', the teacher can guide the learner in intellectual arenas in which the learner could not independently navigate. Vygotsky (1962) referred to this arena as the zone of proximal development. The teacher provides an intellectual framework at the leading edge of the learner's current thinking on a topic. That framework can include questioning designed to help the learner see relationships, can include contradictions designed to help the learner examine subtleties, or can include hypothetical comments to help the learner extend an argument. Although the nature of the scaffolding may be diverse, the scaffolding has a unified purpose: to aid learners in restructuring their current theories. For Vygotsky, language is the basis of cognition. For Piaget, language is a mechanism to express cognition.

Teachers offer learners this guided participation to maximize the likelihood that restructuring will occur. To every learner, his or her present thinking holds a great deal of merit. Therefore, cognitive restructuring is resistant to casual interference. Furthermore, it is even resistant to direct instruction. Much research discusses the inability of direct instruction to dispel the misconceptions widespread over many topics to which learners cling (Clement, 1982). Fostering a learner's restructuring of present conceptions requires an analysis of the learner's current perspective with specific regard to the topic, concept or issue at hand. While a casual observer in such a classroom may not readily see the underlying pedagogy, the pedagogy none the less exists and is powerful. The teacher's pedagogy drives decisions concerning which responses to pursue, which student groupings to establish, which supplies to gather, and which follow-up questions to generate.

CONCEPTUAL CHANGE

The term 'constructivism' holds different meanings in many circles. The radical social constructivists discuss the illusoriness of objective truth (von Glasersfeld, 1998), the cognitive constructivists engage in structural analyses of knowledge generation (Piaget, 1953), and the human constructivists seek a synthesis of epistemological and psychological phenomena (Novak, 1993). Where there is significant intragroup and intergroup variation, a binding construct for all groups is the focus on conceptual change. The goals to which the learner aspires may differ, but the constructivist teacher and researcher are focused on better understanding the learner's conceptual changes over time, the nature of the changes and the contributing variables. (*See* **Conceptual Change**)

Counterfactual Thinking

Intermediate article

Neal J Roese, University of Illinois, Champaign, Illinois, USA
James M Olson, University of Western Ontario, Ontario, Canada

CONTENTS

Mental constructions of alternatives to facts or events. These thoughts of 'what might have been' are linked to a variety of emotional and judgmental consequences.

INTRODUCTION

The term 'counterfactual' means contrary to established facts or actual events. Counterfactual thinking typically involves imaginative speculation about alternatives to past outcomes: that is, about what might have been. Counterfactuals often (though not always) take the form of conditional propositions, containing the dual components of antecedent and consequent. In everyday cognition, counterfactual thinking usually targets personal goals and desires, such that individuals focus on actions that might have brought about particular desired ends (e.g. 'If I had studied harder, I would have earned a higher grade'). Counterfactuals can also be deployed in everyday speech as arguments ('If not for Gorbachev, the Soviet Union and the Cold War would have persisted into the twenty-first century') or invitations to further speculation and elaboration, e.g., 'What if President Kennedy hadn't been assassinated?' Counterfactuals have intrigued philosophers throughout the twentieth century because of their implications for logic and epistemology, but more recently counterfactual thinking has inspired psychological research because such thought processes influence a wide range of emotional, judgmental, and behavioral outcomes.

The form and content of counterfactuals is limitless, and although they may conjure the bizarre and the fantastic, everyday counterfactual thinking is mundane. Indeed, an essential feature seems to be that counterfactuals preserve the integrity of the world as we know it, altering but one or two specific features, then unfurling immediate consequences against a backdrop that is essentially the same as actuality. Thus, one might wonder how the Second World War might have unfolded had Hitler attacked and defeated the British at Dunkirk rather than allowing them to escape, but background features, such as the previous history of Europe, the power of the respective nations' armaments, and for that matter the laws of physics, remain unchanged. Given this rule of restricted alteration, a key theoretical focus has been to specify which finite features of reality are perceived to be more changeable, or mutable, as opposed to the infinite background features that remain constant within one's mind. The sections below on determinants of counterfactual thought are descriptions of these patterns.

Counterfactual thinking is a rule-bound creative act, and as such has been construed as a principal ingredient of consciousness and language. Hofstadter (1985), for example, argued that a comprehensive attempt to create artificial intelligence must include some facility for production of counterfactuals that operates in a manner similar to that of human cognition. A further elaboration of this theme is that counterfactuals are constrained by reality because they are functional; that is, they often provide useful prescriptions for how a goal might have been achieved in the past, and hence how it might yet be achieved in the future (Roese, 1994).

TYPOLOGY

Counterfactuals have been classified in two main ways: direction and structure. Direction refers to whether the counterfactual specifies a state that is better than actuality (an upward counterfactual) or worse than actuality (a downward counterfactual). Counterfactuals are also described in terms of structure of their phrasing. The counterfactual antecedent may be an addition of some feature not in fact present (an additive counterfactual), or

it may remove a feature that was present (a subtractive counterfactual). These two typologies have proved effective in delineating a variety of theoretical relations, described below.

PSYCHOLOGICAL CONSEQUENCES

Causation

Counterfactuals are intimately related to causal inferences. Causation may be defined as a relation between two variables (objects, states, etc.) in which one produces or generates changes in the other. A counterfactual conditional nearly always implies causation. Counterfactual conditionals denote an antecedent-consequent pair that diverges from a related, factual antecedent-consequent pair, thereby satisfying the logic of J. S. Mill's method of difference for inferring causation. For example, the observation that a match held motionless remains bereft of flame might be followed by the counterfactual supposition that 'if the match had struck a hard surface, it would have ignited.' The mental alteration of but one feature of actuality (striking as opposed to not striking the match), when accompanied by the imagined consequential variation in ignition, provides the basis for inferring that the antecedent of match strike causally influences ignition. The logic of the method of difference is the same as the covariation criterion for causation that forms the theoretical platform for many theories of causal attribution, in that counterfactuals present one datum, albeit imagined, that may be added to a set of divergent background observations. Although absence of covariation may be used to rule out causation, presence of covariation is not in itself sufficient to infer causation. Therefore, the same problems of induction that bedevil formal analyses of causation apply similarly to counterfactual reasoning (Spellman and Mandel, 1999). Nearly all psychological consequences of counterfactual thinking appear to be rooted either in this causal inference mechanism or in a contrast effect mechanism.

Contrast Effects

In comparative judgment, the juxtaposition of one object with a second can render judgments of the features of the latter more extreme. Thus, as demonstrated in classical psychophysics experiments, an object may be judged to be heavier after holding a lighter object, a color may be deemed darker if set against a lighter background, and so on. Counterfactual comparisons may similarly influence emotional appraisals of specific outcomes by making them, in contrast, seem better or worse. Thus, upward counterfactuals make an actual event seem less favorable, whereas downward counterfactuals make an actual event seem more favorable. This contrast effect underlies a variety of effects of counterfactual thinking on social judgment.

Social Judgment

A variety of social judgmental consequences of counterfactual thinking have been mapped; five are detailed here.

First, counterfactuals influence emotion, typically making emotional reactions more extreme (by way of a contrast effect) than would otherwise have been the case. Regret is an affective state predicated on upward counterfactual thinking and is the subject of much research in its own right. Counterfactual-induced affective changes can then influence judgment further. For example, in responses to victimization, inferring that a victim's misfortune could easily have been averted might create greater sympathy for the victim, but also greater recommendations for monetary compensation to the victim (Miller and McFarland, 1986).

Second, counterfactuals influence likelihood estimates in at least two ways, both rooted in the causal inference mechanism. The mental simulation of an alternative antecedent event can make future, similar events seem more likely. This would occur to the extent that the prior action is controllable and presumed to be sufficient to have brought about a favorable outcome. That is, the individual might intend to perform the action in the future to bring about a desired goal, in part because the individual infers that performing it in the past would have brought about that desired goal in the past (Roese, 1994). Counterfactuals can also make past events seem more predictable (the hindsight bias) to the extent that they clarify causal linkages, i.e. specify how an event was brought about and thus how it might have been improved or negated (Roese and Olson, 1996). For example, a student who reacts to a poor grade with the counterfactual, 'If only I had studied harder, I would have performed better', has used the counterfactual to articulate the causal power of studying to influence performance. This causal inference may then form the basis of a behavioral intention to study more thoroughly for the next examination, which then yields beliefs in the heightened probability of future success.

Third, and drawing directly on the previous description of heightened likelihood estimates,

counterfactuals can heighten perceived control, again by way of causal inferences. To the extent that a desired event is seen to be attainable had one only acted in a certain way, it confers a belief in personal control (Nasco and Marsh, 1999). In other words, one may generalize from the specific instance of having been able to effect positive outcomes ('If I had studied harder, I would have performed better') to the beliefs regarding global personal efficacy ('I can accomplish many things with a little extra effort').

Fourth, counterfactuals can influence decision-making. If a decision is made but an alternative decision might have brought about clearly better rewards, the resulting emotion of regret may compel changes in decision-making strategy, altering the course of subsequent behavior. Research on cognitive dissonance theory specifies conditions under which individuals alter appraisals as a function of postdecisional regret, but theory linking dissonance to counterfactuals is underdeveloped.

Fifth, counterfactuals can make observers suspicious. If an event occurs but is surprising because it is easy to imagine it occurring differently, an observer might be more suspicious regarding ulterior goals of the actor than in cases in which it is easy to imagine the event occurring in many similar ways, even if the probability of event occurrence remains constant. Take the example of a child who loves chocolate-chip cookies: the child is permitted to have just one cookie before dinner, but is required to select the cookie with eyes closed from a jar containing one chocolate-chip cookie and nine oatmeal cookies. If the child happens to select the coveted chocolate-chip cookie, an observer might suspect that the child had peeked. If, however, the cookie jar contained ten chocolate-chip cookies and ninety oatmeal cookies, suspicion might be reduced as there are ten similar ways for the coveted cookie to be selected without intent. Even though the probability of selecting the chocolate chip cookie is identical in both cases, ease of generation of alternatives differs and results in variation in suspicion (Miller *et al.*, 1989).

DETERMINANTS OF COUNTERFACTUAL THINKING

Activation

When does counterfactual thinking occur? A principal trigger is negative affect resulting from an undesirable outcome (Sanna and Turley, 1996). When things go wrong, people often ruminate about how the outcome could have been avoided. Thus, thoughts about 'what might have been' are more common following defeats than victories, failures than successes, and penalties than rewards. A second activator of counterfactual thinking is surprise resulting from an unexpected event. Unexpected occurrences violate implicit predictions and thereby attract attention, which induces consideration of why the outcome occurred. A third trigger of counterfactual thinking is a near miss, or an event that almost occurred. When something nearly happens, it seizes the perceiver's imagination. An athlete who finishes second by a hair's breadth in a 100 m race is likely to experience vivid thoughts about the counterfactual outcome of winning, whereas finishing a distant second evokes fewer thoughts of hypothetical victory.

These triggers of counterfactual thinking correspond to situations where this activity is most useful. As noted earlier, counterfactual thinking provides causal information about an outcome. What kinds of outcomes are most important to understand? Negative outcomes demand comprehension for survival reasons (prevention). Unexpected outcomes, by definition, indicate failures of prediction. Outcomes that almost occurred might occur in the future. Thus, these triggers reflect adaptive coping and support a functional view of counterfactual thinking (Roese, 1994).

Content

Of the infinite number of possible alternatives to reality, which does the mind select for consideration? That is, what are the typical contents of mental reconstructions? Researchers have identified several qualities that render events or antecedents more mutable. As Hofstadter (1985: p. 239) argued, there are natural 'fault lines' of the mind along which reality is cognitively cleaved.

One variable influencing the content of counterfactual thoughts is the normality of the antecedents to an event (Kahneman and Miller, 1986). When considering alternative possibilities, perceivers often focus on unusual things preceding an outcome, rather than routine aspects of the situation, with the mental reconstruction transforming the unusual antecedent into a more normal form. For example, a student who spends less time than usual studying for an examination and performs poorly is likely to think, 'If only I had studied more, I would have done better', even though many other mutations are also theoretically possible (e.g. 'If only the test had been easier').

A second feature of antecedents that increases the probability that they will be selected for counterfactual mutation is controllability. Perceivers are more likely to mutate controllable than uncontrollable aspects of a situation. For example, following a car accident at high speed on a slippery winter road, the driver is more likely to think 'If only I had driven more slowly' than 'If only it hadn't been snowing'. Serial position also influences counterfactual content. Typically, the most recent antecedents are mutated. A missed shot at the buzzer of a one-point loss in basketball is more likely to be altered than preceding misses, even though all misses were equally responsible for the outcome. If, however, several antecedents constitute a causal chain, then early events are likely to be mutated. For example, if a truck blows a tire and hits a car, which then runs into a school bus injuring some children, perceivers will think 'If only the truck hadn't blown a tire', rather than 'If only the car hadn't hit the bus'.

CONCLUSION

Counterfactual thinking, or thoughts of alternatives to past outcomes, is a common feature of everyday mental life. It exerts a variety of effects on emotion and judgment, and is thought to do so primarily through underlying mechanisms rooted in causal inference effects or contrast effects.

CONTENTS

Creativity is the result of the convergence of basic cognitive processes, core domain knowledge, and environmental, personal, and motivational factors which allow an individual to produce an object or behavior that is considered both novel and appropriate in a particular context.

INTRODUCTION

One of the most salient features of the human mind is its capacity to generate novel ideas that are useful and appropriate for a given task or problem, that is, to exhibit creativity. Creativity is a complex phenomenon, determined by a wide range of factors, and requiring a multifaceted approach to arrive at even a partially complete understanding of the topic. This article addresses some of the issues that are important to that understanding, including a consideration of whether or not there are different types of creativity, what cognitive processes are most associated with creative outcomes, the extent to which machines can be said to be creative, the factors that limit creativity, the techniques that have been purported to enhance creativity, and the sources of individual differences in creative performance.

TYPES OF CREATIVITY

Although it is possible to describe creativity as the production of novel and useful outcomes from a convergence of skills, processes, knowledge, personal traits, environmental factors, and motivation, this general statement belies potentially important distinctions among types of creativity. These distinctions include contrasts between extraordinary and more mundane instances of creativity, and between general and specific manifestations of creativity.

Examples of the attempt to differentiate between extraordinary and commonplace forms of creativity include Boden's (1992) distinction between psychological (P) and historical (H) creativity, Gardner's (1993) contrast between 'little C' and 'big C' types of creativity, and Czikszentmihalyi's (1988) separation of personally creative and unqualifiedly creative individuals. Ideas that are P-creative are said to be novel in the mind of the individual currently having the idea, although the same ideas may have occurred to many other people before; in contrast, H-creative ideas are novel with respect to all of human history. Similarly, 'little C' creativity is manifested in everyday, small variations on themes, whereas 'big C' creativity occurs rarely and can represent a striking departure from what has come before. Personally creative people can adopt original perspectives, but unqualifiedly creative people radically alter whole domains of endeavor.

Sternberg's (1999) propulsion model introduces still more distinctions among various types of creative contributions. The model views creative work as propelling a field in different ways. These include replications that keep the field where it is, redefinitions that provide a new perspective, incrementations that move the field further in the direction it is already going, and redirections that take it in a new direction.

A question of some debate is how best to account for extraordinary versus everyday manifestations of creative behavior. One approach is to suggest that the minds of those who make notable creative contributions operate according to fundamentally different sets of rules than the minds of those whose generative accomplishments are more mundane. Alternatively, the cognitive processes may be similar, but major breakthroughs may occur only with very special convergences of personal, social, historical, and societal factors. The thought processes presumed to be involved in generating novel ideas (e.g. combining of concepts, analogical

reasoning, imagery) are ones available to most humans, albeit on perhaps a lesser scale for most, but it remains for future research to delineate the ways in which these processes are invoked in everyday and extraordinary creative accomplishments.

Another long-standing issue in the field is whether creativity can best be characterized as domain-specific or domain-general. Do creative individuals, in general, possess some common, core set of traits and abilities that would allow them to function creatively in any of a variety of domains, or do the traits and abilities needed for creative accomplishment differ considerably from one domain to the next? One approach to providing evidence on this question has been to assess the personality traits of creative artists versus those of creative scientists. Data from these types of studies support a position between the extremes of pure domain-specificity and complete domain-generality. Creative artists and creative scientists appear to share some traits and differ on others (Barron and Harrington, 1981; Feist, 1999). For example, creative artists have been reported to be more open to experience, fantasy-oriented, imaginative, driven, and ambitious, and to demonstrate higher levels of anxiety, emotional sensitivity, and independence than non-artists. Creative scientists, on the other hand, have been described as possessing traits of arrogance, drive, introversion, flexibility of thought, ambition, and independence. Thus, in either domain, a basic level of unorthodox thought and behavior is characteristic, but achieving eminence in a scientific frontier may require a greater degree of conscientiousness, responsibility, and emotional stability than that which is found in the creative artist.

Another approach to the question of how different or similar artistic and scientific creativity are is to examine the cognitive processes associated with the production of novel ideas in each of the domains. Although specialized skills would be expected to contribute differentially to success in particular domains (e.g. visuo-spatial ability for art or pitch discrimination for music), many of the most basic generative processes, such as combining previously separate concepts and using analogies, are relevant in virtually all creative domains (e.g. Finke *et al*., 1992).

INCUBATION, INSIGHT, AND OTHER CREATIVE PROCESSES

A widely noted creative phenomenon is incubation, defined as a temporary withdrawal from the problem at hand, which may culminate in an illumination or insight; that is, a sudden realization of a problem solution. Interestingly, there is much less experimental evidence regarding incubation than would be expected from the broad dissemination of the term. Historical anecdotes abound, including Archimedes' purported recognition of the principle of displacement while bathing, and Kekulé's realization regarding the circular structure of benzene while dozing by the fire. What such anecdotes have in common is a solution sequence in which the thinker devotes considerable deliberate effort towards solving a problem, reaches an impasse, withdraws temporarily, and is then struck with a sudden realization for a problem solution.

Although the phenomena of incubation and insight are broadly noted, the mechanisms by which incubation may facilitate insights are not well established. Theoretical mechanisms that have been proposed include conscious work, unconscious work, forgetting of interfering material, recovery from fatigue, and assimilation of cues encountered by chance during the incubation period.

According to the conscious work hypothesis, deliberate effort can continue on the problem while the thinker is engaged in routine tasks, such as bathing, which require only limited cognitive resources. Because the conscious thoughts that led to the solution may be quickly forgotten, the insight may appear to come 'from out of the blue'.

The unconscious work hypothesis also holds that work continues on the problem during the incubation phase, but the work occurs below the level of conscious awareness. That is, the effort is not consciously noted and then forgotten, but rather it is not available to consciousness at all.

The forgetting hypothesis states that inappropriate strategies adopted and ideas considered during initial work on a problem may be forgotten during incubation, which can facilitate the retrieval or generation of more appropriate ideas.

Recovery from fatigue holds that incubation serves as a kind of rest period during which the problem-solver can recover from the debilitating effects of an extended period of deliberate mental effort on the problem.

Finally, according to the opportunistic assimilation view, the problem-solver remains sensitive to cues in the environment that may relate to unsolved problems, even while not engaged in deliberate effort on the task.

There is little experimental research that clearly favors one view of incubation over the others, but at least some laboratory studies by S. Smith and his

collaborators (e.g. Smith, 1995) are consistent with the forgetting hypothesis.

Some models of insight attempt to specify component processes that work in concert to produce the phenomenon. For example, Sternberg and Davidson's (1995) model includes subprocesses of selective encoding of problem-relevant information, selective comparison of new and old information, and selective combination of different pieces of information.

Experimental findings do reveal some differences between insight problem-solving and analytic or logical problem-solving. For example, Metcalfe (1986) has shown that feelings of 'warmth' or progress towards a solution increase gradually as subjects near solutions to analytic problems, whereas they jump dramatically for insight problems. In addition, J. Schooler has shown that verbalization can interfere with insight problem-solving, but not analytic problem-solving (Schooler and Melcher, 1995). Such results suggest that insight may be the result of special processes unlike those involved in noncreative problem-solving. However, Weisberg (1995) has attempted to show that insights, even those described in historical anecdotes, are the result of ordinary cognitive processes applied to existing knowledge. By this view, what appears as a dramatic change in awareness of a solution may well reflect a more incremental building of solution-relevant knowledge.

Although incubation occupies a special historical role in attempts to understand creative functioning, several fundamental cognitive processes have been either theorized or demonstrated to be central to the production of novel and useful ideas (see, e.g. contributions to Ward *et al*., 1997). These include conceptual combination, analogical reasoning, and mental imagery.

In conceptual combination, the thinker merges two concepts that had previously been separate. Anecdotal accounts from creative individuals often include reference to a combining of concepts underlying some important creative advance. In addition, some theorists (e.g. Rothenberg, 1979) suggest that a simultaneous consideration of opposing concepts, termed 'Janusian' thinking, is a particularly important source of emergently creative ideas, and laboratory research on how people interpret novel combinations of concepts is beginning to provide support for this idea.

Analogical reasoning, in which a thinker uses information from a familiar domain to aid in understanding a less familiar domain, is also a central process underlying creative accomplishment. Historical cases abound in science, music, art, and literature. Recent analyses, such as Gentner's (1997) examination of Johannes Kepler's use of analogy in reasoning about the nature of the solar system, have related historical accounts directly to principles from contemporary process theories. That work has helped to establish the validity of claims that analogies between distant knowledge domains can underlie great creative advances. Studies of reasoning among contemporary scientists, such as Dunbar's (1997) look at the ongoing activities of molecular biology laboratories, also reveals that analogies to closely related domains (as opposed to distant domains) often dominate the day-to-day reasoning involved in creative breakthroughs.

MAKING MACHINES CREATIVE

A number of attempts have been made to get computers to function creatively, and Boden (1992) has provided a thorough account of these efforts. An important goal of such computational approaches is to develop a better understanding of human creativity by attempting to simulate it. In that sense, to the extent that creative outcomes spring from fundamental cognitive processes, even computational models of basic processes such as analogy (e.g. Structure Mapping Engine, or SME) are relevant to the issue of making machines creative.

In addition to computational attempts to understand broad processes such as analogy, there are also more direct attempts at simulating specific instances of creativity (e.g. scientific discovery). One of the best-known examples of such an attempt is BACON, which used heuristics to simulate the discovery of scientific laws (Bradshaw *et al*., 1983). BACON was shown to be able to rediscover Kepler's laws of planetary motion from a set of heuristics and data on observations of planetary motion, although it has come under criticism for underrepresenting the complexities involved in real-world instances of discovery. Such programs, along with others concerned with creativity in drawing, literature, and music, still leave much to be desired, but they do represent important first steps.

LIMITS TO CREATIVITY

Both individual and environmental factors can provide limits to creativity. It is clear that below some minimum level of intellectual ability (e.g. an IQ of 85), a person would have a limited capacity to generate and express creative ideas, although studies tend not to examine creative functioning in

those individuals. Studies on individuals with somewhat higher scores have shown that creative performance is linked with intellect in individuals with an IQ below 120, but this link all but disappears in individuals with IQs above 120 (Barron and Harrington, 1981).

Environmental factors also play a role in the expression of creativity. Extensive research by Amabile has found that the use of external rewards or evaluations decreases task motivation for creativity and overall creative performance in both adults and children (Hennessey and Amabile, 1988). This negative effect of reward on creative performance is so strong, in fact, that Amabile found that merely the expectation of some sort of external reward or evaluation diminished creative task motivation and performance in the same way that actually using such external constraints had.

TECHNIQUES FOR IMPROVING CREATIVITY

A wide variety of techniques have been developed with the goal of trying to improve creative performance. Some have emphasized the dynamics of group interaction, others the learning of specific idea-generation techniques, and still others the enhancement of intrinsic motivation.

One of the earliest and best-known techniques is brainstorming. Developed by Osborn (1953), this technique is designed to enhance creativity by encouraging groups (and individuals) to generate as many ideas as possible about a problem without expressing criticism towards those ideas. By eliminating criticism and allowing individuals to 'piggy-back' on ideas suggested by other group members, brainstorming is supposed to result in more ideas being generated, some of which may be extremely creative and provide excellent solutions to the problem being considered. Although there is some support for the usefulness of the procedure, a number of studies have actually shown a productivity loss in groups. That is, groups sometimes produce fewer ideas than the same number of individuals working independently. Thus, the question of where, when, and how brainstorming improves creative performance is yet to be resolved.

Another well-known attempt to enhance creativity is Edward deBono's (1970) lateral thinking approach, which encourages people to engage in thinking that moves off in different directions and to adopt many different perspectives on a problem, rather than thinking along a single narrow path. A major aspect of the approach is to teach people specific techniques designed to facilitate this type of broad attack on a problem, including the 'six hats' approach, in which people 'wear different types of hats', that correspond to different modes of thought (e.g. critical versus generative) (de Bono, 1985). An approach that makes use of idea-generation techniques and principles to facilitate group interaction is Gordon's (1961) synectics procedure, in which group members are coached to generate ideas using analogies and metaphor while also being instructed to suspend criticism of ideas generated by others.

Brainstorming, lateral thinking, synectics, and a host of other procedures have enjoyed a great deal of popular success, but do they make people more creative? To some extent the answer depends on how one defines and measures creativity. Although any given technique may be shown to facilitate performance on a particular task, the extent to which such changes in generative performance last or generalize beyond the immediate situation is less clear. Thus, it may be more appropriate to state that various training procedures can alter patterns of performance on a range of generative tasks, rather than to claim that they make people more creative.

Another avenue of training for improving creativity has been to increase creative motivation. Developed by Amabile and colleagues, this training paradigm, called inoculation training, seeks to increase creativity by training individuals to focus on the intrinsic joy that creative activities bring (Hennessey and Amabile, 1988). Developed as a way to counteract the negative effects of external reward on creative performance, inoculation training involves talking to groups about the internal or intrinsic rewards of behaving creatively. This is done in conjunction with watching videos demonstrating others behaving creatively in the face of external reward and finding pleasure in just engaging in the creative act alone. The use of this type of training has been shown to increase creative performance of both schoolchildren and adults on tasks which have an element of reward or evaluation associated with them.

MODELS OF CREATIVITY

Models of creativity differ in their scope, in the factors they emphasize, and in the tendency to view creativity as stable or malleable. Although historical models of creativity sought to explain creative behaviors as a reflection of differences in individual personalities, beginning with Guilford

(e.g. 1967, 1968) creativity began to be viewed as a set of traits which, though stable, were influenced by motivation and temperament (Brown, 1989). Creativity was seen as the result of a set of traits such as problem sensitivity, fluency, flexibility, complexity, evaluation, the use of novel ideas, the ability to break down existing symbolic structure, and the general tendency to organize ideas into larger patterns. When conceptualized this way, variations in creativity could be measured using a variety of open-ended tests.

Torrance modified Guilford's definition slightly, viewing creativity as the combination of ability, skills, and motivation (Ford and Harris, 1992). By including skills in the account of individual differences, creativity became a teachable entity to the degree that a person's creative skills could be improved.

In a further departure from the focus on creativity as a personality trait, Amabile developed a model in which creativity cannot be simply the result of a single isolated personality trait or process, but rather must be accounted for by a constellation of personal characteristics, cognitive abilities and processes, and social environment factors. By this approach, creativity emerges from the confluence of domain-relevant skills, creativity-relevant skills, and task motivation (Amabile, 1990).

Gruber (1988), in what is known as the evolving systems approach, has also regarded creativity as the merging of personal knowledge, affect, and purpose. According to this developmental approach, creativity is the result of developmental changes in knowledge systems that result from the increasingly different situations that a person encounters over time. In this theory, creativity is an extended process, with a person having more than one insight or metaphor over time, and with multiple changes in thoughts and knowledge systems along the way.

A focus on a concert of factors as the root of creativity can also be seen in the burgeoning of research attempting to explain creativity as a multifaceted concept. Called *componential theories of creativity*, such theories hold that creativity occurs when a variety of biological, cognitive, and social factors merge or interact. As an example of one of the modern componential theories, Czikszentmihalyi (1988) regards creativity as an interaction of components both within and outside the individual. According to this model, creativity results from the interaction of the individual with any given domain of knowledge and those controlling the field of that domain. An individual is creative only to the extent that he or she can use cognitive processes, personality traits, and motivation to alter a particular domain in a way that is acceptable to the field at large. More recently, Sternberg and Lubart (1999) have also pursued this idea of creativity as the convergence of multiple components. In their *investment theory of creativity*, creative people are those who can 'buy low and sell high'; that is, generate or adopt ideas before they become popular, then popularize them, thus becoming associated with novel, impact-producing ideas. Such behavior is thought to require the merging of six resources: intellectual abilities, knowledge, thinking styles, personality traits, motivation, and environment.

In contrast to componential approaches, which provide a global account of the factors that interact to determine the creative impact of novel ideas, cognitive models focus more narrowly on the way in which basic cognitive processes operate on existing knowledge structures to produce those novel ideas. The models acknowledge that social and motivational factors can influence the likelihood or intensity of engaging in particular processes. Similarly, they acknowledge that factors outside the individual's thought processes will determine the extent to which an idea is judged acceptable or has an impact. However, they view cognitive processes as the crucial source of the ideas to be judged, and to some extent of the judgments as well.

Often called *process approaches*, these cognitive models focus on the acts of problem-identification and solution-generation as the keys to creative production. An example of this type of model is the Geneplore model of Finke *et al*. (1992), which characterizes the development of novel and useful ideas as resulting from an interplay between *generative* processes, that produce candidate ideas of varying degrees of creative potential, and *exploratory* processes that expand on that potential. Generative processes such as retrieval, conceptual combination, and analogical reminding are assumed to result in candidate ideas, which vary in their apparent novelty, surprisingness, aesthetic appeal, or other factors that would influence the creative person's perception that they hold promise for solving the current problem. People can use such properties to determine which ideas to develop by way of exploratory processes that modify, elaborate, consider the implications, assess the limitations, or otherwise transform the candidate ideas. The model also assumes that real-world constraints, such as the social acceptability of particular ideas, can influence the form of initially generated ideas, the person's judgment about which ideas to

explore, or the way in which a candidate idea is modified through exploratory processes.

Other models focus on the production and retention of novel ideas, and make use of a Darwinian perspective: many variations on ideas may be developed but only the fittest will be selected and survive. Simonton (1999b) has extended the evolutionary view and claimed that the production of creative ideas should be viewed as akin to blind variation, in which the creator does not have any notion of whether a given generated idea will be successful or not. While others adopt a somewhat similar generation/selection view, they do not necessarily endorse the blind variation notion (e.g. Johnson-Laird, 1988; Perkins, 1998; Sternberg, 1998).

UNDERSTANDING INDIVIDUAL DIFFERENCES IN CREATIVITY

Traditional research concerned with individual differences in creative performance attributes those differences to one of two sources: differences in the ability or tendency to use particular creative thought processes, and differences in personality attributes thought to be related to creative behaviors. The work has made use of psychometric procedures as well as assessments of the historical record of the achievements of eminent creators.

Research concerned with thought processes has focused on individual differences in the ability to identify or recognize problems or solutions that have creative potential, to tap into broad thought networks, and to apply this expanded base of knowledge to the task at hand. Defining differences in creativity as the result of individual differences in the ability to associate or bring together different elements of thought to form new and useful creations is the hallmark of the associative approach to creativity (Brown, 1989). This associative approach is not a new one in psychology, as can be seen in the many introspective studies and historical anecdotes concerning the creative process (Barron and Harrington, 1981; Brown, 1989). Mednick (1962) extended this approach by defining creativity as the forming of associative elements into new combinations, which either meet specific requirements or are in some way useful. By this view, individual differences would be attributable to the ability to access remote associations, which in turn gives rise to the use of the Remote Associates Test as a measurement technique (Mednick and Mednick, 1967).

Individual differences in creative thought have also been explained by variations in divergent thinking ability, including fluency (the tendency to produce many ideas), flexibility (the tendency to produce differing ideas), and originality (the tendency to produce ideas that are normatively uncommon). A classic example of a divergent thinking task used to measure such differences is the Torrance Test of Creative Thinking (Torrance, 1974) in which people generate questions, unusual uses, and/or drawings in response to particular stimuli.

One question that can be raised about paper-and-pencil measures of divergent thinking ability is whether or not performance on those measures is indicative of real-world creative skill. Although various researchers have found a relationship between test performance and real-world indicators, such findings have not been consistent. Measures of divergent thinking, while related to some indices of creative achievement, are often unable to significantly predict creative achievement and behaviors in a real-world setting (Barron and Harrington, 1981; Brown, 1989). In addition, concerns have been raised about the domain-specificity of divergent thinking.

Another type of explanation for individual differences in creativity focuses on personality traits, and assumes that creativity differences are based on variations in personality attributes that are thought to contribute to creative production. The characteristics that have been identified as important to creativity are tolerance for ambiguity, openness, independence, positive sense of self, high energy, general curiosity, wide interests, as well as introversion, attraction to complexity, need for recognition, and a variety of others (Barron and Harrington, 1981). As indicated previously, however, the importance of each of the characteristics may vary according to the domain of creativity being pursued. In fact, the search for the single set of 'creative personality' traits that map onto real-world creative performance has, so far, been unsuccessful.

Variations in intrinsic motivation are another possible source of individual differences in creative performance. For instance, Amabile, in her seminal research on the relationship between intrinsic motivation and creativity, found that creative performance in such areas as writing and art can be both enhanced and hindered by changes in intrinsic interest in a task. Hennessey and Amabile (1988), in a continuation of this line of research, have proposed the intrinsic motivation principle of creativity which says that people will be the most creative when they feel motivated to perform primarily by the interest and enjoyment of the task, and not by external factors such as reward or

punishment. Thus, all individual differences in creative performance are due to those differences in motivation towards the task at hand, and hence, all creativity is, at heart, domain-specific to the interests of the individual.

Although much contemporary work on individual differences relies on tests or laboratory observations of a broad sampling of participants, another approach involves detailed, narrative case studies of a small set of highly creative individuals in history. Somewhere between these extremes is Simonton's (1999a) historiometric approach in which historical data (e.g. number of publications, citations, performances, and so on) is sampled for a large number of contributors to a field, and statistical tests are performed to relate those measures to other indices. The approach can be used to examine a broad range of factors, including intellectual precocity, family background, and propensity towards mental illness. It goes beyond paper-and-pencil measures of the attributes of the many to a detailed look at individual differences among the eminent.

Cultural Differences in Abstract Thinking

Introductory article

Fons J R van de Vijver, Tilburg University, The Netherlands

CONTENTS

Abstract thinking is a central part of reasoning and the highest cognitive attainment in Piagetian theory. Studies of cross-cultural differences and similarities in abstract thinking show its relationship with culture.

INTRODUCTION

There are two research traditions in cognitive psychology for examining the relationship between culture and abstract thinking: the formal and the informal approach (Table 1). In formal research the scientific approach is the normative model of good problem-solving; there is an emphasis on the application of inductive and deductive reasoning, the solution of formalized problems that are unlikely to be met in everyday life, and the correctness of solutions (e.g., 'continue the following series: 1, 2, 4, 8, 16, …'). In the informal tradition the 'bricoleur' (jack-of-all-trades) is the implicit model of problem-solving. There is an emphasis on problem-solving in everyday life: an example would be, 'What would you do when you are due for promotion at your work and a reliable source tells you that your direct colleague may be promoted instead of you?' These two more or less independent traditions have their own models of cross-cultural differences and similarities of abstract thinking.

FORMAL STUDIES OF ABSTRACT THINKING

Two types of study predominate in the formal tradition, differing in theoretical orientation and assessment procedures: psychometric research (based on Western models of intelligence and using psychological 'paper and pencil' tests) and the Piagetian approach (applying Piagetian theory and tasks).

Psychometric studies of abstract thinking have used a variety of tests (such as Raven's Progressive Matrices, Wechsler's Intelligence Scales and Cattell's Culture Fair Intelligence Test) and investigated a number of cultures. Many cultural comparisons involved participants from different countries; especially in the USA, research often compared the performance of different ethnic groups, mainly African Americans and Anglo-Americans. These studies have shown a remarkable consistency in results. Using advanced statistical techniques (mainly exploratory and confirmatory factor analysis), it has been shown that the structure of intelligence is identical across cultural groups; tests of abstract thinking tend to be related to reasoning and general intelligence. Broad cognitive abilities, such as reasoning, memory and visualization, are universal. Moreover, analyses of test performances have consistently shown that the difficulty order of items tends to be invariant across cultures; within the homogeneous domains used in the tests items that are easy in one culture are likely to be easy in another culture (though not necessarily solved by the same proportion of the population). The psychometric tradition does not support the alleged qualitative difference in abstract thinking between Western and non-Western individuals, historically often associated with Lévy-Bruhl. To the best of our knowledge abstract thinking is a universal attainment that can be found in all cultural groups.

Nevertheless, studies have reported consistent differences in scores on tests of abstract thinking between Western and non-Western groups, with the former groups usually obtaining higher scores. Similarly, comparisons of scores obtained by different ethnic groups in the USA have shown consistent differences in scores, ranking as follows (from high to low): East Asians (e.g. Chinese and Japanese), European Americans, Hispanics and African Americans. Interpretation of these differences has been controversial. Some researchers, such as Jensen and Eysenck, argue that the differences in performance are to be interpreted as cultural

Table 1. Differences between formal and informal research traditions

Formal tradition	*Informal tradition*
Closed problem spaces	Open problem spaces
Deterministic problems with one correct answer	Probabilistic problems with several correct answers
Contrived problems	Problems derived from everyday life
Academic intelligence	Practical intelligence
Focus on correctness of solution (is the solution correct?)	Focus on practical value of the solution (does the solution solve the problem?)
Problems and solutions are context-independent	Problems and solutions are context-dependent
Scientist as normative model of good problem-solver	Bricoleur as normative model of problem-solver
Algorithmic solutions	Heuristic solutions
Product-oriented (psychological tests, Piagetian tasks)	Process-oriented
Solution requires conceptual, theoretical knowledge	Solution requires practical intelligence
Cross-cultural comparison of test performance	Studies within a single culture

differences in cognitive ability. These authors attributed these performance differences to genetic differences between cultures. The current immature status of knowledge in behavior and molecular genetics does not yet allow for precise estimates of the role of genetics in cross-cultural differences in abstract thinking. Critics of Jensen and Eysenck often point to the influence of schooling and potential problems in the tests used to assess abstract thinking as a source of cross-cultural performance differences. Many psychological tests in the formal tradition have a format and test contents that are school-related. Schooling has been found to enhance the performance on tests of abstract thinking but has no formative influence on abstract thinking; however, the occurrence of abstract thinking among illiterate individuals and groups demonstrates that schooling is not a precondition for developing abstract thinking.

In Piagetian theory abstract thinking is part of formal-operational reasoning, which, according to Piaget, is acquired by Western subjects at age 12–15 years. Various measures of formal-operational reasoning are available; these are often based on elementary laws from physics. The person tested has to evaluate the impact of presumably relevant variables by experimental manipulation. One such task deals with the oscillation time of a pendulum. The variables that are presumably relevant are the length of the pendulum string, the weight of the object fastened to the string, the angle of the swing of the weight, and the momentum given to the weight at the start of the swing. The participant is asked to determine experimentally which of the four variables determines the oscillation time.

Many cross-cultural studies have addressed earlier Piagetian stages (e.g. the transition from preoperational to concrete-operational thinking), but formal-operational thinking has not been extensively studied. Studies among unschooled non-Western individuals invariably showed a poor performance, which was sometimes interpreted as evidence that non-Western individuals did not show abstract thinking. Some theoreticians even conjectured that abstract thinking was an achievement of Western, industrialized nation states. Later research redressed the picture. First, cognitive anthropological evidence argues strongly against the cultural specificity of abstract thinking; for example, Kalahari Bushmen show on average low scores on intelligence tests, yet their tracking and navigation skills in the desert far exceed those of Westerners and show great cognitive complexity. Moreover, even in Western societies many participants gave a poor performance on Piagetian tests. It was increasingly appreciated that the method of assessment may affect the test outcome; that individuals are unable to solve physics problems which are remote from their daily reality does not imply that their abstract thinking is undeveloped. A distinction was introduced between competence and performance: whereas the latter refers to actual test performance, the former refers to the performance in optimal conditions dealing with common tasks. The distinction implicitly points to the potential problems of Piagetian tasks in cross-cultural research, but subsequent research has not identified new procedures to assess the competence. It is widely believed now that although the performance on Piagetian tests of formal-operational thinking often points to the absence of abstract thinking, the competence is universal. Abstract thinking is a universal attainment, but the domains of application may vary across individuals and cultures. A car mechanic may be able to use abstract thinking in dealing with cars, but

perform badly when applying laws of logic to other domains. It is paradoxical that abstract thinking, theoretically based on context-independent rules such as the laws of logic, turned out to be domain-specific.

INFORMAL STUDIES OF ABSTRACT THINKING

The label 'informal' is used here as a summary label for various traditions in the psychological literature, such as 'everyday cognition', 'indigenous cognition' and 'practical intelligence'. Common to these studies is their emphasis on the observation of cognitive processes in everyday problem-solving.

Mathematical thinking has been often studied. For example, shoppers were interviewed while they bought groceries in order to determine how they determined 'best buys'. It was consistently found that they seldom relied on the arithmetic competence they acquired in school. Rather, arithmetic in school and in everyday life seem to constitute different competencies. In one experiment a group of women were asked which of two cans of peanuts they would buy on the basis of a comparison of prices: can A weighing 10 oz for 90 cents, or can B weighing 4 oz for 45 cents. In another test the same women were asked to compare the ratios 90/45 and 10/4. From a mathematical perspective the two problems are identical, but from a psychological perspective they are very different. The former problem was correctly solved more often.

Some studies have examined the relationship between skills applied in everyday life and skills to solve tests in the formal tradition. It has been consistently found that, possibly contrary to expectation, there is no relationship between the scores on 'school' tests and 'everyday' tests in the same domain. Individuals who are capable of displaying highly skilled behavior in the context of their professional specialization are not necessarily the individuals with the highest scores on intelligence tests.

Another line of research has examined to what extent complex cognitive skills acquired in the course of learning a profession generalize beyond this professional context. For example, Zinancanteco women in Mexico can weave highly complex patterns. These women showed superior planning skills in a weaving task when they had to reproduce known patterns, but did not outperform nonweavers when the planning involved an unfamiliar task. Planning skills acquired in the context of professional training did not generalize broadly across the cognitive spectrum. This result exemplifies the findings in studies of specialized cognitive skills: the cognitive effects of mastery of a craft often do not go beyond the specific domain in which the craft is applied.

CONCLUSION

Abstract thinking has been studied from two different perspectives in cross-cultural psychology. The first, the formal tradition, focuses on the application of general principles such as the laws of logic and inductive schemes. Studies in this tradition have shown that abstract thinking is a universal attainment, but cultures may well differ in their areas of specialization. Cross-cultural differences in scores on tests of abstract thinking are typically open to multiple interpretations (e.g. valid cultural differences in abstract thinking, familiarity with testing procedures, differential cultural appropriateness of tests, confounding of cross-cultural differences in schooling). The second, the informal tradition, studies abstract thinking in action. This tradition has shed further light on the domain specificity as studied in the formal tradition. Within an area of expertise such as a profession, individuals can display remarkably high levels of performance. From a cognitive perspective these areas are often sharply delineated. The training of professional expertise often does not have a broad impact on cognitive functioning. Virtuoso performance is often restricted to one domain.

Abstract thinking shows both important similarities and differences across cultures. There is ample evidence for the universality of the basic structures of abstract thinking (general reasoning, Piagetian formal-operational thinking). There is no evidence for the existence of qualitatively different types of abstract thinking across cultures. On the other hand, there are massive cross-cultural differences on tests of abstract thinking. Moreover, domains in which individuals are able to use abstract thinking show some variation across cultures.

Cultural Differences in Causal Attribution

Intermediate article

Douglas S Krull, Northern Kentucky University, Highland Heights, Kentucky, USA
Michael W Morris, Stanford University, Stanford, California, USA

CONTENTS

An attribution is a judgment about why an event (typically another person's behavior) occurred. Research suggests that cultures differ in the types of attributions that their members prefer.

ATTRIBUTION THEORY

An attribution is an explanation, a judgment about the cause of an event. Psychological research on attribution has primarily studied judgments about the cause of another person's behavior. Attributions for behavior are ubiquitous in everyday life (e.g. 'I think Luis achieved the highest score on the calculus exam because he has a talent for mathematics', 'Mariko is sad because her best friend moved away'). Moreover, attributions have important implications for social interaction in that they shape perceivers' expectations about others' future behavior (e.g. 'I helped Robert because I thought he was trying his best to succeed', 'I'm angry at Torsten because he took my car keys on purpose'). The ubiquity and importance of attributions has made them a central topic of social psychological research. (*See* **Judgment**)

A foundational premise of attribution theory is Heider's (1958) contention that perceivers seek to attribute fleeting behavior to stable dispositions in order to learn about the social environment. He wrote: 'It is an important principle of commonsense psychology … that man grasps reality, and can predict and control it, by referring transient and variable behavior and events to relatively unchanging underlying conditions, the so-called dispositional properties of his world' (1958, p. 79). For example, upon noticing the anxious behavior of her new co-worker, Susan would make a judgment about something stable in the environment, either that the co-worker has an anxious personality or that the co-worker's job is stressful. Although most behaviors can reflect either situational or personal influences, Heider suggested that perceivers tend to trace action to dispositions of the actor. The existence and consequences of this tendency were documented by social psychology experiments (see Ross and Nisbett, 1991 for a review). Because of its apparent ubiquity and potentially important consequences, this tendency was designated the *fundamental attribution error* (Ross, 1977).

INDIVIDUALIST AND COLLECTIVIST CULTURES

Until recently, psychologists paid little attention to the possibility that attributions might differ across cultures, but lately the study of cultural differences has captured the attention of attribution researchers. Although the study of culture in causal attribution is in its infancy, research suggests that there are substantial and potentially important differences in how people from different cultures think about behavior, as well as potentially important similarities across cultures. (*See* **Cultural Psychology**; **Cultural Differences in Abstract Thinking**)

However, the attribution researcher who desires to learn something about culture is faced with a dilemma. Given that there are many cultures, how can one hope to reach general conclusions about the role that culture plays in attribution? Without denying the fact that there may be important differences between many different cultures, psychologists have found it useful to divide cultures into those that tend towards individualism and those that tend towards collectivism. In individualist cultures (e.g. Australia, Britain, the United States), personal autonomy is emphasized, and so, for the most part, people are seen as free agents who behave as they choose. In contrast, collectivist cultures (e.g. China, Guatemala, India) tend to emphasize supporting the goals of groups and behaving in a collectively appropriate manner, and so people

are seen as constrained by social forces. As described in the sections that follow, these differences between individualist cultures and collectivist cultures have important implications for explanations of behavior.

CULTURAL DIFFERENCES IN ATTRIBUTION TENDENCIES

Judging Causes of Actions by Persons

Although the tendency to favor dispositional attributions for others' actions may well be fundamental in the sense of having many consequences, it does not seem to be fundamental in the sense of being universal. Ethnographers have long reported that lay people in some collectivist cultures refer to personality dispositions rarely and instead attribute behavior frequently to social roles (for a review, see Shore, 1996). More controlled, quantitative evidence for this claim first came in a study by Miller (1984) which asked participants of various ages from the USA and India to explain everyday actions that they had observed. Young children in both cultures were alike in the proportional frequency of their references to personality traits and to situational factors. However, as age increased, Americans showed an increasing reliance on attributions to personality, and Indians an increasing reliance on situational attributions. Thus, it seems that North Americans learn that behavior is primarily caused by personality, whereas Indians learn that behavior is primarily caused by the circumstances.

Although this initial evidence for cultural differences from everyday explanations of behavior had compelling external validity, it is open to multiple interpretations. It might reflect cultural differences in attributions, but it might reflect merely that everyday behaviors, and the actual causes thereof, differ across cultures. Indeed, there is evidence that personality traits do account for more variance in behavior in individualist cultures, whereas social roles and situations account for more variance in collectivist cultures (e.g. Argyle *et al*., 1978; Triandis, 1995). To clarify the role of culture, Morris and Peng (1994) conducted several studies that examined attributions for the same event, such as a prominent crime covered by American and Chinese newspapers. Results showed that attributions for these events differed across cultures, suggesting that cultural differences indicate a difference in the interpretive tendencies of perceivers, not just in the events they typically explain. Insight about how perceivers differ is accumulating from studies of different kinds of attributions. (*See* **Causal Reasoning, Psychology of**; **Causal Perception, Development of**)

Judging Personal Traits from Behaviors

One of the most important research paradigms within attribution theory focuses on how perceivers judge traits from situationally constrained behavior. Strictly speaking, the task in these studies is not to explain the cause of the actor's behavior but to judge the degree to which an actor's personality corresponds to his or her behavior. A wealth of research with individualist participants suggests that people often infer that personality matches behavior, even when situational forces that are sufficient to explain the behavior are present. For example, although we know that television actors are only playing roles, we may assume that their personalities correspond to the characters that they play. This tendency has been called the *correspondence bias* (see e.g. Gilbert and Malone, 1995 for a review).

The correspondence bias seems to be a multiply determined phenomenon. Gilbert and Malone (1995) have suggested that the bias can arise through at least four distinct mechanisms. People may display correspondence bias because the situation is not immediately apparent (e.g. Bernard infers that Tia's anxiety reflects an anxious personality, because Bernard does not know that Tia is about to give an important speech). People may display correspondence bias because they fail to appreciate the power of the situation (e.g. Anne may infer that Tia has an anxious personality because Anne does not realize that making a speech can be anxiety-provoking). People may display correspondence bias because they are too busy to consider the influence of the situation (e.g. Dolf infers that Tia is an anxious sort of person because he is distracted and so does not fully consider the anxiety-provoking situation). Finally, people may display correspondence bias because their knowledge of the situation inflates their perceptions of the behavior (e.g. Roland knows how anxiety-provoking giving a speech can be, so he perceives greater anxiety in Tia's behavior, and infers that only a dispositionally anxious person would be so anxious).

Given these different mechanisms, one might expect that whether or not the correspondence bias is found across cultures depends on a variety of factors. Research indeed bears out that sometimes the correspondence bias is found across cultures (e.g. Choi and Nisbett, 1998, experiment 1;

Krull *et al*., 1999). However, cultural differences arise under some conditions as a function of these mechanisms. First, although perceivers across cultures are capable of ignoring situational forces, when such forces are made salient, collectivists become less likely than individualists to show the bias (Choi and Nisbett, 1998, experiment 2). Second, collectivists recognize the strength of some situational forces, such as authority pressure, that individualists underestimate, and this is another source of cultural differences (Morris *et al*., 2000). Third, collectivists, perhaps because they are more practiced in thinking about situational constraint, are not hindered by cognitive busyness as much as are individualists (Knowles *et al*., 2001).

Judging Causes of Actions by Groups

The findings described heretofore might lead one to conclude that collectivists generally attribute to the context rather than to dispositions of actors. However, such a conclusion would be incomplete. Recent research suggests that collectivists readily attribute actions by groups to dispositions of the group, and make more reference to group dispositions when attributing events involving a combination of actions by individuals and groups (Menon *et al*., 1999, Studies 1 and 2). In another study, perceivers in separate conditions read about an act of wrongdoing by an individual or a group (Study 3); results showed that Americans showed a stronger tendency towards dispositions in response to the individual actor, and Chinese, in response to the group actor.

Additional research by Chiu and colleagues (Chiu *et al*., 2000) investigated how the need for cognitive closure affects perceivers. Results showed that time pressure increased Chinese perceivers' attributions to dispositions of groups, and increased American perceivers' attributions to dispositions of individuals. Another study that examined individuals who were chronically high or low on the need for cognitive closure found the same pattern. Thus, the desire to identify stable, dispositional properties of the social environment is by no means limited to perceivers in individualist cultures. However, perceivers in collectivist cultures are more likely to look for such properties in groups than in individuals.

TOWARDS A MODEL OF HOW CULTURE INFLUENCES ATTRIBUTION

Because research on culture and attribution is relatively new, there is no consensus on an explanatory model of how culture affects the attribution process. Broadly speaking, one model of cultural differences suggests that culture shapes general thinking principles or cognitive styles (Witkin and Berry, 1975). According to this view, collectivists are more holistic in their thinking and individualists are more analytical. In support of this view, research indicates that collectivists often seem to be more sensitive to context in a variety of perceptual and cognitive tasks (see, e.g. Nisbett *et al*., 2001, for a review). Thus, collectivists may be more aware of the situational forces that influence behavior as part of a general contextual focus of attention.

A second model suggests that differences between individualists and collectivists stem from differences in implicit causal theories. Recent research on individual differences in attribution biases (Dweck *et al*., 1995) has revealed that implicit theories can be proximal determinants of attributional biases. Accordingly, differences between cultures may or may not emerge, depending upon whether the cultures possess similar or dissimilar theories with regard to the specific domain and whether the circumstances foster theory-based processing. In support of this view, some clear boundary conditions on cultural differences have been identified, corresponding to the applicability of implicit theories. For example, Morris and Peng (1994) found that although Chinese individuals were more situational than North Americans in their judgments of behavior induced by social causality (e.g. an individual moving away from the pressure of a group), cultural differences were not obtained in judgments of behavior induced by mechanical causality (e.g. an object moving after being struck by another object). Further evidence that implicit theories are a mechanism through which cultural differences or similarities are produced comes from studies that demonstrate that cultural differences in attribution can be evoked by priming cultural knowledge (Hong *et al*., 2000). (*See* **Implicit Learning**; **Memory: Implicit versus Explicit**)

In sum, attributions may only differ across cultures when different implicit theories are activated, and activation depends on the applicability of theories to the domain and the cognitive dynamics of the perceiver (Morris *et al*., 2001). However, the two models – cognitive style and implicit theories – need not be considered as rivals, in that the former serves as a heuristic framework whereas the latter serves as a middle-range hypothesis-testing model. As described here, holism can be manifested in an implicit theory about the causal role of context in the behavior of individuals, or in an implicit theory

of groups as actors. In sum, cultural differences depend on a variety of factors, but this complexity seems amenable to social cognition models.

CONTENTS

Cultural psychology is an interdisciplinary program of research that explores the relationship between individual minds and the complex environments in which they are deployed. The approach focuses on the contribution that content-rich, complex environments – ranging from workplaces to cultural traditions to nation states – make in shaping basic cognitive processes.

INTRODUCTION

Do cognitive theories predict the mental and behavioral processes of humans in all societies and communities? Is a scientific study of cultural variations in meaning, perceiving, thinking, and feeling across groups of people part of cognitive science? If the answer to the first question is 'no', and the second 'yes', how should cognitive science approach cultural differences? Cultural psychology is a loose amalgam of scholarship in psychology, anthropology, and linguistics that explores these questions. In broad terms, cultural psychology makes the empirical claims that (1) there exist substantial group differences in cognition, emotion, and motivation that cannot be understood without the study of cultural life; (2) aspects of cognition are extra-individual and need to be studied at the population level; and (3) differences in the content of thought result in differences in psychological processes in some, but not all, areas of cognition.

Cognitive scientists typically approach cognition by examining the processes that take place in individual minds or brains. Research in this vein has ordinarily assumed that the processes observed are primary. Higher-level phenomena such as categorization, perception, language use, and the capacity for culture are all supposed to be built upon universal, individual, cognitive processes. For these reasons, the content chosen to test cognitive processes is frequently assumed to be transparent. Stated differently, content is not considered to affect the process under examination.

In contrast, a central argument of much cultural psychological research is that content and process mutually constrain cognition. Myriad scholars from Darwin onwards have proposed that the human mind evolved to solve social problems. Therefore, it is not only plausible but probable that the brain is extremely sensitive to social context. Stated in these terms, much of cultural psychological research can be viewed as an attempt to isolate the effects of social context on cognition. Nevertheless, exactly what constitutes 'social context' is still debatable and evident in the three main methods used in cultural psychology: the comparative, situated/distributed, and epidemiological approaches.

The *comparative approach*, or cross-cultural approach, uses experimental methods to compare and contrast groups in their performance on a range of psychological tasks with the objective of demonstrating cultural difference and commonality on some psychological aspect in the lab and field. For example, Richard Nisbett and colleagues have shown differences among North Americans and members of various East Asian societies in their performance on tasks ranging from perception to categorization. Americans tend to perceive and recognize an object in isolation from its surrounding field and to categorize an object using its traits. In contrast, subjects from several East Asian societies tend to perceive and recognize an object in relation to its surrounding field and to categorize it according to its relationship with other objects. Nisbett and colleagues argue that these differences arise out of socialization in the home, school, and community that emphasize individuality and

agency on the one hand, or harmony and compromise on the other.

The *situated/distributed approach* focuses primarily on cognition in specific, typically coordinated, contexts characterized by common sets of artifacts and habitual activities. This approach uses the distribution and locations of activities and their relation to the material environment as the units of analysis and has the advantage of examining how thought emerges as part of a system of local social practices in a continually evolving process of socialization. For example, Jean Lave studied arithmetic activity in grocery shopping using the supermarket as the arena for cognitive activity. She demonstrated that shoppers who made frequent arithmetic errors in formal testing situations did not make similar errors in best-buy problems in the supermarket. In a situated method, context is conceived as a relation between actors and the setting in which they act, as opposed to a singular 'cultural' unit determining behavior. The situated/distributed approach therefore de-emphasizes the independent study of the innate characteristics of individuals and the particular properties of the context in which action occurs. Instead, it focuses on everyday practices, the locus of interaction between a person and the environment as paramount to understanding cognition.

The *epidemiological approach* explores the processes that underlie the distribution of both mental and public representations, especially those representations that are widespread and enduring. A central question in the epidemiological approach is why some representations, such as myths and folk tales, are stable in a population, while others, such as gossip and rumors, are not. Dan Sperber, who developed the approach, argues that cultural beliefs, including apparently irrational ones, that resonate with common sense are more easily learned and remembered and hence are more likely to become widespread and enduring. In an empirical application of this proposal, Lawrence Hirschfeld has shown that underlying, and substantially constraining, historically recent and socially constructed concepts like 'race' and 'ethnicity' is a special-purpose knowledge structure treating input relevant to collectivities in the socio-political environment.

While the comparative, situated/distributed, and epidemiological approaches make transparent how group life and cultural content (i.e., beliefs, attitudes, domains of knowledge) shape psychological process (i.e., thinking, feeling, perceiving), they differ in how they highlight context. For example, the situated/distributed approach demonstrates not only context-specificity in thinking across everyday events, such as problem solving in the classroom versus the supermarket, but flexibility across everyday actions. The locus of motivating cognitive performance is in the dynamic rituals of daily habits. On the other hand, a comparative or cross-cultural approach centers the discussion of cognition-in-context on cognition in groups that have a set of shared, identifiable, and fairly stable practices. Comparative psychologists complain that the situated/distributed approach has lost sight of psychology and individual minds. Situated/distributed cognitive psychologists argue that comparative approaches mistake groups for daily contexts and fail to account for dynamics in cultural systems. Advocates of the epidemiological approach, in turn, caution that psychologists working in the comparative tradition often overestimate the coherence, stability, and boundedness of culture, hence misattributing causal properties to a fairly fluid environment. They similarly observe that the situated/distributed approach, while intriguing, has no principled way to delimit the context in which a task is situated or distributed.

COMPARATIVE STUDIES OF COGNITION

Language

Cultural psychologists are not the first to suggest that language, culture, and cognition are inextricably linked. Benjamin Lee Whorf and Edward Sapir each proposed, in what became known as the Whorf–Sapir hypothesis, that the cognition of a member of a particular culture is constrained by what can be said in the language the person speaks. For example, Whorf famously proposed that the Hopi have 'no general notion or intuition of TIME as a smooth flowing continuum … [because the Hopi language contains] no words, grammatical forms, constructions or expressions that refer directly to what we call "time," or to past, present, or future'. While this strong version of linguistic relativity is no longer seriously entertained, a number of scholars have explored more modest versions.

Counting

J. A. Lucy, in studies involving English and Yucatec Mayan speakers, has demonstrated that variations in grammatical form governing counting can influence categorization. Yucatec requires the speaker to use both numeric modifiers and classifiers when counting: whereas an English speaker counts, 'one

candle, two candles', a Yucatec speaker counts, 'one, long-thin wax, two, long-thin wax'. Lucy contends that this grammatical difference accounts for differences in English and Yucatec Mayan-speaking participants' similarity judgments when asked to put together objects which could be sorted either by shape or substance. Yucatec speakers grouped substances together based on their construction from like substances, while English speakers grouped objects together based on shape.

Noun extension

Linguistic influences on the nature of categories were similarly demonstrated among English and Japanese speakers: children aged two, two-and-a-half, and four, and adults. As in Yucatec, nouns are not pluralized in Japanese. In an experimental procedure similar to the one described above, American children as early as two years of age extended a noun label to other objects based on shape, whereas Japanese children extended the label based on substance.

Early differences in language socialization and pragmatics may underlie linguistic variation in categorization. For example, Fernald and Morikawa compared Japanese and American mother–infant interactions at home in a study of lexical development. Infants were preverbal: aged six, 12, and 19 months. They found that American mothers labeled objects more often than Japanese mothers. While American mothers reported trying to direct their children's attention to objects and teaching them the proper noun labels, Japanese mothers reported emphasizing polite exchanges of the objects with the infant in fostering social exchange. Comparisons of American mothers with Korean and Chinese provide further evidence of socialization practices that differentially emphasize target objects and noun labels on the one hand, and social interactions and substance on the other.

Categorization

There has been a long tradition in both psychology and anthropology of trying to understand the origins of the categories humans use. Anthropologists long assumed that the systematic variation in lexicalized and covert categories reflected systematic variations in cognition. Cognitive psychologists long assumed that the representations of and computations over contrived unfamiliar categories reflected universal cognitive processes. Pioneering studies by Brent Berlin and Paul Kay, in anthropology, and Elinor Rosch, in psychology, refuted both assumptions.

Previous to Berlin and Kay's research, anthropologists assumed that each culture arbitrarily divided and named different colors on the color spectrum. After surveying color terms from over 80 different languages, both universal and culture-specific patterns were observed. Not all languages identified the same number of basic color terms. The number of color terms in any given language, however, was found to be a function of a closely organized system (in a comprehensive survey of languages Berlin and Kay found that only 11 of over 2000 combinations of basic color terms are actually used). Importantly, although Berlin and Kay found that there was great variation in the boundaries of color terms across (and within) languages, speakers of all languages converged on the same focal colors which best represented the color category.

Eleanor Rosch demonstrated that natural language categories are organized differently from contrived categories. As Berlin and Kay revealed for color terms, natural language categories are internally structured such that (a) some category members are better examples of the category than others, and (b) these prototypical members are linked to other category memberships by a relation of family resemblance, not common necessary and sufficient features.

Recently, it has been demonstrated that exemplar use can also vary across cultures, as can the principles around which objects are organized. For example, in one study, Chinese and American college students were asked to judge similarity among objects in which grouping by category (e.g., notebook and magazine) or relationship (e.g., pencil and notebook) was possible. Chinese were more likely to group objects by relationship and to justify their decision by invoking relationships, whereas Americans were more likely to group objects by shared categories and to refer to category membership as the explanation.

Reasoning

Cultural psychologists have demonstrated group differences in inductive and deductive reasoning. These differences have been explained as differences in expertise, as well as differences in intellectual traditions and resulting styles of reasoning.

Inductive reasoning

Scott Atran and Douglas Medin have carried out experiments comparing conceptualization of and reasoning about living beings across different cultures to demonstrate both universals and cultural

specificity in inductive reasoning. In support of universal principles of folk biological categorization, Atran and Medin found that undergraduates from two Midwestern American universities and Itzaj Maya of Guatemala grouped different animals in ways that reliably correlated with scientific taxonomies. These groupings, organized around taxonomic rank, strongly influenced reasoning: across both groups, one taxonomic level (the folk-generic) was found to be the most inferentially rich despite differences in which level is most 'psychologically' basic in the sense identified by Rosch and her colleagues.

Having shown commonalties in the conceptual domain between the undergraduates and Itzaj Maya, Atran and Medin also examined specificity in category-based induction about living beings. For example, Atran and Medin asked American students and Itzaj Maya to judge which of two arguments is stronger: (1) all mammals will share a trait if it is known that two diverse mammals (e.g., a mouse and a jaguar) share the trait, or (2) all mammals will share a trait is if is known that two similar mammals (e.g., a jaguar and a leopard) share the trait. American students reasoned that (1) is the stronger argument, whereas Itzaj Maya reasoned that (2) is the stronger argument. Atran and Medin speculated that the Itzaj based their judgments on what they knew about the behavior and ecology of the species in the argument rather than reasoning from taxonomic positions. Choi, Nisbett, and Smith also found a cultural effect in inductions based on diversity. Koreans are less likely than their American counterparts to feel that increasing diversity of two given examples strengthens inductions about the higher category of which both examples are members. Nevertheless, when the higher category is made more salient to the Korean subjects through a manipulation, they perform the same as their American counterparts.

Deductive reasoning

Research also demonstrates cultural differences in how people use formal logic versus experiential knowledge in reasoning based on typicality. Sloman demonstrated that the typicality of an exemplar (e.g., eagles versus penguins as birds) influences the persuasiveness of deductive arguments for all subjects (a claim about all birds). Norenzaya found that the effect is stronger among Koreans than European Americans, with Asian American scores falling between the two populations. Further, Koreans, unlike their American counterparts, were less likely to dismiss conclusions as implausible based solely on logic. Rather, they more frequently used empirically derived beliefs about the world than logic to judge the plausibility of the conclusions.

Kaiping Peng and Richard Nisbett suggest that unlike Americans, subjects from several East Asian societies tolerate contradiction and are not as concerned with demands of consistency. Chinese and American students were compared in their preference for argument form and judgments about contradictory propositions. Whereas the Americans preferred logical arguments (i.e., God exists because there had to be a first cause), the Chinese preferred 'dialectical' arguments (i.e., God exists because there must be a truth that rises above all individual perspectives). Likewise, whereas the Americans rejected one proposition in face of a contradicting proposition, the Chinese embraced both propositions, finding merit in the middle ground.

Rather than concluding that individuals from these East Asian societies apply faulty logic, this work suggests that distinct, fully integrated systems of reasoning may exist among different groups. Nisbett and colleagues argue that American participants tend to prefer abstract logic over complex experience in highlighting how the world works. They stress the parts of a system that are coherent and noncontradictory, marginalizing and trying to resolve inconsistencies. It is argued that East Asian participants, on the other hand, tend to rely on empirical experience over logical models to understand their environment, which they view as constantly changing and inextricably interconnected. Within this framework, contradictions and inconsistencies are prevalent, natural, and even necessary.

Moral reasoning

Although a topic that has not traditionally attracted great attention in the cognitive sciences, the interest in evolutionary psychology has brought issues of morality to the forefront. This interest flows from morality's role in explanations of adaptations to social life – including the necessity to attend to and conceptually represent increasingly larger, more disperse, and more internally complex social groupings and the need to track exchange and acts of altruism. Morality is particularly salient in setting out, stabilizing, and justifying sanctions that underlie systems of complex social control.

Developmental psychologists have identified correlates of this salience in children's early reasoning, specifically about the differences between transgressions of social conventions and

moral transgressions. Turiel and his colleagues have proposed that children spontaneously employ a universal moral appraisal involving expectations about harm and welfare. They provide experimental evidence that children everywhere discriminate among social conventions – which they believe vary readily from culture to culture and situation to situation, from moral transgressions – which they identify as harming others and believe to be wrong under any system of thought or in any situation.

For example, Smetana *et al*. presented American preschool children with accounts of both hypothetical and real transgressions. The children were asked to rate how 'bad' each was, whether it would be as equally bad if it occurred elsewhere, and whether it deserved punishment. Some were transgressions of social convention ('this child is not saying "please" when asking for something'); others were moral transgressions ('this child is hitting this child'). Even three-year-olds judged moral transgressions as more serious, more generalizable, and more deserving of punishment than social conventional transgressions. This pattern of reasoning appears to be robust across cultures and across individuals who personally suffered harm and violations of welfare (e.g., among abused, neglected, and maltreated children).

Other cognitive scientists have challenged this view, arguing that moral appraisals are culturally specific. Against Turiel's universalist position, Shweder and his colleagues contend that the distinction between morality and social convention is not universal and that moral appraisal is contingent on a particularly socio-historical context. For instance, when they asked Brahman and American children to rate how harmful various acts were, they found significant disagreement across the two populations. American children, but not Brahman children, accepted that it is wrong to cane a naughty child or eat with one's hands; whereas Brahman children, but not American children, deemed that eating beef or chicken or cutting hair after one's father's death is wrong. In short, in this view content is a function of context. Unlike other areas of reasoning, whether or not content affects the cognitive process is not addressed.

Spatial Cognition

Beginning with the last two decades of the twentieth century, a body of literature exploring the effects of language and culture on spatial reasoning has emerged. Several ways of identifying an object's relation in space to other objects have been identified: reference can be made with respect to the cardinal directions (the bus is to the south of the car), with respect to the position of the speaker (the bus is to the right of the car), and with respect to fixed geographical features (the bus is uphill from the car). Not all languages provide speakers with as ready means to express these relationships; nor do speakers of different languages employ all strategies with the same frequency. For example Steven Levinson and his colleagues found that Guugu Yimmithirr aboriginals are more likely to anchor an array of objects by reference to cardinality than speakers of Dutch, who are more likely to describe spatial arrangement with reference to their own body.

Attention and Visual Perception

All humans appear to be susceptible to most visual illusions. A well-studied exception is the Müller–Lyer illusion, which Herkovits *et al*. found did not affect the perception of members of some African societies. The researchers explained this by citing the absence of a susceptibility to the 'carpentered-world hypothesis'. On this hypothesis, susceptibility to the illusion is a function of experiencing a material world in which 90-degree angles are common (i.e., 'the carpentered world'), but in the African societies studied round shape architecture prevails.

In a study of change blindness, Masuda and Nisbett showed animations of scenes, which included stationary and moving objects, to Japanese and Americans; some animations were altered in later displays. The Japanese were more aware of changes in the background of a picture and in the changing location of objects in it, whereas the Americans were more aware of changes in the characteristics of objects.

Developmental evidence of group differences in attention suggests that differences can be learned. Chavajay and Rogoff demonstrated differences between Guatemalan Mayan and American 14–20 month-olds and their caregivers in attention management. Mayan caregivers and toddlers were more likely to attend simultaneously to competing events, unlike American caregivers and toddlers who were more likely to alternate their attention between competing events.

SITUATED/DISTRIBUTED STUDIES OF COGNITION

Cognitive scientists have typically examined how individual humans or their machine counterparts

process information, traditionally through controlled investigations and laboratory studies. A number of cultural psychologists caution, however, that cognition cannot be fully understood as (1) taking place in individual minds, or (2) apparent place under controlled conditions. On the contrary, researchers who use the situated/distributed approach propose that the interactions between individual minds in their natural environments are mediated by extra-individual cognitive phenomena. Reflecting the influence of Lev Vygotsky's notion of 'the zone of proximal development' (and its variant, scaffolding), considerable work in this approach is developmental. According to Vygotsky, novices gain expertise by participating in contexts that extend their own skills sufficiently to boost performance and to stabilize enhanced competencies rather than acquiring skills through formal teaching.

Edwin Hutchins and others have proposed that cognition may be distributed among individuals in ways that argue for the existence of extra-individual cognitive systems. These systems are comprised of the habitual interactions between individuals and artifacts and, because of their emergent quality, cannot be understood from the perspective of the cognitions of the individuals participating. For example, Hutchins proposes that the speed of an airplane is remembered by the cockpit, arguing that the task is distributed over each of the crew and each of the instruments and manuals that they use, so that the cockpit itself is the level at which the cognitive task is being accomplished.

In a study of situated cognition, Geoffrey Saxe compared the mathematical competencies of three different groups of Brazilian children: urban street vendors, urban nonvendors, and rural nonvendors. None had received any formal schooling, and all three groups did poorly on abstract, orthographic tasks involving large number representation. When essentially the same tasks were repeated using large bills of money, the performance of urban children, who regularly deal with currency exchange, significantly improved, but the performances of both the rural children or nonvender urban children did not.

THE EPIDEMIOLOGICAL APPROACH

Both the comparative and situated/distributed approaches seek to demonstrate that culturally varying content affects underlying cognitive processes. The epidemiological approach, pioneered by Dan Sperber, in contrast understands cultural variation as a function of underlying and invariant cognitive processes. In particular, the approach focuses on the conditions by which beliefs and practices become distributed in populations, much as medical epidemiology focuses on how disease and pathogens are distributed.

Richard Dawkins proposed a similar notion, which he calls the 'meme', the cultural evolutionary analogue to a gene. Dawkins proposes that memes, like genes, replicate. He further suggests that the psychological processes underlying the reproduction of memes, specifically imitation, is fairly low level. In contrast, Sperber argues that cultural reproduction involves both ecological and higher-order psychological processes that in interaction determine the distribution of cultural phenomena in a given population. For Sperber to account for culture 'is to explain why some representations become widely distributed … to explain why some representations are more successful – more contagious – than others'.

The epidemiological approach, accordingly, is closely linked with specific claims about cognitive architecture. The predominant view holds that humans are endowed with a general set of reasoning abilities that are brought to bear on a myriad of cognitive tasks. In the latter decades of the twentieth century researchers in psychology, linguistics, anthropology, and philosophy concluded that many cognitive abilities are specialized to handle specific types of information: the mind is composed of domain-specific or modular devices that, among other things, underlie much of common sense. For example, all normally endowed humans have a folk or naive theory of mind that interprets human behavior to be the result of mental states like belief and desire. Similarly, all humans have a naive physics that interprets the movement of inanimate objects. Those representations whose processing are subsumed by these various modularized dimensions of common sense are, according to Sperber, more likely to become widespread and relatively stable. Culture, then, is the totality of representations with these particular properties of distribution.

Building on the model of symbolism developed by Sperber, Pascal Boyer argues that supernatural entities are easily accepted and remembered not because they can be subsumed under common sense, but because they achieve a balance between commonsense expectations and violations of commonsense expectations. For example, Barrett and Keil have shown that folk notions of the Judeo-Christian concept of God tend to make God more humanlike (more consistent with commonsense expectations about humans), de-emphasizing aspects

of formal theological beliefs that attribute omnipotence *and* omnipresence to God.

CONCLUDING REMARKS

Cultural psychologists and their counterparts in anthropology, cognitive anthropologists, are committed to developing an interdisciplinary program of research that explores the relationship between individuals' minds and the complex environments in which they exist. Much cultural psychological research is now focusing on topics that have tended to receive less attention in the cognitive sciences (e.g., the self and emotions). Cultural psychology is contributing significant insights into higher-order cognitive processes of central concern to cognitive science. Cultural psychology challenges the widely accepted assumption in cognitive science that the relationship between content and process is transparent, that the environment 'merely' provides content for cognitive processes. Instead, cultural psychology proposes that cognition must be understood in relation to population-level phenomena, ranging from local task-specific environments such as work groups to global, comprehensive domains such as cultures.

Culture and Cognitive Development

Intermediate article

Michael Cole, University of California at San Diego, La Jolla, California, USA

CONTENTS

Although it is widely believed that culture is fundamental to cognitive development, theoretical and empirical advances are impeded by severe methodological problems which render firm conclusions elusive.

INTRODUCTION

Controversies over the relationship between culture and cognition began well before the formation of contemporary behavioral sciences, and continue to this day (Cole, 1996). Discussion of the topic was, and remains, complicated by confusion over each of the basic terms under discussion as well as by the severe limitations placed on the experimental method when it is used to deal with naturally occurring differences among human beings involving unknown mixtures of phylogenetic, cultural-historical and ontogenetic variations – all of which are involved in seeking to understand the relation of culture to cognitive development.

It is useful to begin by tracing the concept of culture as it has evolved since the term entered the English language from Latin many centuries ago. Modern conceptions of culture originate in terms that refer to the process of helping things to grow. From earliest times, this notion of culture included a general theory of how to promote growth: the creation of an artificial environment in which young organisms would have optimal conditions to develop. Such tending requires tools: both material (e.g. hoes) and mental (e.g. the knowledge of how and when to use a hoe). These tools were perfected over generations and designed for the special tasks to which they were put, and constitute culture in the present.

In contemporary social science writing, the term 'culture' is generally used to refer to the entire body of socially inherited past human accomplishments that serves as the resource for the current life of a social group ordinarily thought of as the inhabitants of a country or region. Although there is evidence of the rudiments of culture in nonhuman species, human beings are unique in their dependence upon the medium of culture and the forms of organism–environment interactions that culture supports to sustain and reproduce themselves.

Combining the historical notion of culture as a process of growing things with the modern conception of culture as social inheritance of prior generations' accomplishments, the study of culture in development can be seen to focus on the way in which biologically immature human beings incorporate and are incorporated into the cultural 'designs for living' that are their social heritage.

The interpenetration of cultural and phylogenetic contributions to human development was driven home several decades ago by Clifford Geertz, who noted the mounting evidence that the human body, and most especially the human brain, underwent a long (perhaps 3 million year) coevolution with the basic ability to create and use culture, and was led to conclude that

> man's nervous system does not merely enable him to acquire culture, it positively demands that he do so if it is going to function at all. Rather than culture acting only to supplement, develop, and extend organically based capacities logically and genetically prior to it, it would seem to be ingredient to those capacities themselves. A cultureless human being would probably turn out to be not an intrinsically talented, though unfulfilled ape, but a wholly mindless and consequently unworkable monstrosity (Geertz, 1973: p. 68).

As a consequence, those who wish to understand the role of culture in cognitive development are faced with the difficult interdisciplinary task of studying development in terms of antecedents that are tightly interwoven.

METHODOLOGICAL PROBLEMS

Culture-free versus Culture-based Measures of Cognitive Development

For most of the history of scholarly interest in the role of culture in development, research been based upon 'cross-cultural' comparisons. This phrase is placed in quotation marks because often the comparisons are cross-national in nature, involving social groups thought to differ in some theoretically interesting way (for example, with respect to language, natural ecology, or social institutions) such that cultural, biological, social and ecological factors all differ simultaneously.

The hazards of restricting such comparisons to only two naturally occurring groups has long been recognized. As a consequence, leading researchers into culture and cognitive development have routinely included a range of societies in their studies to reduce the risk that some factor other than the one under investigation is covertly influencing the results. However, such multisociety research is expensive, and also carries with it the difficulty that although it might reduce the probability of undetected covarying factors it does not eliminate it completely, often leading to such an apparently endless set of possibilities that definitive conclusions elude further research.

The problem of culturally valid cognitive assessment has been most extensively discussed with respect to the possibility of creating culture-free measures of cognition, seemingly a prerequisite for valid cross-cultural comparisons (the same issue applies, but is rarely addressed, when age comparisons within a single homogeneous group are of interest). A variety of cognitive measures used in cross-cultural comparisons have been the object of such analyses. Research using intelligence quotient (IQ) tests and Piagetian tests of conservation can serve as accessible examples.

Long ago, Florence Goodenough identified the crucial shortcoming of the cross-cultural use of IQ tests in a way that has broad – if rarely recognized – implications for all cross-cultural cognitive research, when she wrote that 'the fact can hardly be too strongly emphasized that neither intelligence tests nor the so-called tests of personality and character are measuring devices. They are sampling devices'.

Goodenough argued that when applied in American society, IQ tests may represent a reasonable sampling device because they are 'representative samples of the kind of intellectual tasks that American city dwellers are likely to be called upon to perform'. However, such tests are not representative of life in other cultural circumstances and hence their use as measuring devices for purposes of comparison is inappropriate. This injunction applies as much to variations among subgroups living in the USA as it does to people living in a wide variety of other societies.

It might be thought, on the basis of Goodenough's critique, that attempts to discover the influence of culture on the development of intelligence using IQ tests would have been abandoned long ago. However, the usefulness and theoretical implications of cross-cultural IQ testing continue to be heatedly debated. Logically, the only way to obtain a culture-free test is to construct items and procedures that are equally a part of the experience of all cultures. Following Goodenough's approach, this would require us to sample the valued adult activities in all cultures (or at least two!) and identify activities equivalent in their structure, their valuation and their frequency of occurrence. No one has carried out such a research program.

The same problem can be seen in the widespread use of Piagetian conservation tasks as measures of cognitive development during the late decades of the twentieth century. It was Piaget's initial hypothesis that the development of conservation would be a universal achievement, occurring in an invariant sequence at roughly equal ages across cultures because it represents a universally applicable logical principle (Piaget, 1974). However, application of standardized Piagetian procedures in different societies produced widely varying results, leading some to speculate not only that some cultures promote more cognitive development than others, but that without particular kinds of cultural experience, such as formal schooling, development might cease at the level of concrete operations.

However, this same literature contained within it anomalies that implicated cultural differences in interpretation of the task – not differences in logical development – as the source of cultural differences. The standard procedure, following methods developed in Geneva, was to present the participant with two beakers of equal circumference and height, filled with equal amounts of water. The water from one beaker was then poured into another, taller beaker with a smaller circumference, and the person was asked which of the two beakers containing water had the most water in it. Children and young adults from nonliterate societies of a given age were significantly more likely to assert that the taller, thinner beaker, contained more water; see Cole (1996) for a summary. However, an experiment on the effects of modifying testing

procedures to match local cultural knowledge revealed a different pattern of results. Early research had shown that conservation was much more likely to be achieved if children were allowed to pour the liquid themselves instead of observing the experimenter. It was speculated that this change in procedure reduced the children's tendency to interpret the experiment as something of a magic show, allowing their real competence concerning the conservation of volume to be revealed.

In the revised procedure, participants were asked to solve the conservation task and then to act as informants whose job it was to clarify, for the experimenter, the local terms for resemblance and equivalence with respect to the task. When confronted with the critical test in which one beaker of water was poured into a narrower, taller beaker, the participants asked to play the role of informant gave the wrong response – they said that the beaker with water higher up its sides contained more liquid. However, in the role of linguistic informants these same people went on to explain that while the level of water was 'more', the quantity was the same. Such results provide nice examples of the kinds of performance factors that can block the actualization of competence and mislead researchers about the nature of cultural differences.

THEORIES OF CULTURAL CONTRIBUTIONS TO COGNITIVE DEVELOPMENT

Two major lines of theory have dominated discussions of culture and cognitive development, those of Jean Piaget and Lev Vygotsky. (*See* **Piaget, Jean**; **Vygotsky, Lev**)

Jean Piaget

According to Piaget, cognitive development occurs through a process of equilibration where accommodation to existing environmental circumstances constantly vies with assimilation of environmental structures to existing mental structures. In a widely cited article, Piaget (1974) divided potential influences on cognitive development into four main factors, each of which could be expected to influence the timing of developmental milestones resulting from the interplay of assimilation and accommodation.

- Biological factors: here Piaget mentions nutrition and general health, factors that influence what might be called the rate of physical maturation.
- Coordination of individual actions: this factor refers to equilibration, the active process of self-regulation resulting from the back-and-forth tug and pull of accommodation and assimilation. Equilibration is the proximal mechanism of development. All other factors operate through their influence on equilibration.
- The social factor of interpersonal coordination: the process by which children 'ask questions, share information, work together, argue, object, etc.' (Piaget, 1974: p. 302).
- Educational and cultural transmission. Piaget reasoned that children acquire specific skills and knowledge through interaction in culturally specific social institutions. In so far as some societies provide more overall experience relevant to discovering the nature of the world, true developmental differences would be created in either the rate or the final level of development.

Piaget recognized that the four contributing factors he identified are all tightly interconnected with each other in any given society. However, barring conditions of extreme malnutrition, he assumed that rates and levels of cognitive development would be universal across societies with respect to the first three factors, and would differ only with respect to the fourth. In early writings, he assumed that modern industrial societies would provide the requisite additional experiences to speed cognitive development, but it is interesting that Piaget was skeptical of schooling's development-enhancing properties, since this social institution varies greatly across cultures and in popular thinking ought to have a major influence on cognitive development. He argued that the asymmetrical power relations of teacher and student created an imbalance of equilibration, because the pressure to accommodate to teachers' views far outweighed the pressure for assimilation of instruction to the child's already existing schemas. The result was learning of a superficial kind that was unlikely to create fundamental cognitive change. He believed that fundamental change was more likely to occur in informal actions where the asymmetry of power relations was reduced, allowing for a more equal balance between assimilation and accommodation. Evidence on this matter was too inconclusive in the 1960s to support more than speculation.

Confronted by subsequent research with evidence of cultural variations in performance on his tasks, and particularly evidence that schooling enhanced performance within cultures, Piaget (1972) concluded that all individuals reach a universal stage of formal operational thinking, but that formal operations are attained first (and perhaps only) in fields of adult specialization or as a consequence of school-based training. This view offers an obvious line of reconciliation of Piagetian theory with the facts about cultural variability. The overall

conclusion, however, accords a restricted role to culture in cognitive development, which is more a matter of individual invention through action on the environment than of environmental, and particularly cultural, influences, on the child.

Lev Vygotsky

The Russian psychologist Lev Vygotsky, unlike Piaget, accorded culture and the influence of children's social environments a central role in cognitive development (Vygotsky, 1978). The central thesis upon which his 'cultural-historical' school of psychology was founded is that the structure and development of human psychological processes emerge in the process of humanity's culturally mediated, historically developing, practical activity. Each term in this formulation is tightly interconnected with and in some sense implies the others, making it difficult at times to discern how each contributes to description and analysis of the dynamics of psychological experience.

1. Mediation through artifacts. The initial premise of the cultural-historical school is that the psychological processes of humans emerged simultaneously with a new form of behavior in which material objects were modified by human beings as a means of regulating their interactions with the world and each other.
2. Historical development. In addition to using and making cultural artifacts, human beings arrange for the rediscovery of the already created artifacts in each succeeding generation, which in turn adds its modifications to the culture pool of artifacts. The accumulated artifacts of a group – culture – is then seen as the species-specific medium of human development. Cognitive development, as a consequence, represents the capacity to develop within that medium and to arrange for its reproduction in succeeding generations.
3. Practical activity. The third premise of the cultural-historical approach, adopted from Hegel by way of Marx, is that the analysis of human psychological functions must be grounded in their everyday activities. It was only through such an approach, Marx claimed, that the duality of materialism versus idealism could be superseded, because it is in activity that people experience the ideal/material residue of the activity of prior generations.

Vygotsky's emphasis on the historical accumulation of artifacts and their infusion in activity led him to emphasize the social origins of human thought processes. Vygotsky argued it is only through the mediation of socialized others that the child can come to experience, and hence acquire, the cultural heritage which is the foundation of cognitive development. This view of social origins requires that special attention be paid to the power of adults to arrange the environments of children in a way that optimizes their development according to existing norms. It generates the idea of a 'zone of proximal development' which affords the proximal, relevant environment of experience for development.

CONTEMPORARY RESEARCH ON CULTURE AND COGNITIVE DEVELOPMENT

Because of the methodological problems inherent in cross-cultural approaches to the study of development, the pace of such work has now slackened. At the same time, there has been an increase in research within cultures that take advantage of naturally occurring contrasts associated with differential participation in particular cultural practices in order to show how culture enters into the process of development. This does not mean that cross-cultural research has come to a standstill. For example, faced with the ambiguities inherent in research carried out in different cultures, where differences in language, nutrition and social relations can so easily enter unbidden into comparisons that seek to highlight specific cultural factors, some researchers interested in studying the relation of culture to development have turned to studies within societies that greatly reduce the chances of undetected contamination by uncontrolled factors. One such method is referred to as the 'school cut-off strategy' (Christian *et al*., 2001).

In many countries school boards require that in order to begin attending school, a child be a certain age by a particular date. For example, to enter grade 1 in September of a given year, children in Edmonton in Canada must have passed their sixth birthday by March 1 of that year. Six-year-olds born after that date must attend kindergarten instead, so their formal education is delayed for a year. Such policies allow researchers to assess the impact of early schooling on different domains of cognitive development while holding age virtually constant: they simply compare the intellectual performances of children who turn six in January or February with those who turn six in March or April, testing both groups at the beginning and at the end of the school year.

Researchers who have used this strategy find that the first year of schooling brings about a marked increase in the sophistication of some cognitive processes but not others. Frederick Morrison and his colleagues, for example, compared the ability of children to perform on tasks

ranging from picture recall to word and number manipulation, and Piagetian number conservation tasks (Christian *et al*., 2001). The first-grade children were, on average, only a month older than those in kindergarten, and at the start of the school year the performances of the two groups were virtually identical. At the end of the school year, however, the first-graders could remember twice as many pictures as they did at the beginning, whereas the kindergarten group showed no improvement at all. Significantly, the first-grade children engaged in active rehearsal during the testing, but the kindergarten children did not. Clearly, a year of schooling had brought about marked changes in memory strategies and performance. The same pattern of results was obtained for standardized reading and mathematics tests. However, similar differences were not obtained for a standard Piagetian test of number conservation. This evidence shows clear influences of a cultural factor, schooling, on cognitive development, while supporting Piaget's skepticism about the cognitive benefits of schooling.

Meanwhile, cross-cultural research with respect to a variety of cognitive functions including categorization, logical reasoning and memory continues to show significant effects. In some cases schooling appears to be critical to the results; in others it does not. For example, Alexander Luria (described in Cole, 1996) compared the performance of Central Asian peasants who had been organized into collective farms and exposed to a modicum of Western-style schooling with those who had not. He reported that categorization processes grounded in 'graphic, object-oriented experience' gave way to 'more complex processes which combine what is perceived into a system of abstract, linguistic, categories.' Thought processes grounded in 'practical, situational' thinking gave way to more abstract theory-driven modes of thinking, which Luria referred to as the 'the transition from the sensory to the rational'. While Luria attributed such findings to involvement in modern industrialized practices including schooling, more recent research into cultural influence on the development of categorization has shown that even among people without schooling, both density of experience and cultural variations in world views substantially influence the development of biological thinking in addition to physical similarity (Medin and Atran, 1999). This latter work fits well the idea that cultural variations build upon panhuman, phylogenetically derived perceptual processes to construct local theories appropriate to local circumstances.

A considerable body of work has been devoted to the study of cultural variations in syllogistic reasoning, one of the hallmarks of Piaget's stage of formal operations. According to Luria's data, as well as research conducted in other nonliterate societies in different parts of the world, syllogistic reasoning appears to be closely linked to the sociocultural institutions of Western-style schooling. However, cases where nonliterate peasant workers succeed in responding to formal syllogisms, as well as cases where college-educated adults do not, have been reported.

The tradition of studying the role of participation in culturally organized activities within a single culture has emphasized the many ways in which cultural practices beyond schooling enter into the process of cognitive development. Here we can mention research on the development of mathematical thinking among street-vendor children in Brazil as well as work among Nepalese youth who become engaged in new forms of economic activity (Saxe, 1994; Beach, 1995; Ueno, 1995).

CONCLUSION

Taken as a whole, research on culture and cognitive development persuasively demonstrates the centrality of culture and cultural variation to cognitive development. The current challenge facing researchers is to solve the methodological difficulties (which themselves involve cultural factors) in order to identify more clearly the necessary and sufficient conditions involved.

Decision-making

Introductory article

Barbara A Mellers, University of California, Berkeley, California, USA

CONTENTS

The field of decision-making focuses on normative questions – how should we make decisions if we want to do it right? – and description questions – how do we actually make decisions when dealing with uncertainties? Numerous demonstrations of how people violate the axioms of normative theory have given rise to a deeper understanding of the processes underlying actual decision-making.

INTRODUCTION

Expected utility theory is widely accepted as the standard for normative decision-making. It tells us how we 'should' make decisions if we want our choices to be internally consistent and coherent. However, we do not always follow those principles. Researchers in decision-making have constructed puzzles and paradoxes that show how people violate the axioms of expected utility theory. People focus on many other factors, including personal, social and cultural rules, justifiability, and emotional rewards. Despite these numerous other factors, actual choice behavior is often systematic and orderly.

EXPECTED UTILITY THEORY AND ITS VIOLATIONS

Expected utility theory has been, and continues to be, the dominant theoretical framework in the social sciences. The classical theory dates back to 1738 when Daniel Bernoulli suggested that people should make decisions that maximize their expected utilities (subjective values). Utilities reflect the psychological satisfaction of wealth, rather than wealth *per se*. Bernoulli suggested that the utility of wealth increased rapidly at first, then gradually slowed, consistent with a logarithmic function. A function of this shape describes the fact that people are often risk-averse in their preferences, although less risk-averse as wealth increases.

Modern utility theory began in 1947 with a book called *Theory of Games and Economic Behavior*. In this book, von Neumann and Morgenstern provided a mathematical foundation for expected utility theory. Suppose decisions can be represented as choices between gambles. If people can rank order their preferences for gambles, and their preferences are consistent with a small set of axioms, choices can be represented 'as if' they were based on the maximization of expected utilities.

Allais' Paradox

Soon after von Neumann and Morgenstern completed their work, researchers started to devise examples showing how people violate the axioms of expected utility theory. One famous example is Allais' paradox. Consider a choice between options A and B. Option A is \$1 million for sure. Option B is a 10% chance of winning \$2 million, an 89% chance of winning \$1 million, and a 1% chance of winning nothing. When presented with this hypothetical choice, most people prefer A to B. If the utility of nothing is zero, this preference can be expressed in the expected utility framework as:

$$1.0u(\$1\text{m}) > [0.10u(\$2\text{m}) + 0.89u(\$1\text{m})] \qquad (1)$$

where $u(\$1\text{m})$ and $u(\$2\text{m})$ are the utilities of \$1 million and \$2 million respectively. The expression can also be written:

$$0.11u(\$1\text{m}) > 0.10u(\$2\text{m}) \qquad (2)$$

Now consider a choice between options C and D: option C is an 11% chance of \$1 million, and option D is a 10% chance of \$2 million. Most people prefer to D to C, which implies:

$$0.10u(\$2m) > 0.11u(\$1m)$$

which directly contradicts the previous expression. A preference for A implies a preference for C, or a preference for B implies a preference for D; but one

cannot prefer both A and D (or B and C). Examples such as this led researchers to question whether expected utility theory was both a normative and a descriptive theory of choice.

PROSPECT THEORY

In 1979 Kahneman and Tversky proposed a descriptive theory of risk choice called prospect theory. Prospect theory differs from expected utility theory in several respects. In expected utility theory, decision-makers evaluate the utility of total wealth. In prospect theory, utilities (which are referred to as values) are associated with changes in wealth relative to the status quo. Furthermore, losses have greater impact than gains of equal magnitude, an assumption known as loss aversion.

Endowment Effects

Loss aversion provides an explanation for a well-known finding called endowment effects. Consider an experiment that takes place in a college classroom. Half of the students are randomly assigned a gift, such as a university coffee mug. These students are sellers. Those without mugs are buyers. Sellers are asked to report the minimum amount of money they would accept to sell their mug. Buyers report the maximum amount of money they would be willing pay to buy a mug. An experimental market is conducted; if there are transactions, mugs and money are exchanged.

According to expected utility theory, the experimental market will ensure that mug owners are those who value mugs the most. Since mugs were randomly assigned to students, there is no reason to think that students designated as sellers would value the mugs more than those assigned the role of buyers. In order for those students who value mugs most to become mug owners, approximately half of the mugs would, on average, be exchanged. However, that is not what happens. Few mugs are ever traded. Selling prices are typically larger than buying prices by a factor of two or more. The explanation for the effect is loss aversion; the pain of losing the mug is greater in magnitude than the pleasure of gaining the mug.

The way in which an object is endowed also influences its value. People who are rewarded with an object for an exemplary performance tend to value that object more highly than people who obtain the same object through chance or poor performance. Furthermore, windfall gains, such as lottery winnings or inheritances, are spent more readily than other assets, presumably because they are valued less.

Framing Effects

Endowment effects demonstrate how shifts in the status quo can influence the value of objects. Framing effects demonstrate how shifts in the perception of the status quo can lead to preference reversals. Framing effects were initially demonstrated by Tversky and Kahneman in a story called the Asian disease problem. Participants were told, 'Imagine that the USA is preparing for the outbreak of an unusual Asian disease which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows: with program A, 200 people will be saved; with program B, there is a 1/3 chance that 600 people will be saved, otherwise no one will be saved.' Participants were asked to select a program, and the majority chose program A. Another group of participants were told the same story, except descriptions of the programs were presented in terms of lives lost. They were told, 'With program A, 400 people will die. With program B, there is a 1/3 chance that no one will die, otherwise 600 people will die.' The majority selected program B.

Although programs A and B are identical, preferences reverse with framing. The majority of participants preferred the safer option when alternatives were described as gains (lives saved), and the majority preferred the riskier option when alternatives were described as losses (lives lost). Prospect theory predicts these reversals. Both gains and losses have diminishing sensitivity. Saving 200 lives with certainty has greater value that a 1 in 3 chance of saving 600 lives. Furthermore, the certain death of 400 people is more painful than a 2 in 3 chance that 600 will die.

Framing effects go far beyond laboratory demonstrations. Researchers in the USA examined preferences for automobile insurance among drivers in New Jersey and Pennsylvania. Both states offered insurance at similar costs, and both states allowed drivers to cut costs by giving up their right to sue if an accident occurred. In New Jersey, the default coverage offered by insurance companies contained no right to sue, although a driver could buy that right at additional cost. In Pennsylvania, the default coverage contained the right to sue, although drivers could decline the right and reduce costs. The different reference points led to big differences in coverage. Only 20% of New Jersey

drivers purchased the right to sue at additional cost, but as many as 75% of the Pennsylvania drivers purchased the right as part of the package. Drivers tended to accept the default coverage. If the default coverage in Pennsylvania had resembled the default coverage in New Jersey, Pennsylvania drivers would have saved approximately $200 million in annual insurance costs.

Contextual Effects

Expected utility theory implies that the relative preference for one option over another should not change when additional options are added in the choice set. This principle is called 'regularity'. Researchers have shown that relative preferences vary systematically with the context. In one study, decision-makers are asked to choose between two options, A and B, each described in terms of two attributes. At a later point, the same decision-makers choose among A and B, and a new option, C. Option C is worse than A on one attribute, and worse than B on both attributes. Suddenly in the context of C, option B starts to look better, and the relative preference for B over A increases.

Decisions can also be influenced by the global context or the implicit comparisons people make across many choices. A given change in an attribute has a greater effect on choice when the attribute range is narrow than when the attribute range is wide. In one experiment, students made choices between apartments that varied in monthly rent and distance to campus. When monthly rents ranged from $200 to $400, a $50 increase in monthly rent was much more aversive than when monthly rents ranged from $100 to $1000. Such contextual effects are also inconsistent with expected utility theory.

ALTERNATIVE FRAMEWORKS FOR CHOICE

It is clear that the decision strategies people use vary with the individual, the task, the context and the frame. Prospect theory describes some of these phenomena, such as endowment effects and framing effects, but not all of them. Contextual effects, for example, require other explanations. What other psychological processes describe choice processes? A number of researchers have explored alternative frameworks.

Rule Following

Researchers point out that some choices are based on the application of rules or norms to situations. People ask themselves, 'What kind of situation is this?', 'What kind of person am I?', and 'What does a person like me do in a situation like this?'. Rules do not involve the calculus of cost–benefit analysis. They are adopted simply because they seem right and reflect our social or professional identities. Generally, doctors make decisions that coincide with medical guidelines, teachers make decisions that follow academic codes, and lawyers make decisions that build on legal precedents.

Rules may also reflect our personal identities. Prudential rules of thumb are often used to cope with issues of self-control. Some courses of action have minimal effects when done once, but large effects when done repeatedly. Smoking a cigarette or eating a slice of chocolate cake has a small effect in the short run, but done habitually has large effects in the long run. In these cases, the short-term benefits loom large, and the long-term costs are remote. Following a rule minimizes effort and guards the decision-maker against both temptation and potentially painful trade-offs.

Some have argued that interactions among people can be categorized in terms of four fundamental social rules. These rules are communal sharing, authority ranking, equality matching, and market pricing. Communal sharing rules stress the common bonds among members of a group, such as families, lovers or nations. Rules based on authority ranking highlight asymmetries in rank, privilege or prestige, as found in the military or the workplace. Equality matching stresses reciprocity. Decisions to join babysitting cooperatives or car pools imply that one agrees to give back whatever one takes. Finally, market pricing rules are governed by supply and demand, expected utilities, or trade-offs between costs and benefits. People often find these rules intrinsically satisfying for their own sake. They also insist that others adhere to the rules and punish those who do not conform.

When decision-makers apply the wrong rule to a social situation, they may make 'taboo' trade-offs. To attach a monetary value to one's friendship, one's children or one's academic integrity is to demonstrate that one is not really a friend, a parent or a scholar. In fact, the mere mention of selling priceless things can degrade the reputation of the person suggesting it.

Reason-based Choice

When rules conflict or seem irrelevant, people look for reasons to justify their decisions to themselves or others. This approach to decision-making

involves a balance of arguments for and against a course of action. Reasons might be lists of the pros and cons, or they might be stories. Jurors often construct stories to explain the facts. Courtroom evidence presented in the form of stories often leads to stronger decisions and more confident jurors than evidence presented in the form of issues.

Reason-based choices can be peculiar. In one study, the researchers asked students to imagine they were serving on a jury deciding the award of sole custody of an only child following a messy divorce. Parent A was described as having an average income, average health, average working hours, reasonable rapport with the child, and a relatively stable social life. Parent B was described as having an above-average income, a very close relationship with the child, an extremely active social life, lots of work-related travel, and minor health problems.

One group of students decided which parent would be awarded sole custody of the child. The majority selected parent B because of the positive features, such as the close relationship with the child and the good income. Another group decided which parent would be denied custody of the child. These students also selected parent B because of the negative features, such as the extensive travel schedule and health problems. Positive reasons can be more compelling when we select, and negative reasons can be more compelling when we reject. In these cases, we might accept and reject the same option.

Pattern Matching

Although many researchers have adopted the gamble as a template for a decision, other researchers reject this metaphor. They argue that decisions made by experienced people under time pressure in real-world settings are better represented by recognizing patterns. In these cases, decision-makers do not necessarily compare two or more options. Their experiences allow them to see situations as examples of prototypes, and they often know a course of action that is likely to succeed without making comparisons. This form of decision-making involves pattern matching.

Emotion-based Choice

Sometimes we make choices to feel good. Which film to watch, which book to read or which perfume to buy might depend on our view of what seems pleasurable. 'Feeling good' might mean avoiding regret. Researchers have shown that women who anticipated regret about their child dying as the result of a vaccination were less likely to have the child vaccinated, even when the mortality risks of the disease were greater than those of the vaccination. Consumers who imagined purchasing an unfamiliar product that later malfunctioned were more likely to buy a familiar product. Finally, students who were given a lottery ticket and asked if they would trade their ticket for a new one with objectively better odds tended not to trade because of the regret they anticipated if their original ticket were to win.

In other cases, 'feeling good' might mean anticipating the pleasure of positive outcomes and the pain of negative outcomes, and selecting the option that feels better on average. This rule is similar, though not identical, to expected utility theory. Expected utility theory predicts that people will choose the option with greater average utility, not greater average pleasure. Differences between the theories arise when anticipated pleasure deviates from utilities. This is often the case. Unlike utility, anticipated pleasure varies with multiple reference points. Comparisons with one's past performance, with other peoples' performance, with outcomes under different states of the world, and with outcomes under different choices might influence the anticipated pleasure of consequences, but they are typically not included in utilities.

Such comparisons have systematic effects on anticipated pleasure. Exceeding one's expectations adds to the pleasure of an outcome, and falling short of one's expectations detracts from the outcome. Furthermore, the impact of these comparisons is asymmetric. The incremental pain of doing worse than expected is greater in magnitude than incremental pleasure of doing better. In a gambling context, a small win can become more pleasurable if one avoids a big loss; but the same small win can be extremely disappointing if one fails to win an even larger amount. Another way in which anticipated pleasure and utilities differ involves our beliefs about outcomes. Pleasure depends on beliefs, while utilities are independent of beliefs. Unexpected outcomes are associated with more intense pleasure and pain. Utilities should be independent of likelihoods. Surprise effects are strong enough to make a smaller but surprising win more pleasurable than a larger win that was almost certain. In contrast, the utility of the smaller win could never exceed that of the larger win.

If decision-makers base their choices on the anticipated pleasure of future outcomes, the accuracy

of their forecasts is essential. Inaccurate predictions can surely lead to suboptimal choice. Researchers have identified some systematic errors in forecasting. One source of error is our immediate emotions: feelings of joy, anger, and sadness influence our attention, perception, memory and information processing strategies. When happy, we are better at retrieving happy memories, and when sad, we are better at recalling sad events. When happy, we use more flexible and creative problem-solving strategies. Sadness can lead to greater analytical thinking and longer response times, while anger has been linked to faster and less discriminate use of information.

Another source of error is the tendency to focus on whatever is salient at the moment, even when it has little effect later. In one study, students in the American Midwest and in California were asked to assess how happy they were, and how happy students like them in the other region of the country would be. The comparison highlighted the cultural opportunities, better climate and greater natural beauty of California. Both groups thought that students in California were happier; but in fact, the students were equally happy.

Researchers also asked college professors who were coming up for tenure how they expected to feel if they did or did not receive tenure. The professors expected to be happy if given tenure and extremely unhappy otherwise. Later the researchers contacted the professors to ask them what had happened and how they felt about it. Those denied tenure were actually much happier than they expected to be.

People also overestimate the pleasure of future experiences. In a classic study, researchers examined the happiness of lottery winners, matched control subjects, and people who were paraplegic. Although the lottery winners might have been thrilled about their wins in the days or weeks immediately after the event, they were no happier than the control subjects approximately a year later. Furthermore, the control subjects were only mildly happier than the paraplegic subjects. The tendency to focus on a single event can lead to overestimates of both pain and pleasure.

Deciding How to Decide

What determines the strategy for making decisions? Researchers argue that people are limited information processors who have access to many possible choice rules. Holding all else constant, they want to minimize the effort involved in a decision, and make accurate decisions. The strategies they use depend on trade-offs between effort and accuracy. More recently, this framework has been extended to include trade-offs between accuracy and negative emotions. People want to make accurate choices, and simultaneously avoid painful trade-offs. These goals can also determine choice strategies.

THE PSYCHOLOGY OF BELIEFS

Most decisions are associated with uncertainty, and beliefs play an important role. Researchers investigated the extent to which people update their beliefs according to normative principles, such as Bayes' theorem. Some argued that people shift their beliefs in the appropriate direction, but not to the right extent. Others argued that people are not Bayesians at all; instead, they use at least three heuristics. Representativeness is judgment based on the similarity of the event to the category. Availability is judgment based on the ease with which instances come to mind. Anchoring and adjustment are judgment based on insufficient movement from a reference point. These heuristics are rules that influence judgments of probability.

Base Rate Neglect

Researchers have argued that people often neglect base rate information. Evidence comes from a famous story, the 'cab problem'. Participants are told, 'A cab was involved in a hit-and-run accident at night. Two cab companies, the Green and the Blue, operate in the city: 85% of the cabs in the city are green and 15% are blue. A witness identified the cab as blue. The court tested the reliability of the witness under the same circumstances that existed on the night of the accident and concluded that the witness correctly identified each one of the two colors 80% of the time and failed 20% of the time. What is the probability that the cab involved in the accident was blue rather than green?' The Bayesian solution is 41%, but the majority of participants say 80%. This judgment is sensitive to the accuracy of the witness, but not the base rate. People estimate probabilities based on the information that seems most salient and compelling. In the cab problem, that information is the accuracy of the witness.

Conjunctive Probabilities

Researchers have also argued that people violate the conjunctive rule, according to which the judged probability of the intersection of two events cannot

exceed the judged probability of either single event. In these studies, participants are told a story about a woman named Linda who is described as 31 years old, single, outspoken, and very bright. She majored in philosophy and cared deeply about issues of discrimination and social justice. She also participated in antinuclear demonstrations. Participants are asked to rank the likelihood of various statements, including 'Linda is a bank teller' and 'Linda is a bank teller and a feminist'. Participants report that the statement, 'Linda is a bank teller and a feminist' is more probable than 'Linda is a bank teller'. Some researchers claim that representativeness, or the similarity of the target description to the category, governs these probabilities, and this heuristic can lead to mistakes.

Is it possible to 'fix' these mistakes? Some researchers have presented information using frequency formats. Participants are told to imagine 100 women who fit the description of Linda. Of those, how many are bank tellers? Feminists? Bank tellers and feminists? With this format, probability judgments are more likely to resemble the correct solutions with both base rate problems and conjunction problems.

Fast and Frugal Heuristics

Not all heuristics lead to errors. Some heuristics work well because they exploit the structure in the environment. Fast and frugal heuristics require a minimum of time, knowledge and computation, and tend to focus on one-reason decision-making. Such heuristics are based on easily computable search and stopping rules. The recognition heuristic involves the use of recognition to draw inferences. In some conditions, the lack of knowledge is beneficial. In one study, students at the University of Chicago were asked to decide which of two US cities had the larger population. University of Chicago students tend to be quite knowledgeable about US cities, yet despite their knowledge, they were less likely than German students to judge correctly whether San Diego or San Antonio had the larger population. Most of the German students had never heard of San Antonio, and using the recognition heuristic, they answered the question correctly.

Another heuristic called 'take the best' applies to predictions, inferences and decisions based on multiple imperfect cues. Suppose decision-makers are asked which of two cities is larger, and both cities are recognized. They compare cities on the basis of the most valid cue, and if that does not discriminate, they take the next best cue, and so on. With this rule they 'take the best, ignore the rest'. This heuristic can do almost as well as statistical rules in many cue environments.

CONCLUSION

Research on decision-making has demonstrated important strengths and limitations in human judgment and choice. These insights have led to descriptive theories that incorporate psychological concerns, such as social pressure, conformity, justifiability, and emotional satisfaction. Behavioral assumptions like these can greatly improve the prediction of human decision-making. Although people violate rational principles, their decisions are still regular and orderly. Uncovering this lawfulness will provide fertile ground for future research.

Deductive Reasoning

Introductory article

PN Johnson-Laird, Princeton University, Princeton, New Jersey, USA

CONTENTS

Deductive reasoning yields conclusions that must be true given that the premises are true. The challenge to cognitive scientists is to discover the valid conclusions that human reasoners are competent to draw, and the mental processes underlying deductive performance.

INTRODUCTION

Deductive reasoning is a process yielding valid conclusions from premises, where a conclusion is valid if it must be true given that the premises are true. The premises may be assertions, perceptions, memories or thoughts. The conclusion is in the first instance a thought that may lead on to an assertion or to an action. A typical example of a valid deduction is:

Either government invests or a recession occurs.
Government doesn't invest.
Therefore, a recession occurs.

If the premises are true, then the conclusion must be true. If the premises are false, however, a valid deduction may yield a true or a false conclusion. Invalid inferences, such as inductions from experience, can be useful, but they lack a guarantee of truth even if their premises are true.

The business of life depends on deductive reasoning. Individuals differ in this ability, and those who are better at it also perform better on tests of intelligence. They also appear to be more successful in life. A person who is poor at deductive reasoning is liable to blunder. Conversely, without deductive reasoning, there would be no logic, mathematics, science, law or society. The challenge to cognitive scientists is to discover the valid conclusions that human reasoners are competent to draw, and the mental processes that underlie their performance.

LOGIC

Logic is the science of valid deduction, and logicians have systematized many different logical calculi. They approach the task in two distinct ways. The first way concerns the formal pattern or syntax of symbols, and it is known as 'proof' theory. Consider as an example the sentential calculus, which concerns negation and idealized versions of such connectives as 'if', 'or' and 'and'. The calculus can be formalized by specifying rules of inference that govern it. The following rule, for example, concerns disjunctions:

A or B.
Not-A.
Therefore, B.

This rule states that given a disjunction of the form *A or B*, such as:

Either government invests or a recession occurs.

and an assertion of the form *not-A*:

Government does not invest.

then one can derive a conclusion of the form *B*:

A recession occurs.

When logicians formalize a calculus, they bear in mind the intended meaning of the connectives, but the formal rules themselves make no use of this meaning. They are rules for writing new patterns of symbols, which are sensitive only to the syntax or form of sentences. Hence, formal rules operate like a computer program. When a computer program predicts the economy, for example, the computer has no idea of what an economy is or of what it is doing. It merely slavishly follows its instructions, and displays symbols that economists can interpret as predictions. Indeed, an intimate relation exists between computer programs and formal proofs: logic can be used to prove theorems about programs, and programs can be used to construct logical proofs.

Formalization can be carried out in different, though equivalent, ways. One way, which has been influential in cognitive science, is known as the method of 'natural deduction'. It uses formal

rules of inference for each of the main sentential connectives. Some rules introduce connectives, such as the following three rules:

A B Therefore, A and B	A Therefore, A or B, or both	A|− B Therefore, If A then B

where A|− B signifies that the assumption of A for the sake of argument yields a proof of B. Other rules eliminate connectives, such as:

	A or B, or both	If A then B
A and B	Not-A	A
Therefore, B	Therefore, B	Therefore, B

Natural deduction had a vogue in textbooks, but still more intuitive methods exist for teaching logic.

The second way in which logicians systematize a calculus is semantic; i.e. it is concerned with meaning and truth. It is known as 'model' theory. For the sentential calculus, this method states the truth or falsity of a proposition containing a connective in terms of the truth or falsity of its constituent propositions. The ultimate constituents are atomic propositions, propositions that contain neither negation nor connectives. Consider a disjunction of the form *A or B, or both*, such as:

> Either government invests or a recession occurs, or both.

Logicians assume that it is true if at least one of its two atomic propositions (government invests, a recession occurs) is true, and it is false if both of them are false. These conditions apply to many other disjunctions. Natural language, however, is not always so tidy. Just as there is poetic license, so there is logical license – a need for logicians to make simplifying assumptions about the meanings of logical terms. Logicians lay out the truth conditions for connectives in a truth table, such as that shown in Table 1. Each row in the table shows a possible combination of truth values of A and B, and the resulting truth value of the disjunction. The first row in the table, for instance, represents the case where A is true and B is true, and so the disjunction as a whole is true.

Table 1. Truth table for the disjunction *A or B, or both*

A	*B*	*A or B, or both*
True	True	True
True	False	True
False	True	True
False	False	False

To complete the semantic characterization of the sentential calculus, definitions of each connective need to be made. One tricky connective is 'if'. A conditional assertion such as:

> If government invests then inflation occurs.

is true given that government invests and inflation occurs, and false given that government invests and inflation does not occur. What is its status when its antecedent is false – that is, when government does not invest? This puzzle has generated a vast literature. The simplest semantics, however, may govern usage in daily life. It treats the conditional as true when its antecedent is false. In other words, granted that the conditional is true but that the government does not invest, then inflation may or may not occur.

As logicians have proved, any conclusion that can be derived using the formal rules of the sentential calculus is also valid using truth tables, and vice versa. They have also proved that there is a decision procedure for the calculus; i.e. a method that takes a finite number of steps to decide whether an inference is valid or invalid. However, this happy state of affairs does not apply to all logical calculi. An important extension of the sentential calculus is known as the predicate calculus. It deals with proofs concerning quantifiers, such as 'some' and 'all', as in the following syllogism:

> Some of those economies are inflationary.
> All inflationary economies are unstable.
> Therefore, some of those economies are unstable.

The predicate calculus is only semi-decidable. That is, any valid inference can be derived in a finite number of steps; but if an inference is invalid, no guarantee exists that its invalidity can be established in a finite number of steps. The most important logical discovery, as Kurt Gödel showed, is that logics exist in which not all valid inferences can be proved using formal rules. As he also famously proved, there are truths in arithmetic that cannot be derived in any consistent formal calculus. Some theorists have taken an analogous proof about computer programs to show that human creativity is not computable. Alan Turing, the intellectual father of the programmable digital computer, anticipated and rebutted this argument when he pointed out that human beings are unlikely to be consistent.

DEDUCTIVE COMPETENCE

Once, the task for cognitive scientists seemed to be to isolate the logic (or logics) that people have in their minds. The challenge was the variety of

candidates. For example, there are infinitely many distinct modal logics, which deal with possibility and necessity. Nevertheless, theorists argued throughout the twentieth century that logic is *the* theory of deductive competence. Jean Piaget, the famous investigator of children's mental development, argued that 'reasoning is nothing more than the propositional [i.e. sentential] calculus itself'. Yet there is a flaw in this claim. The sentential calculus yields infinitely many different valid conclusions from any set of premises. For instance, the following premises:

If government invests then inflation occurs.
Government invests.

yield the valid conclusions:

Government invests and government invests.
Government invests and government invests and government invests.

… and so on *ad infinitem*.

Of course such conclusions are preposterous. No sane individual – other than a logician – is likely to draw them. Yet they are all valid. Given, say, the following two premises and asked what follows from them:

A villanelle is a poem.
Ruislip is in London.

most people respond, 'Nothing'. Yet, to repeat, logic allows infinitely many valid conclusions from any premises. So, the response is wrong. However, the conclusions that follow from these premises are of no interest or use:

A villanelle is a poem *and* Ruislip is in London.

People are sensible. They do not draw just any valid conclusion, and sometimes they respond that nothing follows. Logic is therefore not a theory of deductive competence (*pace* Piaget). It captures which conclusions are valid, but it has nothing to say about which particular valid conclusions, if any, individuals draw.

The conclusions that people do draw tend to conform to three general principles. First, the conclusion maintains the semantic information given in the premises; that is, individuals do not throw away semantic information by adding disjunctive alternatives. Thus, the inference:

Government invests.
Therefore, government invests *or* inflation occurs.

is valid. Yet logically untrained individuals baulk at it. They do so for the excellent reason that the premise conveys more information than the conclusion, i.e. the premise is compatible with fewer possibilities than the conclusion. Second, reasoners are parsimonious in their conclusions. They do not spontaneously make deductions such as:

Government invests.
Inflation occurs.
Therefore, government invests *and* inflation occurs.

This conclusion uses more words to say no more than the premises do. Third, reasoners try to draw conclusions that make explicit something that was not stated as such in the premises. For example, given the premises:

If government invests then inflation occurs.
Government invests.

they do not draw the conclusion:

Government invests.

The conclusion is parsimonious, but it does not say anything new. Valid deductions cannot add semantic information to the premises, and so sceptics sometimes suggest that valid deductions serve no useful purpose. In fact, they are wrong. Valid deductions can convey propositions that are not obvious consequences of the premises. They can make explicit a proposition that was not asserted as such by any of the premises. It is these inferences that naive individuals strive to make. Hence, given the preceding premises, they almost always infer:

Inflation occurs.

If there is no conclusion that satisfies these three principles, then people are sensible. They say that nothing follows.

In short, to deduce is to maintain semantic information, to simplify, and to reach a new conclusion. None of these principles can be derived from logic.

THEORIES OF DEDUCTIVE PERFORMANCE

How people make deductions is a matter of controversy. Do their mental processes depend on a single system, or, as evolutionary psychologists suppose, on a set of separate systems shaped by natural selection? Do the processes rely on formal rules like those of a logical calculus, or on rules with a specific content, or, as some researchers in artificial intelligence suggest, on calling to mind past cases of valid reasoning? Psychologists have been struggling with deduction for nearly a century; cognitive scientists have recently homed in on it, and defended each of the preceding positions. The controversy is hot because deduction is an excellent test case: if cognitive scientists cannot

understand it, they are unlikely to understand much about any sort of thinking.

You can make valid deductions about matters of which you have no substantial knowledge. Even if you know nothing about poetry, for instance, you can still grasp the validity of the following inference:

If a poem is a villanelle then it has five tercets followed by a quatrain.
Elizabeth Bishop's *One Art* is a villanelle.
Therefore, it has five tercets followed by a quatrain.

Hence, theories based on knowledge of a domain can at best tell only part of the story of reasoning. Among the theories above, however, are two that can cope with inferences in general. These two theories run in parallel with the distinction in logic between proof theory and model theory. The first sort of theory postulates that your mind is equipped with formal rules of inference akin to those of a 'natural deduction' system. Lance Rips, Daniel Osherson, Martin Braine and others have proposed theories of this sort. You are not aware of these rules when you reason, and so if they exist, then they must be unconscious. One such rule is of the following form (see the earlier section on logic):

If A then B.
A.
Therefore, B.

You can make the preceding inference by matching its premises to the premises of this rule, and then by drawing the conclusion permitted by the rule.

The Selection Task

The British psychologist Peter Wason and his students pioneered the modern experimental study of deductive reasoning, and established that two main factors affect performance: the logical structure of inferences, and their semantic content. These studies showed, for example, that responses in Wason's well-known selection task were qualitatively different depending on the content of problems. In the abstract version of the task, the experimenter laid out four cards bearing letters or numbers as follows in front of the participants:

A B 2 3

The participants knew that each card had a letter on one side and a number on the other side. They were given a conditional assertion:

If a card has the letter 'A' on one side then it has the number '2' on the other side.

Their task was to select those cards that needed to be turned over to discover whether the rule was true or false about the four cards. Most people selected the A card alone, or the A and 2 cards. What was puzzling was their failure to select the 3 card: if it has an A on its other side, then the conditional assertion is false. Indeed, nearly everyone judges it to be false in this case. When the content of the assertion in the selection task was changed to a sensible everyday generalization, such as:

Every time I go to Manchester I travel by train.

many people made the correct selections. Each of four cards had the name of a destination on one side and the mode of transport for getting there on the other side, and the four cards shown to the participants were:

Manchester Sheffield train car

The participants tended to select the 'Manchester' and 'car' cards.

The selection task has been the most popular paradigm in the experimental study of deductive reasoning. Its large literature yields one overwhelming message: certain contents improve performance. Evolutionary psychologists argue that the mind has developed a set of specialized systems (or modules) as adaptations to the lives of our forebears. Thus, they have proposed an innate module for reasoning about cheating, because social exchanges were important to the hunter-gatherers of the Pleistocene epoch. Experiments have shown that selection tasks about potential cheaters do indeed improve performance; but, as the example above shows, such contents are not necessary to elicit insight into the task. Formal rules of inference cannot account for these phenomena either, because manipulations of content that have no bearing on logic can have a large effect on accuracy. These phenomena, however, did not deter subsequent theorists from postulating that reasoning relies on formal rules of inference.

Mental Models

As a reaction to the phenomena of the selection task, a second theory of deduction makes no use of formal rules of inference. This theory postulates that reasoning is not a formal matter (unless you have learned logic), but depends instead on your understanding of the meaning of the premises, on your perception of the situation, and on your general knowledge. You use this information to construct mental models of the situations described by the premises. You formulate a conclusion that

holds in the models but that was not explicitly asserted by any premise. The strength of your inference depends on the proportion of the models in which the conclusion holds. A conclusion that holds in all the models is *necessary* given the premises, and a conclusion that purports to be necessary can be refuted by a counter-example; that is, by a model that satisfies the premises but not the conclusion. A conclusion that holds in most of the models is *probable* given the premises, and a conclusion that holds in at least one model is *possible* given the premises. Models accordingly go beyond formal rule theories to provide a unified account of logical, modal, and probabilistic reasoning.

The theory makes three principal assumptions. The first assumption is that possibilities, not truth values, are fundamental, and that each mental model represents a possibility. Thus, the disjunction:

> Either government invests or a recession occurs, or both.

calls for three mental models, shown here on separate lines, which represent the three possibilities:

```
Government invests
                    recession
Government invests  recession
```

where 'Government invests' denotes a model of the government investing, 'recession' denotes a model of the occurrence of a recession, and the third line denotes their conjunction in a single model. The diagram uses words, but that does not imply that mental models are made up of words. There is a critical difference between the diagram and what it denotes, namely a set of mental models. You understand what it means for government to invest. Your understanding is represented in your mind in a way that is independent of your language. Indeed, if such a thought comes to you, you may have difficulty in putting it into words. Moreover, if you also speak Spanish, then you are likely to build the same mental models from the corresponding assertion in Spanish.

The second assumption of the theory is known as the 'principle of truth'. It postulates that mental models represent only what is true, and not what is false. Hence, the preceding set of models does not represent the case in which the disjunction as a whole is false. In addition, however, each model represents the clauses in the premises only when they are true in a possibility. For instance, the first model in the preceding set represents the possibility that government invests, but it does not make explicit that in this possibility it is false that a recession occurs. People represent what is false in 'mental footnotes', but these footnotes are ephemeral and normally soon forgotten. The failure to consider what might falsify the conditional assertion accounts for the difficulty of the abstract selection task. The failure is mitigated, however, when the content of the task yields more familiar counter-examples.

The third assumption is that the parts of a mental model correspond to the parts of what it represents, and so the structure of the model corresponds to the structure of what it represents. A mental model is therefore like an architect's model of a building. Mental models underlie visual images, which are projections from them, but not all mental models can be visualized. Complex mental models of systems can be built up in long-term memory.

To illustrate reasoning by model, consider again the inference:

> If government invests then inflation occurs.
> Government invests.
> Therefore, inflation occurs.

The conditional calls for a model of the case in which its antecedent and consequent are both true. People realize that there are other possibilities consistent with the conditional – in particular, those in which it is false that government invests. However, they do not represent them explicitly. The conditional therefore elicits two models:

```
Government invests    inflation
                  …
```

where the ellipsis denotes a model that has no explicit content. This implicit model is a 'place holder' for the cases in which it is false that government invests. The premise that government invests eliminates this second model, and the first model yields the conclusion that inflation occurs.

Illusions and Departures from the Norms of Logical Validity

Do individuals reason using formal rules or mental models? A recently discovered phenomenon may answer the question. Consider the following problem:

> Only one of the following assertions is true about a hand of cards:
> There is a king in the hand or an ace, or both.
> There is a queen in the hand or an ace, or both.
> There is a jack in the hand or a ten, or both.
> Is it possible that there is an ace in the hand?

Nearly everyone responds, 'Yes,' and the conclusion seems obvious. Yet the inference is illusory. It

is impossible for an ace to be in the hand. If there were an ace then the first two assertions would both be true, contrary to the claim that only one of the three assertions is true. People succumb to the illusion because they think only about what is true, and the truth of the first assertion suggests that an ace is possible. But, when the first assertion is true, the other two assertions must be false. And the falsity of the second assertion means that there is neither a queen nor an ace in the hand.

Individuals are vulnerable to a variety of illusions in modal and probabilistic reasoning. The rubric 'Only one of the assertions is true' is equivalent to an exclusive disjunction, and a compelling illusion occurs in the following inference about a particular hand of cards:

> If there is a king in the hand then there is an ace in the hand, or else if there isn't a king in the hand then there is an ace in the hand.
> There is a king in the hand.

What, if anything, follows? Nearly everyone infers that there is an ace in the hand. It follows from the mental models of the premises. Yet it is a fallacy granted a disjunction between the two conditionals. One or other of the conditionals could therefore be false. And if, say, the first conditional is false, then there is no guarantee that there is an ace in the hand even though there is a king. Of course, skeptics can argue that 'or else' is treated as meaning 'and' in the problem, but that argument fails to explain the illusions based on the rubric 'only one of the assertions is true', and it also fails to explain which sentences yield an interpretation of 'or else' as 'and'. They seem to be precisely those for which the model theory predicts that illusions will occur because individuals neglect what is false.

The illusions are so compelling that they go unnoticed in daily life. For example, a professor cautioned students on his Web page:

> Either a grade of zero will be recorded if your absence [from class] is not excused, or else if your absence is excused other work you do in the course will count.

The mental models of this assertion represent the two possibilities that presumably he had in mind, assuming that a zero grade is incompatible with other work counting:

```
not-excused     zero-grade
excused         other-work-counts
```

The students probably made the same interpretation. Yet it is wrong. What really conveys these two possibilities is a conjunction:

> A grade of zero will be recorded if and only if your absence is not excused, *but* if and only if your absence is excused then other work you do in the course will count.

An inclusive disjunction of the two conditionals is a much weaker assertion compatible with more possibilities than those above. It allows that students with an excuse are no different from those without an excuse: both may get a zero grade or have other work on the course count, or neither. An exclusive disjunction of the two conditionals is even stranger: students with an excuse either get a grade of zero or not, but other work never counts; and students without an excuse never get a grade of zero, and other work may or may not count.

The illusions are a litmus test for mental models, because its principle of truth predicts them, but they jeopardize theories of reasoning based on formal rules. These theories currently postulate only valid rules, which cannot explain the systematic invalidity of illusory inferences. If these theories introduced invalid rules to account for the illusions, then it would follow that human beings are intrinsically irrational. However, the illusions have no such implication: people do understand the explanation of their errors. Given the limitations of human working memory, reasoners cannot cope with truth and falsity, that is, with complete truth tables. The principle of taking into account what is true and forgoing what is false is a sensible compromise. Truth is more useful than falsity. Just occasionally, however, truth alone leads human reasoners into the illusion that they grasp a set of possibilities that is in fact beyond them.

Delusions

Introductory article

William O'Donohue, University of Nevada, Reno, Nevada, USA
Andrew Lloyd, University of Nevada, Reno, Nevada, USA

CONTENTS

Delusions are strongly held false beliefs about reality. Although there is only moderate agreement as to what counts as a delusion, delusional beliefs and associated behaviors have long been regarded as evidence of insanity.

INTRODUCTION

Delusions are strongly held false beliefs about reality. The belief that one's thoughts are being stolen by a clandestine government agency or that one's internal organs have been replaced with mechanical replicas are good examples of delusional beliefs. Delusions are associated with over 70 psychological conditions and disorders. Schizophrenia, Alzheimer disease, Parkinson disease (along with other dementing diseases), and many substance abuse-related disorders are often marked by delusions. Delusional beliefs, and the behaviors consistent with them, are frequently the most relevant factors leading to the conclusion that a person is mentally ill. Indeed, delusions have been considered to be the defining, or paradigmatic, feature of madness for centuries. However, despite the clear relevance of delusions to psychological, psychiatric, and general cognitive theories and models, only moderate agreement exists as to what counts as a delusion.

SYMPTOMATOLOGY

Standard definitions of delusions involve at least four components. First, a delusional belief is a false belief or error. Such false beliefs can run from the relatively mundane, such as the belief that a close friend is secretly in love with you, to the very bizarre, for example, that one's head is full of bees. Second, a delusional belief is maintained with great conviction or certainty. Such beliefs have the character of being fundamentally true and incapable of being questioned owing to their perceived importance. Third, a delusional belief is maintained despite, or in the face of, incontrovertible evidence to the contrary. Not only do such beliefs have no empirical support (because they are false), they also persist in the face of what most people would consider incontrovertible evidence of their falsity. The belief that the Earth is flat or that the Holocaust never took place are examples of beliefs maintained in the face of strong counter-evidence. Fourth, a delusional belief is the kind of belief that is not typically supported by the individual's culture. This condition, though it is of critical importance to the definition of delusions, admits of a great deal of complexity and is, by definition, relative to many context-dependent variables. Though certainly false, the belief that consuming the brain of a recently deceased family member can protect one from the cause(s) of that person's demise would not properly be considered delusional in the context of certain South American tribes.

These four components may be construed as the necessary conditions for labeling a belief delusional. That is, each of these criteria must be met before a belief can be considered a delusional belief. Because, however, each of these criteria poses potentially difficult diagnostic problems, it is possible that, even taken together, they do not constitute sufficient criteria for the classification of a belief as delusional. That is, even if it is judged that each of these four conditions has been met, it does not guarantee that the belief in question is delusional.

The number, type, and content of delusional beliefs are unlimited. Because of the unlimited complexity of language it is not possible to identify antecedently what particular beliefs might count as delusional. This further complicates the identification of delusional beliefs. Some beliefs, however, are straightforwardly identifiable as delusional. Some of these beliefs are so common in relation to other delusional beliefs that they have been named and studied in some detail. The Capgras delusion

and the Cotard delusion are prominent examples. The Capgras delusion is marked by the individual's belief that his or her family (close acquaintances, co-workers, etc.) have been replaced by imposters. In the Cotard delusion the individual believes that he or she is dead or possesses no 'real' existence. Both of these exemplar delusions satisfy each of the four criteria outlined above. However, though both the Capgras and Cotard delusions are distinguished by their bizarreness, delusional beliefs need not be bizarre in their content.

One of the most prominent difficulties associated with correctly identifying a belief as delusional is encountered when the truth of the belief is assessed. People may express a number of beliefs that, at face value, seem clearly false. Believing one is dead falls squarely in this category. Little difficulty is associated with classifying such beliefs as false. However, unless care is taken to assess the truth of a belief, it would be hasty to classify the belief as delusional. In one classic example of a mistaken judgment of falsity, in the early 1970s Martha Mitchell, wife to the Attorney General of the United States, expressed seemingly false beliefs regarding illegal activities going on in the White House. Mrs Mitchell was believed to be suffering from some sort of psychopathology based on the bizarreness of her beliefs. As it turned out, however, Mrs Mitchell's accusations were accurate. Mrs Mitchell's claims pertained to the Watergate scandal of 1972. There are countless examples of situations similar to this one. A provisional name has been applied to situations in which the truth-value of a belief has been mistaken, the 'Martha Mitchell Effect'.

Delusional beliefs are distinguished from other forms of erroneous beliefs, such as overvalued ideas, obsessions, and confabulations. Overvalued ideas are recognized by their possessors as being potentially false and, as such, are not maintained with the degree of certainly associated with delusions. Obsessions are defined as persistent ideas, thoughts, impulses, or images. Obsessions are often experienced as distressing, and though the obsessional person attempts to ignore or suppress them, they are clearly recognized as his or her own thoughts. Because people attempt to suppress obsessional thoughts, they fail to count as delusional beliefs that are held with certainty. Confabulation is defined as filling in the gaps of memory and knowledge with false information. This information, however, need not involve beliefs that are generally considered questionable or bizarre by the members of the person's community.

COGNITIVE MECHANISMS

There are a number of cognitive theories that attempt to explain the presence of delusional beliefs. The most prominent features of these theories will be outlined. According to some thinkers, delusions may reflect errors in discriminating the origin of information. Mistakenly attributing one's belief to experiences, rather than to the operation of imagination, can lead to false beliefs. Internal imaginary events can generate local effects in the same pathways used by perception itself, thus increasing the difficulty associated with discriminating the original source of the belief. This phenomenon is similar to the one we experience when we are unable to discriminate accurately between reality and fiction while dreaming. The more elaborate imaginary scenarios are in terms of sensory detail, the more likely they are to be conflated with actual experiences. When we imagine a scene or event in elaborate detail (e.g. the color of the sunset and the odor of the ocean) the imagined event takes on more of the properties of our veridical experiences. This issue has been at the core of the debate regarding repressed memories.

Occasional confusion regarding the source of one's beliefs is, in itself, relatively innocuous. Most people have experienced this kind of confusion during their lives: 'Did somebody tell me that, or do I simply think it?' 'Do I really remember doing that when I was three years old, or am I relying on Mom's stories?' As the definition of delusional beliefs suggests, more than simple confusion or error with respect to the source of one's beliefs is required to classify them as delusional. Two other cognitive mechanisms are required to induce the individual to hold such false beliefs with certainty in the face of evidence otherwise: hypervigilance and an unfounded sense of profoundness.

Hypervigilance has been identified by many theories as one of the critical cognitive dispositions associated with delusional beliefs. Hypervigilance is marked by an increase in a person's awareness of the details of his or her environment. Under normal conditions of vigilance the environmental information to be processed is well within the individual's cognitive capacity to organize and contextualize into a manifold whole. States of hypervigilance, however, may induce a cognitive overload resulting in a sense of ambiguity with respect to environmental stimuli. Human cognitive mechanisms simply cannot contextualize and organize all of the environmental stimuli that are present at any given moment. The ambiguity that results from such experiences may lead to an unusually intense

sense of mystery and profoundness. For example, an individual may notice that there are four pennies in his pocket, four steps in his staircase, four clients he must meet during the day, and four children playing tag on the lawn as he leaves for work. These four events might strike him as being in need of some sort of explanation. How often, after all, does one note four sets of four events on the way to work? The search for an explanation of this series of events may result in the belief that these four events are connected in some important way, despite the fact that they are simply chance observations. The meaning of these seemingly connected events may take on a significance that far outweighs any reasonably objective interpretation of the events. Does it mean that the man has only four years to live? Perhaps this means that the man will meet his soulmate at four o'clock that afternoon.

This profoundness of experience is best described as being similar to that which one has at the birth of a child, the death of a close friend, or the intense spiritual experiences common to many religions. In the normal course of events such experiences are rare and often life-altering. For the delusional individual, mundane daily experiences become increasingly entangled in a sense of mystery and profoundness that can seemingly only be explained in a profound manner. Such profundity may be associated with a feeling of certainty. Further complicating the issue is the increased likelihood that the individual will note that others do not react with a sense of awe at what seem to be awesome events. This, in turn, may incline the person to believe that only he or she is meant to understand, or see, these events as they are. This can lead either to isolation or to a sense of righteousness. When isolated, a person is unlikely to come into contact with enough evidence to dissuade him or herself of the meanings that have been mistakenly associated with random events. Similarly, self-righteousness may interfere with a willingness to accept the input of others when such input contradicts what he or she believes.

Thus, a person who takes close notice of his or her relatives may come to see things that were never noticed before. Behavioral irregularities, a small scar, and a slightly different vocal intonation may be attended to and seem to require explanation. For the individual suffering from the Capgras delusion, the explanation may be that his or her close relatives have been replaced by imposters. Such a belief is unlikely to be openly expressed to those who could counter it. As such, the belief may become more and more ingrained. By the time the individual expresses this belief to others it will be so thoroughly tangled in a web of spurious confirmatory evidence (e.g. Mom never used to like cabbage) that it will be difficult to dispel. The foregoing explanation of the predispositions and factors leading to the development of delusional beliefs are consistent with the view of delusional beliefs as unnecessary and errorful explanatory theories of events that required no explanation.

PERCEPTUAL MECHANISMS

Perceptual mechanisms are implicated in the development of delusional beliefs insofar as they are involved in the individual's experience of the world. The most relevant role that perceptions play with respect to delusions is in the area of hallucinations. Both visual (e.g. seeing snakes when no snakes are present) and auditory (e.g. hearing one's name called when no one is present) hallucinations may result from an elaboration of elementary sensations. For example, *muscae volitantes*, commonly known as 'eye floaters' (which are typically overlooked or ignored), have been experienced as rats, snakes, armies struggling for the person's soul, and so on. In such cases, the experience of something in the visual field is accurate, only the interpretation of what it is is inaccurate. Similarly, individuals suffering from alcohol withdrawal may incorrectly identify the sounds associated with intrinsic tinnitus with the buzzing of bees inside his or her head. Auditory hallucinations are more common than visual hallucinations because of the relative difficulty in identifying the source, either internal or external, of sounds as opposed to images.

NEURAL SUBSTRATES

Though little is known in this area, research continues in the identification of the neural substrates of delusional predispositions. Promising research has suggested that schizophrenic delusions and hallucinations may be associated with overactivity of the left hippocampus and ventral striatum.

Depression

Introductory article

Lyn Y Abramson, University of Wisconsin-Madison, Madison, Wisconsin, USA
Lauren B Alloy, Temple University, Philadelphia, Pennsylvania, USA
Catherine Panzarella, The Philadelphia Behavioral Health System, Philadelphia, Pennsylvania, USA

CONTENTS

Depressive disorders are characterized by persistent depressed mood or loss of interest (normally for at least two weeks) and at least four other symptoms such as change in eating patterns or appetite, sleep disturbance, psychomotor agitation or retardation, fatigue or loss of energy, feelings of worthlessness or guilt, difficulty in concentration, and suicidal thoughts, plans, or attempts.

IMPORTANT FACTS ABOUT DEPRESSION

Descriptive research has produced some important facts about depression. First, depression is a common disorder. Recent estimates indicate that in many western countries, about 20 percent of the population will experience a clinically significant episode of depression at some point in their lives. Moreover, the rate of depression appears to be on the rise, especially among young people. The increased rate of depression in modern society may be due, in part, to increased focus on the self and its accomplishments. Although focus on the self may motivate achievement, it also may lead to depression when people fail to achieve their goals.

Second, depression is recurrent. Over 80 percent of depressed patients have more than one depressive episode in their lifetime. In fact, over 50 percent of depressed patients experience a relapse within two years of recovery. Such recurrence of depression suggests that some individuals are depression-prone because they exhibit a relatively stable vulnerability factor or diathesis for this disorder.

Third, the rates of depression surge during middle to late adolescence. Although young children can experience depression, rates of this disorder are relatively low during childhood. The surge in depression during middle to late adolescence may be due to the consolidation of vulnerability factors for the disorder such as negative cognitive styles as well as increased rates of negative life events within this age group.

Fourth, gender differences in depression exist among adults with twice as many women experiencing depression as men. This gender difference in depression emerges during adolescence.

Fifth, depression is associated with significant physical, vocational, and interpersonal impairment. Epidemiological studies have shown that depression is associated with poor physical health including cardiac problems and elevated rates of smoking. Moreover, depression lowers productivity in the workplace. In one year, it is estimated that in the United States the costs of depression-related lost productivity can exceed $33 billion. Finally, depression has high interpersonal costs. For example, depressed people have a higher divorce rate than nondepressed people.

Sixth, depression can be lethal as it clearly increases the risk for suicide. Research has suggested that hopelessness is the key factor contributing to suicide among depressed individuals.

Seventh, life events play a role in the development of depression. The occurrence of undesirable, major life events is associated with the onset of depression. However, not all people become clinically depressed when confronted with severe life stressors. Vulnerability–stress models posit that individuals exhibiting vulnerability factors (cognitive, genetic, biological, etc.) for depression are more likely to become depressed when confronted with severe stressors than individuals not exhibiting such vulnerability.

Finally, depression long has been viewed as heterogeneous with multiple causes. Thus, there are likely to be different causal pathways that culminate in depression. (*See* **Affective Disorders: Depression and Mania**)

COGNITION AND DEPRESSION

Although depression long has been recognized as an important form of psychopathology, experimental psychopathologists neglected this disorder until the 1970s. At that time, research on depression burgeoned within clinical psychology, and many investigators began to emphasize cognitive processes in the etiology, maintenance, and treatment of depression. A core idea within this cognitive perspective is that different people can perceive the same event differently. Psychologists focus on the characteristic ways that individuals perceive situations and how their perceptions, in turn, relate to their behaviors and emotions. From the cognitive perspective, emotional reactions, such as depression, to events are determined by a combination of characteristics of the event itself and the cognitive construal processes of the perceiver.

COGNITIVE THEORIES OF DEPRESSION

Why are some people vulnerable to depression whereas others never seem to become depressed at all? According to the two major cognitive theories of depression, the hopelessness theory (Abramson *et al*, 1999, 2002) and Beck's theory (Beck, 1987; Clark *et al*, 1999) the meaning or interpretation that people give to their experiences importantly influences whether they will become depressed and whether they will suffer repeated, severe, or long-duration episodes of depression. Indeed, the demonstrated efficacy of cognitive therapy for depression underscores the powerful clinical implications of a cognitive approach to depression.

According to the hopelessness theory, the expectation that highly desired outcomes will not occur or that highly aversive outcomes will occur and that one cannot change this situation – hopelessness – is a precipitant of depressive symptoms. How does a person become hopeless and, in turn, develop the symptoms of depression? As shown in Figure 1, negative life events (or the nonoccurrence of desired positive life events) are 'occasion setters' for people to become hopeless. However, the relation between negative life events and depression is imperfect; not all people become depressed when confronted with negative life events. According to the hopelessness theory, three kinds of inferences or conclusions that people may make when confronted with negative life events contribute to the development of hopelessness and, in turn, depressive symptoms: causal attributions, inferred consequences, and inferred characteristics about the self. In brief, hopelessness and, in turn, depressive symptoms are likely to occur when negative life events are (1) attributed to stable causes (likely to persist over time) and global causes (likely to affect many areas of life) and viewed as important; (2) viewed as likely to lead to other negative consequences; and (3) construed as implying that the person is unworthy or deficient.

For example, suppose a student fails a test. According to the theory, the student is likely to become depressed if he/she believes that the failure:

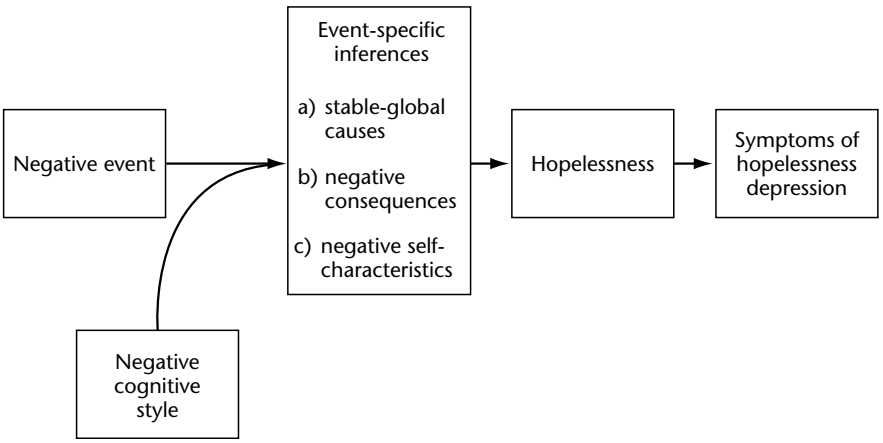

Figure 1. Causal chain in the hopelessness theory.

(1) was due to low intelligence; (2) will prevent him/her from pursuing a particular career; and (3) means that he/she is worthless. In contrast, another student who fails the same test will be protected from becoming depressed if he/she believes that the failure: (1) was due to not studying hard enough; (2) will motivate him/her to do especially well on the next test; and (3) has no implications for his/her self-worth.

In the hopelessness theory, informational cues in the situation as well as individual differences in cognitive style influence the content of people's inferences about cause, consequence, and self when negative life events occur. Individuals who exhibit a general tendency to attribute negative events to stable and global causes, to infer that current negative events will lead to further negative consequences, and to infer that the occurrence of negative events means that they are deficient or unworthy, are more likely to make these depressogenic inferences about a given negative event than individuals who do not exhibit this depressogenic cognitive style. However, in the absence of negative left events, those exhibiting a depressogenic cognitive tendency should be no more likely to develop hopelessness and, in turn, depressive symptoms than people not exhibiting this tendency. This aspect of the theory is a vulnerability–stress component: negative cognitive patterns are the cognitive vulnerability, and negative life events are the stress.

The etiological hypotheses of Beck's cognitive theory of depression are similar to those of the hopelessness theory. To understand Beck's theory, it is useful to describe cognitive schemata. Schemata are generalized core beliefs about the self and world that assist people in processing complex environmental information by: (1) selecting only a fraction of incoming stimuli for processing; (2) abstracting meaning from incoming information and favoring storage of the meaning rather than a veridical representation of the original stimulus; (3) using prior knowledge to assist in processing and interpreting information; and (4) integrating information to favor internal consistency over external accuracy. Schemata pertaining to the self are featured in Beck's theory.

As Figure 2 shows, in Beck's theory, maladaptive self-schemata containing dysfunctional attitudes involving themes of loss, inadequacy, failure, and worthlessness constitute the cognitive vulnerability for depression. Such dysfunctional attitudes often involve the theme that one's happiness and worth depend on being perfect or on other people's approval. Examples of dysfunctional attitudes include, 'If I fail partly, it is as bad as being a complete failure', or 'I am nothing if a person I love doesn't love me'. When these hypothesized depressogenic self-schemata are activated by the occurrence of negative life events (the stress), they generate specific negative cognitions (automatic thoughts) that take the form of overly pessimistic views of oneself, one's world, and one's future (the negative cognitive triad) that, in turn, lead to sadness and other symptoms of depression. In the absence of activation by negative events, however, the depressogenic self-schemata remain latent, less accessible to awareness, and do not directly lead to negative automatic thoughts or depressive mood and symptoms.

Although differing in some specifics, hopelessness and Beck's theories share many important features. At the most basic level, both theories emphasize the role of cognition in the origins and maintenance of depression. In addition, both theories contain a cognitive vulnerability hypothesis in which negative cognitive patterns increase people's vulnerability to depression when they experience

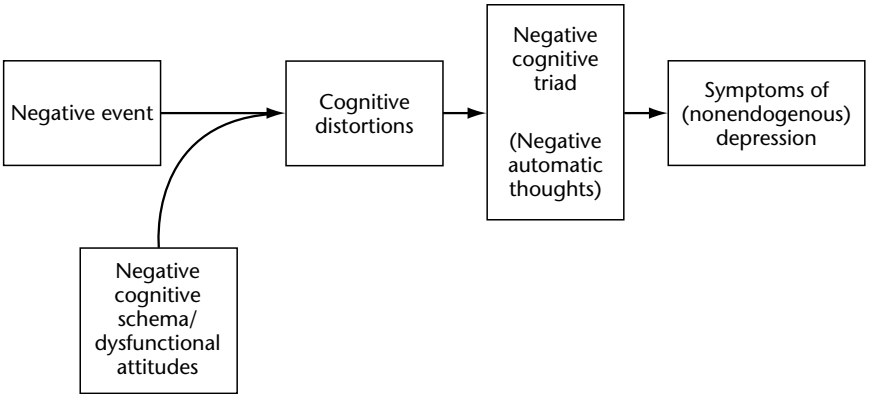

Figure 2. Causal chain in Beck's theory.

negative life events. Moreover, both theories also propose a mediating sequence of negative inferences that influence whether or not negative events will lead to depressive symptoms. Finally, both theories recognize the heterogeneity of depression and acknowledge that other causes of depression may exist.

Despite their similarities, there is one striking difference between hopelessness and Beck's theories. To understand this difference, it is useful to distinguish between cognitive 'processes' and cognitive 'products'. Cognitive processes involve the operations of the cognitive system such as information encoding, retrieval, and attentional allocation. Cognitive products are the end result of the cognitive system's information processing operations and consist of the cognitions and thoughts that the individual experiences. Inferences about cause, consequences, and self, as featured in the hopelessness theory, are examples of cognitive products. According to the hopelessness theory, depressive and nondepressive cognition differ in content (e.g., stable, global versus unstable, specific causal attributions for negative events) but not in process. In contrast, Beck's original theory emphasized that depressive and nondepressive cognition differs not only in content but also in process. Beck suggested that the inference process is 'schema driven' among depressed people and 'data driven' among nondepressed people. Thus, although both theories emphasize that depressed people's inferences are negative, Beck further proposed that depressed people's negative inferences are unwarranted given current information. Specifically, Beck suggested that depressed individuals ignore positive situational information and are unduly influenced by current negative situational information in making their negative inferences. In contrast, Beck hypothesized that nondepressed individuals appropriately utilize current information in making inferences. In short, Beck's original theory emphasized that depressive cognition is distorted whereas hopelessness theory is silent on the distortion issue.

EMPIRICAL FINDINGS ON COGNITION AND DEPRESSION

Supporting the cognitive theories of depression, many cross-sectional studies have established that negative cognitive patterns are associated with depression in adults, children, and adolescents. However, such cross-sectional studies do not provide strong tests of the cognitive vulnerability hypothesis, because they cannot distinguish between the possibility that the cognitive vulnerability came first and contributed to the occurrence of depression, as hypothesized in the cognitive theories of depression, and the alternative possibility that cognitive vulnerability does not contribute to depression and, instead, is a correlate or consequence of depression. Prospective behavioral high-risk studies are needed to establish that cognitive vulnerability actually precedes the occurrence of depression and contributes to its onset.

In the behavioral high-risk design, currently nondepressed people are selected who are at high versus low risk for depression based on the presence versus absence of the hypothesized depressogenic cognitive patterns. These cognitive high and low risk groups would then be followed and compared on their likelihood of developing depression in the future. Although there are some exceptions, in general recent studies with children, adolescents, and adults using the behavioral high-risk design and approximations to it have found that individuals who exhibit the hypothesized cognitive vulnerabilities are more likely to develop depressive moods, symptoms, and clinically significant episodes over time than individuals who do not exhibit cognitive vulnerability. Moreover, individuals exhibiting cognitive vulnerability also show elevated rates of suicidal thoughts when they are followed over time. Thus, work supports the hypothesis that ingrained negative patterns of thinking provide risk for depression.

In addition, some research suggests that attributional style for interpreting positive, rather than negative, events may be important in predicting recovery from depression as well as lower rates of relapse. For example, depressed people who show a tendency to attribute positive events to stable, global causes are more likely to recover from depressive symptoms following the occurrence of positive events than depressed people who attribute positive events to unstable, specific causes. Similarly, depressed patients with an internal, stable, global attributional style for positive events are less likely to relapse in the year following hospital discharge than depressed patients who do not show this attributional style. In other words, depressed people who did *not* show the tendency to minimize or discount positive information were more likely to recover and were less vulnerable to relapse.

In addition to work on cognitive styles as vulnerability and invulnerability factors for depression, much research has focused on documenting the nature of cognitive processes exhibited by depressed persons (Alloy *et al*, 1997). For example,

this research shows that processing negative self-referent information is less effortful and more automatic for depressed than non-depressed people. Depressed people also exhibit more negative memory biases than nondepressed people. Taken together, a vast amount of research unequivocally shows that depressive cognition is more negative than nondepressive cognition. But are depressed people's negative cognitions also more unrealistic than nondepressed people's positive cognitions?

DEPRESSIVE REALISM?

In contrast to Beck's original characterization of 'depressive cognitive distortion' and 'nondepressive accuracy', research has demonstrated pervasive optimistic biases among nondepressed people and a 'depressive realism effect' in which depressed individuals actually are more accurate than nondepressed individuals. For example, nondepressed individuals often exhibit an 'illusion of control' in which they believe that they control outcomes over which they objectively have no control, whereas depressed individuals seem less susceptible to this illusion. Research on optimistic biases among 'normal' people suggests that in formulating theories of depressive cognition, clinical researchers may have been wrong to assume that accuracy is the baseline of normal cognitive functioning. Instead, laboratory work has demonstrated that both depressed and nondepressed people show cognitive biases and illusions that are consistent with their preconceived beliefs or schemas (Dykman *et al*., 1989).

Although work on depressive realism and nondepressive optimistic illusions has not established that depressed people are *always* more accurate than nondepressed people, these studies nevertheless have posed an important challenge to the portrayal of depressed people as either impervious to information in their environments or hopelessly biased by pervasive negative schemata and of nondepressed people as completely data-driven and free from the influence of biasing schemata. Depressive and nondepressive cognition may differ more in content than in process. Thus, the negative cognitive biases that predict risk for depression may be no more distorted than the positive cognitive biases that predict protection from depression. Lively debate continues about the question of who are more accurate in perceiving reality over the long run – depressed people or nondepressed people?

DEVELOPMENTAL ORIGINS OF COGNITIVE VULNERABILITY

Given the growing body of work suggesting that negative cognitive styles may confer vulnerability for depression and suicidality, it is important to understand the developmental origins of these negative patterns of thinking. It is likely that a multitude of factors contributes to negative cognitive patterns such as genetic factors, biologically based temperamental factors, parental 'modeling' of negative cognitive patterns, and parental feedback, to name a few. Recent research has shown that adults who exhibit marked cognitive vulnerability to depression report growing up in environments characterized by maltreatment and neglect. Emotional maltreatment may be an especially potent contributor to cognitive vulnerability. Telling a child that he or she is incompetent, unlovable, or unattractive may 'program' the child to make very depressogenic interpretations of negative events later in life that, in turn, lead to depression. Further research is necessary to establish definitively that emotional maltreatment contributes to cognitive vulnerability to depression.

COGNITIVE-BEHAVIOR THERAPY FOR DEPRESSION

Consistent with the cognitive perspective on depression, cognitive–behavioral therapy (CBT) for depression has been developed that targets the negative cognitions such as hopelessness that are hypothesized to precipitate the onset of depressive symptoms and episodes as well as the negative cognitive patterns such as the tendency to make stable, global, causal attributions for negative events that are hypothesized to provide vulnerability for depression. CBT has been shown to be successful in remediating current depressive episodes and compares favorably with antidepressant medications for all but the most severely depressed patients. Given that depression is a recurrent disorder, it is especially noteworthy that preliminary work suggests that CBT may have an enduring effect that decreases the risk of relapse and recurrence among formerly depressed people. Finally, initial studies suggest that administration

of CBT to currently nondepressed individuals at risk for depression can prevent the onset of first episodes of depression.

INTEGRATION OF COGNITIVE AND NEUROSCIENCE PERSPECTIVES ON DEPRESSION

Given the empirical support for the cognitive theories of depression and the success of cognitive therapy for depression, it is critical to integrate the cognitive approach with other successful approaches to depression. Much important work has been conducted demonstrating the fruitfulness of integrating cognitive and interpersonal approaches to depression. However, little has been done to integrate the cognitive perspective with biological approaches to depression.

Although much important work has been conducted on cognitive and biological vulnerability to depression, these two lines of research have proceeded in relative isolation from each other. Paving the way for an integration of cognitive and biological approaches to depression, recent research has begun to elucidate the neural circuitry involved in implementing the behavioral approach system (BAS) and the behavioral inhibition system (BIS) (Davidson *et al*., 2002). Specifically, activation of the left frontal cortex is a key component of the neural circuitry implementing BAS function, and activation of the right frontal cortex is involved in BIS function. Consistent with this perspective, unipolar depression, which reflects low approach motivation, is associated with relative low left frontal cortical activity.

What is the nature of the relationship between cognitive vulnerability to depression and biological vulnerability to this disorder as indexed by patterns of cerebral asymmetry? To the extent that hopelessness, the expectation to which cognitively vulnerable individuals are predisposed, may be particularly powerful in signaling a shutdown of approach motivation (inactive BAS), cognitively vulnerable individuals may be characterized by relative low left frontal cortical activity. Consistent with this view, there are initial indications that attributionally vulnerable individuals exhibit relative low left frontal hemispheric activation. More generally, pessimism may be associated with low left frontal cortical activity, whereas optimism may show the reverse pattern. An exciting line of work has just begun to document a relationship between cortical activity and pessimism/optimism. For example, the autobiographical memories of patients with left hemisphere lesions, particularly to frontal regions, are more negative than those of patients with right hemisphere lesions. Moreover, activation of the left hemisphere by behavioral methods results in more self-serving attributions and more optimistic expectancies for the future.

Integration of the cognitive and neural approaches to depression promises to be an exciting and important direction for further theory and research.

EVOLUTIONARY APPROACHES TO UNDERSTANDING DEPRESSION

From an evolutionary perspective, depression may appear paradoxical. Depressed people show deficits in many basic human 'instincts' such as the pursuit of pleasure, sexual drive, appetite, sleep, parenting behavior, goal striving, and desire to be with other people. Perhaps most paradoxical of all, in defiance of the 'law of survival', depressed people sometimes actively try to terminate their own lives by suicide.

Despite these paradoxes, depression may be understood from an evolutionary perspective. Drawing on the fact that depression is common, some investigators have suggested that in our evolutionary past, depression may have had adaptational significance (Neese, 2000). For example, depression may facilitate disengagement from the pursuit of an unattainable goal. Alternatively, depression may involve a 'conservation of energy' principle in which a person slows down to reduce depletion of energy in pursuit of an unattainable goal or ceases activity that is likely to be futile or expose the self to some harm, disease, attack, or situation that is even worse than the current one. A complete account of depression is likely to involve an evolutionary perspective.

Depth Perception

Introductory article

Myron L Braunstein, University of California, Irvine, California, USA

CONTENTS

The three-dimensional world that is immediately and effortlessly perceived is a product of inferential mechanisms that rely on many different types of information. Among these are binocular disparity, motion parallax, texture gradients, linear perspective, shading, interposition, accommodation and convergence.

INTRODUCTION

Depth perception has been described as a paradox. We experience a three-dimensional (3D) world immediately and effortlessly, yet our visual information about the external world comes from light imaged on the two-dimensional retinal surfaces at the backs of our eyes. Our experience of the 3D world is unambiguous, yet the information in these images is inherently ambiguous (Figure 1). Before reviewing specific sources of information (cues) for depth perception, it will be useful to state some general principles underlying our ability to perceive a 3D world:

1. Information is available in the retinal images, and in the mechanisms controlling the muscles that change the convergence angle of the two eyes and the shapes of the lenses, that can be used to recover the 3D structure of the world.
2. This information is inherently ambiguous and must be interpreted using constraints – in a sense, biases based on knowledge about how the 3D environment is structured and about the structure of the visual system itself. In interpreting binocular disparities, for example, the assumption of a constant interocular distance would be a constraint. In interpreting image motion, an assumption of rigid 3D motion is a possible constraint.
3. This process of interpretation can be formally regarded as inductive inference. It is important to understand that the use of inductive inference based on prior knowledge does not mean that the perceiver engages in a conscious or even in an unconscious thought-like process. Instead, the inferential processes in depth perception can be implemented by 'hard-wired' biological mechanisms with 'knowledge' of the structure of the 3D environment built into these mechanisms through evolution. These inferential processes may not match the optimum processes that would be theoretically available to an 'ideal' observer. Instead, the human observer appears to use heuristic processes – efficient shortcuts that usually lead to a correct interpretation of the 3D environment, but which can fail when presented with unusual stimuli, leading to illusions.

Different types of information about the 3D world have been labeled as 'cues', based on the concept that there are a small number of ways in which picture-like images on the retinas are interpreted by the brain. These cues are sometimes thought of as involving separate modules that function independently until their outputs are combined to determine what is perceived. Most of what have been regarded as unitary cues, however, have turned out to involve more than one type of information or more than one type of processing, and important interactions among the cues suggest that they may not function as separate modules. The cue concept is a convenient way to summarize what is known about the information used in depth perception, but it should be recognized that this

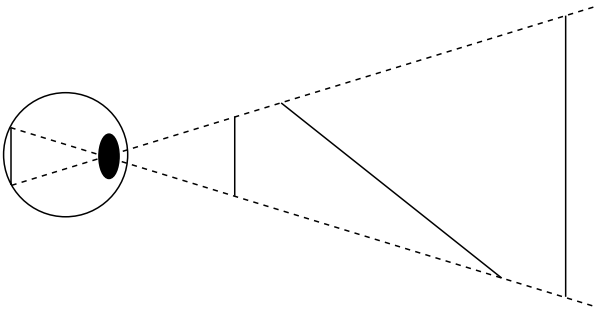

Figure 1. The ambiguity of the retinal image. An edge projected onto the retina is consistent with an infinite number of edges in three dimensions, varying in size, distance and orientation.

concept is a simplification that provides only a rough categorization of types of information used to infer a 3D world.

BINOCULAR DEPTH CUES

The two eyes are separated horizontally by about 6 cm. As a result of this separation the images projected onto the two retinas are different. The primary difference is that the relative positions of points in the images are shifted horizontally; this horizontal shift is a function of the interocular separation and the distances of the points from the eyes (Figure 2). It has been demonstrated using random dot stereograms (Figure 3) that horizontal disparities can lead to perceived variations in depth even in the absence of recognizable features in the individual images. A gradient of disparities, such as that produced by a slanted surface, is not, however, an effective depth stimulus. A discontinuity in disparities is needed, as when a scene contains an edge at which the depth or slant changes. Horizontal disparities appear to provide information about relative depth rather than absolute distance. Research suggests that vertical disparities in the two retinal images, when sufficiently large, can provide absolute distance information. Vertical disparities occur because one eye may be closer to an object, producing a different perspective projection. Another binocular cue is the convergence of the optic axes that occurs when the two eyes fixate a near object (also shown in Figure 2). Convergence is one of the first recognized depth cues, but is effective only at short distances.

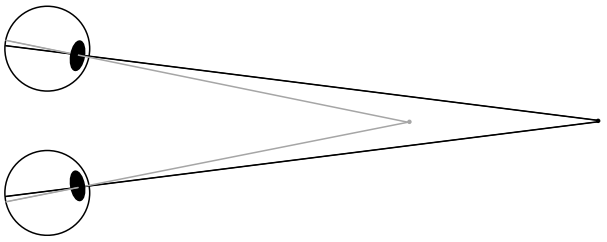

Figure 2. Binocular disparity and convergence. Note that the relative positions of the near and far points are reversed in the two retinal projections. The eyes are fixated on the near point and this determines the convergence angle.

MONOCULAR DEPTH CUES

Accommodation

Along with convergence, accommodation was one of the first recognized depth cues. When we fixate a nearby point the rays of light from this point diverge as they reach the lens of the eye and must be converged by the lens, so that a sharp point is imaged on the retina. This is accomplished by a change in the shape of the lens, which bulges to focus near objects and flattens to focus more distant objects (Figure 4). Information about the changes in the shape of the lens can therefore provide information about the distance of the fixated object. Accommodation is effective at short distances (within 2 m).

Monocular Perspective Cues

Perspective effects occur when the observation point (the eye or a camera) is relatively close to an object. The overall effect of perspective is that 3D distances closer to the observer project to larger

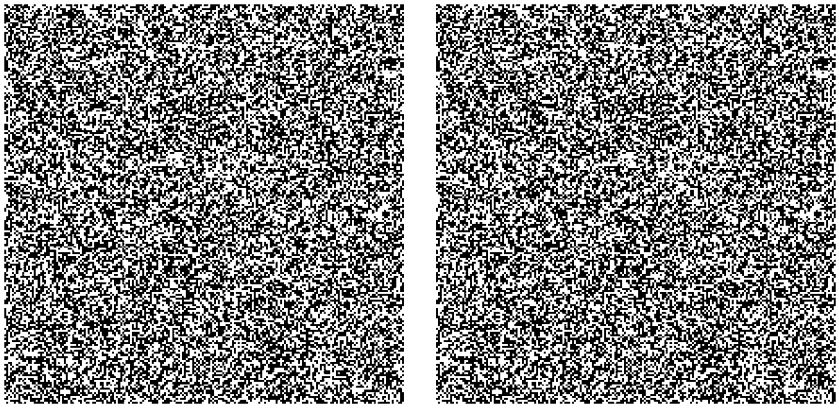

Figure 3. A random dot stereogram of the type introduced by Bela Julesz. If the images are fused by crossing the eyes, a small square should appear in front of the large square.

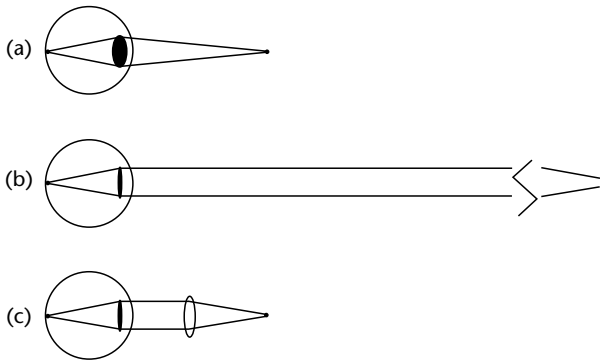

Figure 4. Accommodation to a near point (a) and far point (b). (c) Collimation: a lens is used to place a near point at optical infinity, making it appear to be a distant point.

distances in the retinal image than equivalent 3D distances further from the observer. This is reflected in several ways in a monocular image. Linear perspective, for example, refers to the convergence in the image of parallel lines extending into the distance in the 3D scene. It is a highly effective cue – merely drawing two converging lines can create an impression of a surface extending in depth. Other perspective cues are best described as gradients, as suggested by J. J. Gibson. The projection of a uniform 3D texture extending in depth results in a texture gradient. By itself, a texture gradient is not an especially effective cue unless the texture is regular (for example, a grid pattern), but texture gradients may combine with other information such as shading to provide an effective source of information about 3D layout. The projected sizes of similar objects describes another gradient that may result from perspective projection. This is closely related to the texture gradient. Usually a texture gradient describes spacing between texture elements (like blades of grass), whereas the size of similar objects describes the gradient in the projections of the elements themselves. Figure 5 shows several examples of monocular perspective cues.

Motion

Motion is not a single cue to depth but includes several ways in which changing patterns in the retinal projections over time provide information about 3D relationships. Motion parallax describes the changes that occur in the retinal image when there is relative motion between the eye and an object or a scene that is being observed. This usually occurs when the head moves relative to a stationary scene, but can also occur when an object or surface is moved relative to the head. It is primarily a perspective effect in that motions projected on the retina are more rapid for nearer objects than for more distant objects, assuming that the objects are moving in the same direction and at the same speed in 3D space. Another motion cue, structure from

Figure 5. Examples of perspective, shading and interposition. (a) The road illustrates linear perspective. (b) The rocks form a relative size gradient. (c) The arches form a regular texture gradient; specular highlights are found on the door at the back of the tunnel. Examples of interposition are found in all three photographs. (Images adapted from the Photo Library of the National Oceanic and Atmospheric Administration, US Department of Commerce.)

motion (also called the kinetic depth effect), occurs when an object is rotated relative to the direction of observation. Consider, for example, a cylinder rotating about a vertical axis. As the object rotates, the projections of imaginary lines connecting pairs of points on the cylinder will change in length (Figure 6). If we assume that the 3D distances between the points do not change as the object rotates (a rigidity assumption), the changing distances between points in the image can be used to compute the relative depths of the points on the 3D object. Unlike motion parallax, structure from motion does not depend on viewing distance and can provide information about the shape of a rotating object even when the object is at a great distance – for example, when an object is viewed through a telescope.

Shading

Consider a 3D shape and a light source illuminating that shape. At any point on this shape we can draw a tangent to the surface. The angle between this tangent and a line drawn from that point to the light source will vary over the surface and this will result in variation in the light reflected by points on the surface. The pattern of light reflected by the surface thus provides information about the shape of the surface and this source of depth information is referred to as 'shape from shading'. Note that shape from shading provides relative depth information within a surface, not information about distances from the eye. It is thus a source of object-centered depth information. Cast shadows and specular highlights also provide important information about object depth. Examples of shading cues are also seen in Figure 5. In dynamic scenes, important additional information about depth relationships is provided by changes over time in shading, in the positions of shadows, and in the locations of specular highlights.

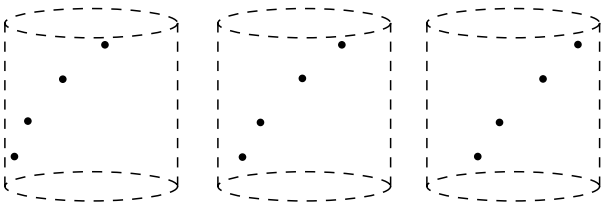

Figure 6. Structure from motion. Shimon Ullman showed that three-dimensional structure can be recovered mathematically from just three views of four non-coplanar points.

Occlusion

Occlusion is an unusual cue in that it provides only ordinal depth information. Occlusion of a far object by a near object, indicated by an interruption in the contours of the far object, is sometimes called interposition. Kinetic occlusion occurs when texture elements on one object disappear as they reach an implicit contour of another object, indicating that the first object is behind the second object.

Atmospheric Attenuation

Atmospheric attenuation refers to the reduced intensity and change in color of light reaching the eye that results from the scattering of light and absorption of light by particles in the atmosphere. Atmospheric effects can produce a gradient of intensity and color in the retinal projections that is informative about relative depth over large distances.

FLATNESS CUES

The retinal images should not be regarded as flat pictures that we can perceive as such in the absence of depth cues. To see a flat image we need information indicating that all points on the image are equally distant; this information is provided by flatness cues. Some flatness cues use the same sources of information as depth cues. For example, absence of differential accommodation to points on a near object indicates that these points are equally distant from the eye. In special applications, such as flight simulators, accommodation is removed as a flatness cue by collimating the image. Collimation, typically with a lens or a parabolic mirror, converts the diverging rays from a near object into parallel rays so that the visual system interprets the near object as a distant object (see Figure 4). Similarly, lack of binocular disparity within a near region suggests that the points within this region are equally distant. An especially interesting cue to flatness is a surrounding frame. Looking at a high-quality motion picture through a tube, which eliminates any explicit or implicit frame surrounding the image (and eliminates disparity if the tube is monocular) makes the picture appear less flat than if the frame were visible. Surrounding a real 3D scene with a frame can make that scene appear more flat, indicating that the frame is indeed a cue to flatness. What happens if there are neither cues to depth nor cues to flatness? This situation can be produced by creating a ganzfeld – a room with uniform illumination and no visible edges. The resulting perception is ambiguous. Usually a 3D fog is perceived.

CONCLUSION

The perceived structure of the 3D world is inferred from information available in the retinal projections and in the oculomotor system. There are many sources of information for depth which have been roughly categorized into 'cues', including binocular disparity, motion parallax, texture gradients, linear perspective, shading, interposition, accommodation and convergence.

CONTENTS

A developmental disorder of language is a significant delay or impairment in the expression and/or comprehension of language in the absence of a known cause.

INTRODUCTION

A developmental disorder of language is a significant delay or impairment in language acquisition (for expression and/or comprehension) in the absence of a known cause. Here we will use the term 'specific language impairment' (SLI) to refer to such language disorders. Specific language impairment (also called developmental dysphasia) is diagnosed on the basis of exclusion, meaning that the child's language difficulties cannot be accounted for by readily identifiable factors such as hearing impairment, neurological disease, psychiatric disability (disorders such as autism or childhood schizophrenia), low intelligence, physical malformation of the vocal apparatus, or severe environmental deprivation. Individuals with SLI exhibit normal nonverbal intelligence and, with the exception of language, have otherwise uncompromised development.

There is no universally accepted criterion for the classification of SLI. The World Health Organization *International Classification of Diseases* (ICD-10) classifies children with language abilities (assessed using a standardized language test) in the lowest 3% of the population as language-impaired (WHO, 1993). The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) has similar diagnostic criteria to the ICD-10, but it also requires that a child's language difficulties interfere with normal, everyday activities – academic, occupational or social (APA, 1994). In addition, researchers sometimes create their own classification or selection criteria for studies of developmental language problems, resulting in a heterogeneous population with the diagnosis of SLI. There is also no general agreement regarding the classification of children with subtypes of SLI, categorizing different patterns of deficits in language skills. Based on psychometric evaluations of language ability, three broad subtypes have been defined: receptive only, expressive only and expressive-receptive mixed (Tomblin, 1996). These categories, reflective of the DSM-IV and ICD-10 classification systems, have been used in many research studies. However, some researchers use a subtype classification based on the work of Rapin and Allen (1987), in which clinical evaluation of a child's spontaneous language during play (including phonologic, syntactic, semantic and pragmatic skills) leads to assignment to one of six subgroups: verbal auditory agnosia, verbal dyspraxia, phonological programming deficit syndrome, phonological–syntactic deficit syndrome, lexical–syntactic deficit syndrome or semantic–pragmatic deficit syndrome. In sum, there are a number of subtypes of SLI that attempt to define precisely an individual's areas of difficulty.

Although there are advantages to using diagnostic criteria specific to the stated research or clinical objectives, consensus about the defining characteristics of SLI, and the classification of its different subtypes, is essential if there is to be meaningful comparison among the many research efforts investigating the etiological conundrum of whether SLI stems from a single common underlying mechanism, or has multiple genetic and or developmental origins.

The traditional view has been that the symptoms exhibited in SLI can be attributed to delays in the

learning of linguistic-specific semantic and syntactic rules, which are critical to the development of language. In addition, there is substantial support for the role of poor phonological processing (perceiving and discriminating phonemes, which are the smallest units of sound in language that alone can differentiate meaning) in children with both language and reading deficits. However, there is also strong evidence that differences in basic auditory processing abilities of children with SLI may be related to their language deficits: see Leonard (1998) and Tallal (2000) for reviews. Leonard (1998) comments that findings of disordered processing of brief or rapidly presented stimuli in children with SLI are both ubiquitous and consistent across laboratories, tasks, and stimulus variations. Thus, it has been posited that basic difficulties in processing the brief, rapid, successive auditory cues that constitute speech could impair or delay the formation of distinct (categorical) representations of the sounds of language (phonemes). This would have an impact on emerging language through a cascade in which each disordered step (beginning with the most basic sound processing) affects subsequent levels of language processing. According to this hypothesis, auditory perceptual deficits lead to weak representations of phonemes, and these weak phonological representations may lead to oral language disabilities, and subsequent reading, writing and/or spelling deficits due to poor phonographic (spoken) to orthographic (visual/written) transfer (Tallal, 2000). However, there is still much debate about the etiology of SLI – in particular, which of the deficits simply co-occur and which are causative (Mody *et al*., 1997; see also Denenberg, 1999, 2001).

Dyslexia is also considered to be a developmental disorder of language, although dyslexia is classically defined as the failure to develop age-appropriate reading ability in the presence of otherwise normal skills. Nevertheless, research has shown that approximately 80% of children classified as SLI go on to develop dyslexia, providing support for the view that developmental language and reading disorders may have a common etiology (APA, 1994). Individuals with SLI and dyslexia often exhibit similar behavioral deficits in rapid sensory processing, and neuroimaging studies have revealed alterations in neuroanatomical substrates common to these two disorders. Further, measurements of brain activation employing event-related potentials (ERPs) (electrical signals recorded from the scalp in response to external stimuli) of SLI and dyslexic individuals are comparable. Thus, it is likely that children with SLI and dyslexia form an overlapping, though not identical, population. For this reason, behavioral, neuroimaging and neuroanatomical studies of both SLI and dyslexia are discussed here.

NEURAL SUBSTRATES

The classic studies of the language areas in the brain described adult patients suffering from various types of aphasia (disturbances in language expression or comprehension) due to brain lesions sustained in adulthood. Disruption of language abilities in these patients was consistently linked to specific areas of damage in the brain, thus allowing a coarse topographic neural map of language function to be constructed. These landmark studies were the basis for the Wernicke–Geschwind model of language function. In this model, auditory information is first processed by the primary auditory cortex (A1; Brodmann's areas 41 and 42, located on Heschl's gyrus on the dorsal surface of the left temporal lobe), and is then sent to secondary auditory cortical areas: Wernicke's area (the left posterior perisylvian area, including Brodmann's area 22), shown to support language comprehension, and Broca's area (the inferior left temporal gyrus containing Brodmann's areas 44 and 45), which mediates speech production (Figure 1). These areas are linked by a number of subcortical fiber systems. The arcuate fasciculus, a fiber bundle that carries information from Wernicke's area to Broca's area, has been of particular interest as it has been implicated in subtypes of aphasia characterized by impairments of language expression.

These early studies were critical in laying the framework for subsequent research into the neural bases of language processing. This research has shown that there are many additional language centers in the brain and that these interact via complex neural networks. However, the precise mechanisms governing language function continue to be the subject of intense study. Many brain areas, including left hemisphere regions of temporal, parietal and frontal cortex, are the focus of contemporary research into the neural substrates of developmental language disorders.

In contrast to acquired language deficits such as aphasia, for which a specific brain lesion can often be identified, SLI and dyslexia (in which normal language skills fail to emerge in the context of otherwise normal development) present a far less clear picture of which brain areas might be disrupted. The search for the underlying neural substrates of these disorders has involved behavioral, neurophysiologic and neuroanatomical approaches

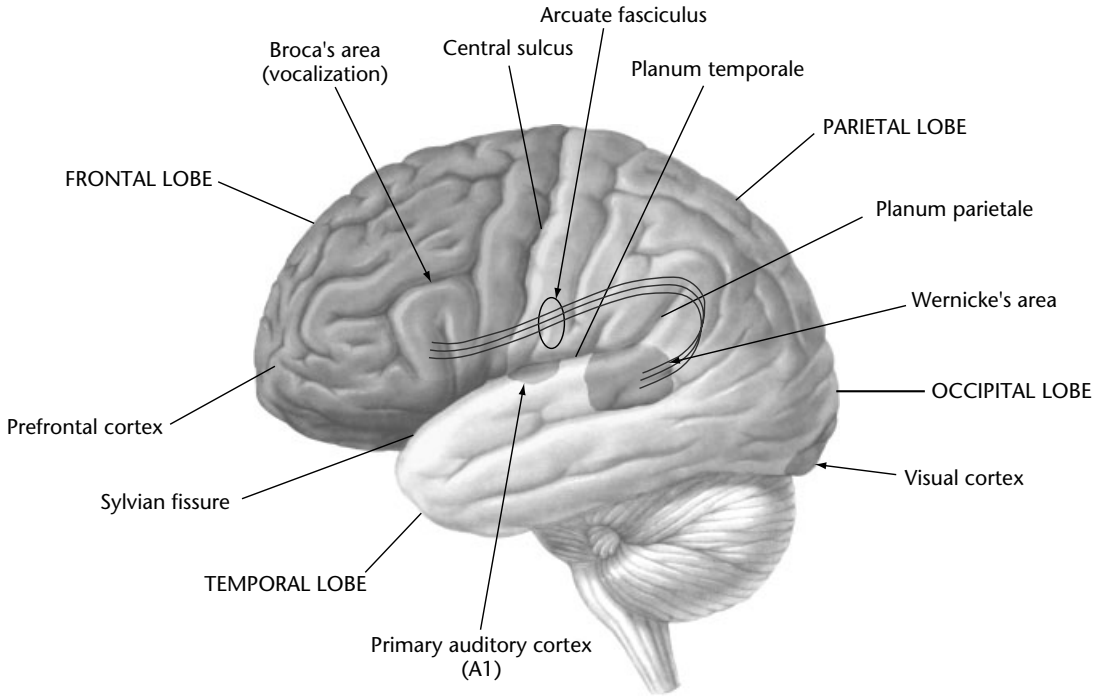

Figure 1. Areas of the human brain that are important for language, including the primary auditory cortex (A1), Wernicke's and Broca's areas, and the arcuate fasciculus.

and has been accelerated by methodological advances in functional neuroimaging and event-related potential (ERP) paradigms.

There is now a substantial literature reporting neurophysiological and neuroanatomic abnormalities in language-impaired children. Although there are generally concordant findings regarding differences in hemispheric asymmetry (see below), a number of studies report inconsistent or conflicting findings concerning other structural brain anomalies. These include alterations in corpus callosum size, extra sulci, white-matter abnormalities, and cortical atrophies. Such findings suggest that a single, focal anatomical abnormality will not be sufficient to explain SLI, and may also account for the variation in the severity, nature and perhaps type of language deficits that individuals with SLI exhibit.

A number of hypotheses have been proposed that attempt to link the structural abnormalities and behavioral deficits found in individuals with SLI and dyslexia. One is that neuroanatomical disruptions in SLI may be bilateral (affecting both hemispheres) rather than unilateral (affecting only one hemisphere), thus reducing the possibility for recovery of language function. Subcortical structures such as the caudate and thalamus might also be involved, and lesions in these areas have been shown to cause lasting and profound language impairments. Another possibility is that a specific disruption of critical language processing systems might be due to delay in brain maturation, induced genetically or by some prenatal or perinatal brain insult. Such a disruption would particularly affect the left hemisphere (given the normal time course of early brain development) and could cause structural brain abnormalities. The resulting deviant brain organization and related alterations in connectivity might disturb critical periods of language development, resulting in delays as well as lasting impairments. Finally, a basic sensory integration deficit in SLI has been posited. This basic deficit would induce dysfunction of neural systems which mediate rapid processing of dynamic sensory information important to rate processing.

LATERALITY

It is generally accepted that, in the normal population, left hemisphere structures are dominant for language function. Evidence for this first came from lesion and psychophysical studies, and with the advent of neuroimaging techniques such as positron emission tomography (PET) and magnetic resonance imaging (MRI) it has been shown that the left hemisphere of the brain is larger than the

right in the vast majority of normal people. Likewise, functional imaging studies (using PET and functional MRI) have revealed that language areas of the left hemisphere show more neural activity (reflected in cerebral blood flow or metabolic activity) during tasks that tap language processes, compared with the right hemisphere.

Interestingly, in individuals with dyslexia and SLI this asymmetry appears to be reversed or altered: right areas are larger or more active than left areas. For instance, differences have been found in the planum temporale, a structure located on the superior surface of the temporal lobe in the posterior perisylvian region (which includes a portion of Wernicke's area) that is important for language comprehension and phonological processing. The planum temporale is larger on the left than on the right in most people; however, in individuals with SLI and dyslexia this is not the case. In studies of dyslexia reversed asymmetry (right larger than left) of the planum temporale has been consistently reported, in both postmortem and neuroimaging studies. Evidence of structural abnormalities in the left hemisphere of individuals with dyslexia is also consistent with ERP studies reporting abnormal brain activation in language regions of the left hemisphere in this population. Other small, focal cellular abnormalities have also been reported in people with dyslexia, including ectopias (the presence of neurons in inappropriate cortical layers) and microgyria (abnormally small gyri). Such anomalies are thought to result from errors in neuronal migration caused by intrinsic genetic factors, or perhaps by prenatal or perinatal brain insult. Examination of the thalamus in dyslexics has also revealed cellular changes, suggesting that the processing of sensory information at this critical subcortical level may be compromised.

There have been few analogous findings in children with SLI owing to the fact that experiments involving imaging techniques are not often feasible in children (imaging studies in dyslexia usually recruit adult participants), and individuals with SLI are not routinely referred to medical professionals for brain scans. Additionally, there have been no postmortem studies of the brains of individuals with SLI, so it is impossible to confirm or rule out the presence of focal cellular abnormalities like those found in the sample of dyslexic individuals examined by Galaburda and colleagues (Galaburda *et al*., 1994). The similar behavioral deficits in SLI and dyslexia suggest a similar neuropathology, but this remains speculative. Despite these limitations, the studies of children with SLI to date are fairly similar to those of adults with SLI and dyslexia in reporting abnormal asymmetry, especially in the perisylvian region. In one MRI study, the volume of the posterior perisylvian region, including the planum temporale, was found to be reduced bilaterally, though more dramatically in the left hemisphere, in language- and learning-impaired participants compared with controls (Jernigan *et al*., 1991). Further, bilateral volumetric reductions were found in subcortical structures, including the caudate and putamen. A number of more recent MRI studies also report atypical asymmetry of perisylvian structures, with areas on the right larger than usual in individuals with SLI. In sum, neuroanatomical abnormalities were most often localized in the perisylvian region, which includes areas important for language processing, and atypical asymmetry in SLI compared with control subjects is consistently reported.

Functional imaging studies of individuals with SLI and dyslexia, using PET and fMRI, also report abnormal patterns of activation. Studies of children with language-related disorders report reduced activation (indexed by cerebral blood flow or glucose metabolism) in the perisylvian region in the left as compared with the right hemisphere during tasks requiring utilization of language areas. Such studies support the idea that the anomalies in anatomic asymmetry described above might be related to the inability of individuals with SLI to use these same areas effectively to process sounds. Brain activation studies of ERPs during visual and auditory sensory processing tasks add to these findings. Across studies, the ERP results support the premise that abnormal patterns of hemispheric activation can be documented in SLI populations.

Examination of results from studies of the brain's functional activity in response to rapidly presented and or brief acoustic cues (both speech and nonspeech) support the relevance of such cues to speech perception. This body of research further suggests that deficits in the underlying ability to process rapid acoustic change are often associated with abnormal patterns of brain activity during processing. It is important to note, however, that such relations are not always found. Some children with SLI do not exhibit abnormal asymmetry, and some individuals with verifiable atypical asymmetry exhibit no language difficulties. Moreover, individuals with SLI and dyslexia have been found to show abnormalities in brain areas outside of language centers. These deviations from the reported pattern of findings reinforce the view that SLI and dyslexia are disorders characterized

by heterogeneous behavioral profiles, and thus may ultimately show variability in the underlying neurobiological substrates.

RATE OF PROCESSING

Individuals with SLI or dyslexia exhibit deficits in the ability to process successive, brief, sensory stimuli which are rapidly presented to the nervous system. Such stimuli may be tactile, visual, somatosensory or acoustic, including linguistic stimuli such as consonant–vowel (CV) syllables, and nonlinguistic stimuli such as tone pairs. The perception of human speech requires the decoding of brief, rapidly changing auditory stimuli that constitute language. Words are made up of phonemes, and phonemes are characterized by formants – frequency patterns created by sound resonating in the vocal tract. Formants provide acoustic cues in the perception of speech and represent sound waveforms across time. Formants of vowels are more or less constant over time, whereas stop consonants (/p, b, t, d, k, g/) are characterized by formant transitions. During a formant transition, frequency position changes rapidly as the stop consonant occlusion (vocal tract is in a closed position specific to a stop consonant) is released and the vocal tract shape changes to form the subsequent vowel (a stop consonant cannot be uttered alone, but must be combined with a vowel). So, in order to discriminate accurately and perceive stop consonants, the rapid formant transitions must be correctly processed by the auditory system. Frequency spectrographs (sound waveforms) for the CV syllables /ba/ and /da/ are shown in Figure 2. Note that the only differences between these CV syllables occur within the first 40 ms of formants 1 and 2. After that point, the spectrographs for /ba/ and /da/ are almost identical. Thus, in order for a listener to distinguish these CV syllables, the rapidly changing frequency information contained in the initial 40 ms of the speech sound must be properly processed by the auditory system. Such brief auditory cues, critical to discrimination of language, enter the central nervous system in rapid succession, and an inability to process such transient, rapid, successive stimuli might ultimately result in deficits symptomatic of SLI and dyslexia. Indeed, in studies of adults with dyslexia, one of the most persistent deficits appears to be in phonological processing, suggesting that underlying auditory processing deficits are extremely long-lasting.

Studies of children with SLI provide further support for an underlying rapid auditory processing

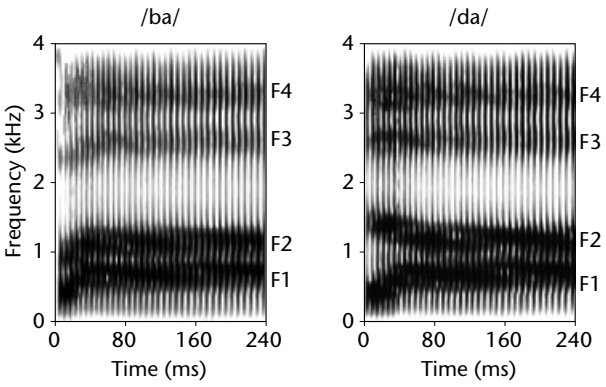

Figure 2. Spectrograph showing the formant transitions for the consonant–vowel (CV) syllables /ba/ and /da/. Notice the difference between /ba/ and /da/ in the 0–1 kHz range during the first 40 ms of formants 1 and 2. This brief sound difference must be detected in order to discriminate /ba/ from /da/. Formants 1 through 4 are noted on the right side of each spectrogram (F1–F4).

(RAP) deficit. Schoolage children with SLI were found to be impaired in processing both verbal and nonverbal stimuli that had brief and rapidly changing auditory components (Tallal *et al*., 1985). The replication and extension of these findings, across many laboratories, supported the hypothesis that an impairment of basic-level RAP hinders the development of normal language and reading abilities. Although children and adults with deficits in RAP and associated language problems hear normally and can sequence sounds, such individuals are selectively impaired in their ability to both perceive and produce speech sounds characterized by brief or rapidly changing temporal cues. These auditory processing limitations may directly interfere with adequate perception of those speech sounds that include rapid acoustic changes – such as stop consonants – and disrupt processing of the speech stream.

Another well-established finding is that SLI occurs within families and that infants born to families with affected close relatives are at greater risk of the disorder. Children from families with a history of SLI are approximately four times more likely to develop SLI than children from control families. These facts, and the insight that the cortical abnormalities implicated in SLI probably occur at an early stage of development as a result of errors in neuronal migration, suggest that different neurophysiological responses in infancy might predict SLI in later childhood. For example, it is thought that the mechanism responsible for causing malformations such as ectopias and microgyria

occurs during prenatal development, approximately between 18 weeks and 24 weeks of gestation. An insult to the prenatal brain or a genetic anomaly could initiate a cascade of events in the developing brain, ultimately resulting in the sensory processing profile characteristic of SLI associated with the underlying abnormal neurobiology described. If this hypothesis is valid, then RAP deficits should be observable in preverbal infants, and would predict subsequent language delay or impairments. Studies suggest that this may indeed be the case.

The links between infants' ability to process brief, rapidly presented stimuli and later language development has been examined in a series of studies by Benasich and colleagues, who found that infants with a family history of SLI performed more poorly on measures of RAP compared with a control group. In a longitudinal follow-up, it was found that the RAP thresholds measured in infancy were strongly related to later language comprehension and production through 36 months of age. Moreover, there are also indications that these basic acoustic processing skills in infancy (e.g. auditory gap detection and RAP) are predictive of later language development even in infants who are not at higher risk for language disorders. Such findings provide support for the notion that poor processing of rapidly presented and/or brief acoustic cues in infancy might be diagnostic of later language delays and impairments (for a review, see Benasich, 1998).

TEMPORAL INTEGRATION

It has been suggested that functional impairments in children with SLI might arise from basic sensory integration deficits, reflecting in turn dysfunctional neural processing of rapidly changing sensory information. So how might temporal integration deficits be propagated within the auditory processing pathways? Within the central auditory system, each neural stage of processing has a unique set of acoustic filtering and temporal integration properties. Thus, the critical linguistic cues of speech (phonemes) are first extracted from the raw acoustic waveforms produced by the vocal apparatus, and then processed by multiple neural stations (Figure 3). At the level of the auditory nerve, which carries sound information from the inner ear to the central nervous system, temporal information is probably encoded millisecond by millisecond. The acoustic information is then processed by the medial geniculate nucleus (MGN) of the thalamus, where the high resolution of the signal carried by the auditory nerve is largely preserved. The first cortical processing area is the primary auditory cortex (A1). At the level of the thalamus and A1, neural responses seem to occur primarily to the onset of temporal change. After A1, the

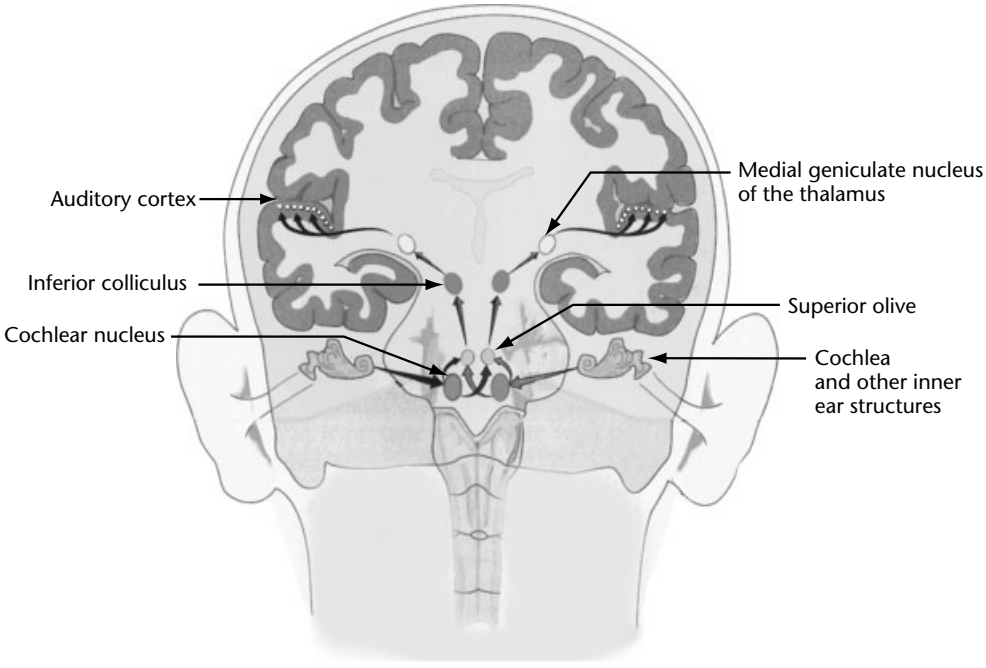

Figure 3. The ascending auditory processing pathways, as seen on a midcoronal section at about a 70° plane.

acoustic information is further processed by secondary and association auditory areas, which appear to respond to increasingly 'segmented' components of the original temporal information. Thus, each area where acoustic information is processed may be specialized for extracting different temporal features from a given sound. This may explain how a deficit at the most basic level of auditory processing could perturb the entire system. The subcortical structures implicated in SLI and dyslexia, such as the thalamus, are likely to be critical for encoding rapid temporal transitions (5–40 ms) embedded within longer acoustic sequences such as the speech stream. Therefore, if the rapid temporal integration capabilities of the thalamus are compromised (information is poorly encoded or incomplete), the cortical representations of the temporal features in a sound would degrade radically. Thus, the key elements of a neurobiological model in which auditory temporal processing defects lead, in a cascading fashion, to deficits in speech and language processing would be in place.

MULTIMODAL VERSUS AMODAL

Although SLI and dyslexia are defined as specific disorders of language in the presence of otherwise normal development (i.e. normal intelligence), there are reasons to question these diagnostic criteria as only applying to the auditory system. Research has shown that individuals with developmental language disorders exhibit processing deficits in other modalities, including motor coordination, and tactile and visual perception; see Tallal *et al*. (1985) for a review. It should be noted, however, that it has been proposed that some of these deficits seen in children with SLI and dyslexia might be the result of poor attention span (not explicitly assessed by traditional intelligence tests), and indeed quite a high proportion of these children meet the criteria for attention deficit disorder. To address this issue, future research must control for or eliminate variations in sustained attention in sample populations. Despite this caveat, there is accumulating evidence in support of the idea of a multimodal rapid sensory processing impairment in individuals with developmental language disorders.

Of particular interest are studies of visual processing that have revealed that the ability to process fast, low-contrast visual stimuli is impaired in people with dyslexia. The system responsible for processing this type of information is called the magnocellular pathway of the visual system. In contrast, no difference was found between participants with dyslexia and control participants in parvocellular visual processing. The parvocellular pathway of the visual system is responsible for processing high-contrast, fine detail, and color information. The magnocellular deficit is evident in behavioral assessment, and is also reflected in neurophysiological measurements: ERPs to rapidly presented visual stimuli have longer latencies in dyslexia, reflecting a slower neural response. Furthermore, postmortem analyses of the brains of individuals with dyslexia have revealed changes in the magnocells (larger cells which have faster conduction velocities than parvocells) in the lateral geniculate nucleus, the visual nucleus of the thalamus. Magnocells in dyslexic brains were abnormally small in comparison with controls. This convergence of behavioral, anatomical and electrophysiological evidence led to suggestions of a visual processing disturbance in dyslexia in the magnocellular system (Lehmkuhle *et al*., 1993; Galaburda *et al*., 1994).

Studies by Talcott, Witton and colleagues have demonstrated that individuals with dyslexia are impaired in processing dynamic visual and auditory events, and also have elevated thresholds for high-frequency tactile stimuli (Talcott *et al*., 2000). These findings, together with the results of physiological investigations (ERP and postmortem studies) support the possibility of a multisensory deficit in rapid processing in individuals with dyslexia. Future experiments with SLI populations may help to characterize potential multimodal temporal processing impairments in developmental language disorders.

CONCLUSION

Much is still unknown about the developmental disorders of language, despite years of research. Debate continues as to whether disorders such as SLI and dyslexia result from deficits in basic sensory processing that affect developing language, or whether the difficulty is primarily one of acquisition of higher-level semantic, syntactic and phonological skills. However, with the focus on atypical or inefficient processing of basic acoustic input, progress has been made in delineating potential causative mechanisms. One scenario that could lead to such effects involves a confluence of genetic and/or environmental factors, which may occur in the perinatal period during key periods of neural development, disrupting the normal cascade of events. Atypical asymmetry, as compared with control subjects, is consistently reported in SLI

and dyslexic groups, as well as a higher incidence of neuroanatomical abnormalities in areas important to language processing. A substantial number of contemporary functional imaging studies report reduced or abnormal patterns of activation in language areas in these populations. Moreover, close examination of the results of such studies supports the idea that processing rapidly presented and/or brief acoustic cues (both speech and nonspeech) is impaired in individuals with developmental language disorders.

Many questions remain unanswered regarding the developmental events and underlying pathological changes that lead to the specific behavioral deficits that are the hallmark of developmental disabilities. Nevertheless, it is possible that the neural characterization of these specific developmental disabilities, in combination with known behavioral profiles, can be used to gain some insight into their etiology. Unfortunately, studies that might link the developmental course of neural anomalies to expressed cognitive deficits in a causal fashion are exceedingly difficult to perform in humans. Furthermore, the nature of higher-order cognitive deficits (e.g. in language and reading) has not lent itself to study in nonhuman models, though such models have been useful in anatomical and basic sensory processing experiments. One promising area of investigation is prospective longitudinal studies of infants at high risk of SLI and dyslexia. This approach may allow the concomitant deficits in sensory processing, phonological processing and attention seen in children with SLI to be parsed. In addition, the emergence of more sensitive and sophisticated neuroimaging technology (both functional and anatomical) promises to provide additional evidence about the deficits implicated in developmental disorders of language. A better understanding of the developmental disorders of language will make the ultimate goal of remediation more attainable.

Dissociation Methodology

Intermediate article

Mark G Packard, Yale University, New Haven, Connecticut, USA

CONTENTS

Dissociation methodology is an experimental design tool used to examine functional dichotomies and independence between and within various domains of psychological function.

INTRODUCTION

The brain is capable of perceiving electrical messages transmitted by the optic nerve as visual information, and those by the auditory nerve as sound information. The nineteenth-century German physiologist Johannes Müller (1801–1858) proposed the 'doctrine of specific nerve energies' to account for these observations. This hypothesis essentially holds that independent neural pathways determine the perceived quality of sensory information, and provides a basis for understanding the empirical data indicating that deaf individuals can possess normal eyesight and blind individuals can possess normal hearing. These findings also provide evidence of a dissociation of the neural circuitry underlying these two sensory capabilities, at least at some fundamental level of psychological processing.

In the psychological sciences, dissociation methodology has been used extensively as an experimental design tool to investigate possible functional dichotomies that might shape understanding of fundamental laws in various domains of cognition and behavior, such as language, memory, and emotion. An early example of the use of this methodology is provided by the discovery of the different roles played by Broca's area and Wernicke's area in language expression and reception, respectively.

In the field of cognitive neuroscience, scientists often discover evidence of a functional dichotomy at the neuroanatomical level, and speculate as to the differences in operating principles that best relate this anatomical (neural level) dissociation to behavior or cognition (psychological level).

Several functional dichotomies have been proposed in different areas of psychological research, and each has influenced theoretical debate in these areas. These include, for example, dissociations between object recognition and localization visual pathways, explicit versus implicit memory, conscious versus unconscious perception in 'blindsight', or effortful versus automatic attention. The development of each of these hypotheses, and several others on their respective topics, relies on dissociation methodology.

SINGLE VERSUS DOUBLE DISSOCIATIONS

A description of the types of dissociations that may be observed in a particular experiment can be readily understood using the following scenario. Consider a black box with two levers (X and Y) protruding from the sides, and containing a latched top and a sliding front drawer. When lever X is pulled, the top of the box flips open (box operation A). However, pulling lever X does not effect the operation of the box drawer. In attempting to elucidate the functions of lever X, this manipulation has produced a single dissociation: pulling lever X effects box operation A but not B. Next, when lever Y is pulled, the drawer in the front of the box slides open (box operation B). However, pulling lever Y does not effect the operation of the box top. These manipulations have produced a double dissociation, in which pulling lever X influences box function A but not B, and pulling lever Y influences box function B but not A. If the black box used in this example represents a mammalian brain, and the two levers represent different brain structures, then one might discover that selective damage to lever X impairs box function A but not B, and selective damage to lever Y impairs box function B but not A.

The double dissociation methodology used above illustrates a fundamental approach for examining the hypothesis that independent neural and/or psychological functions exist. Hans-Lukas Teuber (1955) originally coined the term 'double

dissociation', and provided early arguments for the importance of this pattern of results in supporting the hypothesis of functional independence between neural structures. Teuber noted that neuropsychological studies employing dissociation methodology often reveal only a single dissociation (e.g., damage to structure X impairs performance of A but not B). Although it is tempting to conclude that A and B are functionally independent based on a single dissociation, it is also possible that their operation may be arranged in a hierarchical fashion. Clearly, if the primary goal of dissociation methodology is to provide information concerning the functional independence of various psychological and/or neural processes, then a double dissociation is necessary for the strongest version of such a hypothesis to be advanced.

Within the broader field of cognitive science, examples of double dissociations exist from research in traditional neuropsychology (the study of individuals who have suffered brain damage through injury or disease), more recent studies employing brain imaging techniques and interference tasks in normal humans, as well as research in nonhuman experimental animals. Research on the neurobiology of learning and memory can be considered an exemplar of the historical use of dissociation methodology in the psychological sciences, as this experimental tool has been used effectively across four decades of research in this area. Of course, the logic behind dissociation methodology and the use of this approach are not unique to memory research.

DISSOCIATION METHODOLOGY

Examples from Human Neuropsychology

A double dissociation of the roles of two cortical regions in facial identity illustrates the usefulness of dissociation methodology for providing information about the organization of a particular psychological function. Patients with bilateral damage of the ventromedial frontal cortex are able to recognize the identity of familiar faces in a normal fashion, but are unable to generate a discriminatory skin conductance response (SCR) to the same faces. In contrast, patients with bilateral occipitotemporal cortical damage display impaired identity recognition yet can generate discriminatory SCRs to familiar faces. These findings have been interpreted to suggest that a functional independence exists between the neural circuitry that processes somatic-based 'valence' and nonsomatic-based 'factual' information in this process. Note that interpretation of the psychological operating principles that might account for the anatomical double dissociation observed in any behavioral study ultimately involves debate over theoretical constructs such as emotion and memory, and often relies to some degree on *a priori* assumptions that are made at the time the behavioral tasks are developed. Nonetheless, an empirical double dissociation on task performance in humans with brain damage compromising different neuroanatomical structures provides the necessary evidence for postulating the existence of functionally independent systems.

Neuropsychological studies have also revealed double dissociations in performance of brain-damaged humans on pairs of memory tasks; patients with limbic-diencephalic damage acquire a probabilistic learning task normally, but memory for the training episode as assessed in an interview questionnaire is severely impaired. In contrast, patients with Parkinson disease are severely impaired in acquisition of the probabilistic task, yet demonstrate normal memory for the training episode. These findings have been interpreted as evidence of a double dissociation between the role of limbic-diencephalic and neostriatal brain regions in declarative memory and habit learning, respectively (Knowlton *et al*., 1996). Again, separate theoretical accounts of the critical differences in the psychological operating principles that underlie the dissociations observed in performance of different learning and memory tasks have been offered and debated, and several 'dual-memory' theories describing different sets of principles exist. However, it is the use of dissociation methodology that has ultimately driven the development and refinement of these theories.

Imaging the Living Human Brain

The advent of technologies for imaging the living human brain has provided an extraordinary avenue for the use of dissociation methodology to elucidate the organization of various psychological functions. Neuroimaging studies have revealed double dissociations in the patterns of brain activity associated with performance of different tasks. For example, functional magnetic resonance imaging has been used to demonstrate a double dissociation in levels of activation of the left perisylvian cortex and the dorsolateral prefrontal cortex in working memory processes. Based on these findings, the former structure has been proposed to mediate working memory storage

processes, and the latter to mediate executive control processes contributing to accurate working memory (Postle *et al*., 1999). Other brain imaging research using injections of radiolabeled water in combination with positron emission tomography to measure regional cerebral blood flow has revealed dissociable roles of the ventral and dorsal human extrastriate cortex in object and spatial visual processing, respectively, consistent with a prominent dissociation in these visual pathways or processes originally developed in research with nonhuman primates (Haxby *et al*., 1991).

Research in Experimental Animals

Research in experimental animals (e.g. nonhuman primates and rats), in which brain manipulations can be performed in a localized manner, provides further examples of empirical double dissociations. In monkeys, lesions of the medial temporal lobe impair performance of a delayed nonmatch to sample task, but do not affect acquisition of a concurrent visual discrimination (Mishkin and Petri, 1984). In contrast, lesions of the ventrocaudal neostriatum impair concurrent discrimination learning, but do not affect performance of delayed nonmatch to sample behavior (Fernandez-Ruiz *et al.*, 2001). In rats, a double dissociation between the roles of the hippocampal system and caudate nucleus in acquisition of spatial and visual discrimination tasks, respectively, has been observed following lesions of these two structures (Packard *et al.*, 1989).

The most compelling experimental design using dissociation methodology is one in which as many domains of psychological processes as possible can be equated across different tasks. An important feature of the pairs of tasks used in the rat study is that they each involved similar motor (maze running), sensory (use of visual cues), and motivational (appetitive) characteristics, and were hypothesized to differ primarily in mnemonic requirements.

The hypothesis of functional independence between brain areas in these memory tasks is strengthened by converging evidence from manipulations that affect neurochemical mechanisms. For example, localized intracerebral injections of drugs affecting various neurotransmitter systems have been used to doubly dissociate the roles of different brain regions in memory consolidation. Unlike traditional lesion techniques such as the use of irreversible or reversible lesions in which dissociations are revealed as an impairment in performance, drug injections have been used in these same brain regions to produce double dissociations using memory-enhancing agents (Packard and White, 1991).

CONCLUSION

Dissociation methodology has been used extensively to gather evidence supporting the possible existence of functional dichotomies in various psychological domains. The examples of double dissociations provided in this brief article illustrate the use of this methodology in developing theories of memory organization in the mammalian brain. Historically, the use of dissociation methodology has not been limited to this research topic, and important examples exist of dissociations in tasks measuring perceptual, attentional, and motivational processes, as well as complex language and numerical capabilities in humans.

An important goal of dissociation methodology is to provide evidence of functional dichotomies. However, as dissociation methodology has gained widespread use in psychological science, several scientists have stressed that such conclusions must be made cautiously, and others have raised reasonable concern over the use of dissociation methodology to develop a potentially endless taxonomic classification of various psychological functions. As considered earlier, in view of hierarchical relationships a single dissociation can never be interpreted as providing unequivocal evidence of functional independence. Moreover, even a double dissociation may not be an entirely sufficient condition for offering such a conclusion (Weiskrantz, 1968). For example, the observation of an empirical double dissociation of the effects of damage to different brain structures (X and Y) on performance in two different memory tasks (A and B) could conceivably be influenced by manipulation of a particular parametric setting such as task demand (e.g. delay interval or memory load; Olton, 1989). In this case, rather than posit a strong functional independence between the roles of brain structures X and Y in task performance, one might postulate that a third factor influencing performance on both tasks may be interacting differentially with each structure. Analyses of parametric settings in experiments using dissociation methodology are likely to be of particular importance in the psychological sciences, and may provide constraints on the number of fundamental dichotomies that are ultimately deemed dissociable at a functional level.

As dissociation methodology continues to find widespread use in brain imaging research, it should be noted that there are caveats in interpretation of data obtained in studies measuring

localized increases in brain activity. For example, in some imaging studies activation of particular brain regions has been observed in tasks for which there is neuropsychological data indicating that damage to these same brain areas does not impair task performance. Thus, dissociations between the roles of different brain structures in behavior may be revealed in a neuropsychological study when brain damage is present, but not observed when imaging techniques are applied to the intact human brain. Conclusions about the necessary versus sufficient roles of different brain structures implicated in a dissociation study using neuroimaging techniques may be difficult, and converging evidence from neuropsychological testing in individuals with brain damage is likely to be important for interpretation of the ultimate functional significance of the dissociations observed. A similar caution is necessary in interpreting dissociations at the functional level using electrophysiological methodology, or more recently developed molecular science techniques that use gene expression as for a marker of nerve cell activation (e.g. c-*fos* activation). Nonetheless, if the functional dichotomies proposed to underlie the double dissociations observed at the neural and/or psychological level prove predictive across experimental settings using converging techniques, then the promise of dissociation methodology will continue to be the possible discovery of fundamental scientific laws.

Down Syndrome

Introductory article

Ira T Lott, University of California, Irvine, California, USA

CONTENTS

Down syndrome is a chromosomal disorder characterized by specific dysmorphic features, organ malformations, and variable but often severe learning difficulties.

INTRODUCTION

Down syndrome (DS) is the most common known form of developmental disability. First described by Langdon Down in the *London Hospital Reports* in 1886, the disorder was given scientific focus by Lejeune who identified the chromosomal abnormality in 1960. Despite the mental and physical handicap invariably associated with the disorder, people with Down syndrome have been prominently represented in many areas of daily life, including sports and the entertainment industry.

INCIDENCE AND GENETIC BASIS

Down syndrome (DS) is a genetic disorder that occurs once in every 600–1000 live births and affects all races and both sexes equally. The presence of additional chromosomal material has been shown to be responsible for the condition. The vast majority of individuals with DS have received the extra chromosomal material from an error involving the separation of chromosomes during the cell divisional process of meiosis. During normal meiosis an originator cell containing two copies of each of the 23 chromosomes is divided into daughter cells, each containing a single copy of each chromosome. In DS an error in this process, nondisjunction, results in a sperm or egg cell containing two copies of chromosome 21 instead of the usual single copy. When this sperm or egg cell pairs at fertilization with the other normal complement containing a single copy of chromosome 21, the resulting fertilized egg has three copies of chromosome 21 instead of the usual two – hence the alternative name for the syndrome, 'trisomy 21'. Nondisjunction is much more likely to occur in maternal than paternal meiosis. The actual cause of this error is unknown but it is more likely to occur in older women.

In about 4% of cases the extra copy of chromosome 21 is the result of the attachment of chromosome 21 onto another chromosome. This type of DS is called 'translocation DS' and unlike the disjunction error it occurs equally in males or females and is not age-dependent. Interestingly, one cannot determine by appearance or physical examination whether the condition is a result of a nondisjunction or a translocation. The third mechanism discovered for DS involves a genetic error in which there is a coexistence of normal and trisomic cell lines. This type of DS is called 'mosaic'. It has been argued that people with the mosaic form of DS have a less severe expression of the disorder since not all of the cells are trisomic. However, identifying mosaic DS based on its expression is difficult for even the most experienced clinicians.

It is not clear how the extra genetic material in DS accounts for the spectrum of clinical abnormalities in the disorder. The imbalance in genetic material appears to cause a pertubation in the timing of developmental sequences which eventually results in the clinical expression – phenotype – of the condition. Some individuals diagnosed with DS have only a tiny portion of chromosome 21 existing in triplicate. This small portion is enough to cause the phenotypic expression common to DS, and has thus been identified as the Down syndrome critical region.

CLINICAL SIGNS AND SYMPTOMS

Every physical feature of DS can be seen in a small percentage of the normal population. It is only when the features are combined into a single

individual that one has the appearance or the phenotype of DS. Although Langdon Down became confused about the cause of DS, he was the first to describe the physical characteristics of the disorder. The middle portion of the face is flat. There is an upward slant of the eye sockets (or palpebral fissures). The irises are speckled (Brushfield spots). The hands and feet are short and broad. There is an incurving of the fifth finger (clinodactyly) and there is a separation between the first and second toe. The patterns of the skin creases in the palm impart a particular appearance to the hand of a person with DS, and the major crease across the palm harkens back to an earlier evolutionary appearance (simian crease). The tongue is thickened and this is one of the factors contributing to a lack of clarity in the speech of people with DS.

People with DS are subject to certain illnesses involving organ systems other than the brain. There is a high incidence of thyroid gland dysfunction, which can produce thyroid hormone excess or deficiency (the latter is more common). The immune cells of the body react abnormally in DS and this causes a predilection to infections such as pneumonia and hepatitis. The heart is malformed in DS about 50% of the time and the most common lesion is a defect between the atrium and the ventricle. In some cases surgical repair of the lesion is required, but in many instances the effect on cardiac function is minimal and further intervention is not necessary. The immune problem that underlies the tendency to infection may also contribute to an increased incidence of leukemia in DS. Most cases of leukemia in DS occur in children less than 10 years old.

The ear canals in DS are small and misshapen. As a result, children with DS have frequent ear infections and run the risk of hearing loss along with other complications. A hearing loss that would be a mild handicap for a normal child can be devastating to a school-age child with DS who is struggling against the cognitive disorder associated with the condition. Tongue size and enlargement of the tonsils may provoke periodic cessation of breathing during sleep in DS (sleep apnea) and result in fatigue as well as poor mental performance the next day.

Whether people with DS age prematurely has not been decided with certainty. Skin laxity, adult-onset diabetes, cataracts, and orthopedic difficulties would argue for a precocious biological aging. However, people with DS seem to have a low incidence of atherosclerotic heart disease and hypertension – factors that distinguish them from aging people in the general population. The tendency to Alzheimer disease is a special circumstance (see below).

COURSE OF DS

The infant with DS is often in a vulnerable state. Muscle tone is lax and motor development is often delayed. Infection always looms as a possibility. Congenital heart disease, immune dysfunction, thyroid abnormalities, and the tendency to leukemia are always present. Given so many potential obstacles, it is reassuring to see that so many children with DS grow up and thrive. Particular attention to people with DS is required across the life span, and a universal set of guidelines for preventive intervention is increasingly being applied within the medical profession.

NEURAL CORRELATES

The experienced neuropathologist can often make a diagnosis of Down syndrome by the appearance of the brain. Certain neuroimaging procedures afford the same opportunity. In DS, the brain is slightly underweight, foreshortened front to back, and has a steep decline to the posterior regions.

Muscle tone is abnormally low in infants with DS and this is a sentinel sign of the disorder at birth. The ligaments are lax and this provides a problem in stability for younger children with DS. More worrisome is the ligamentous laxity that occurs in the bones at the top of the spinal column. This atlantoaxial junction is subject to more movement in DS than seen in the general population and occasionally the spinal cord will be compressed by the vertebrae (atlantoaxial dislocation). For this reason, people with DS should have an X-ray examination of the spinal area before participating in certain sports.

Although a cognitive deficit is universally seen in DS, there is a broad range of potential abilities in the disorder. This variation suggests that we do not yet understand the real potential of people with this condition or how to account for the spread of abilities. Social abilities often allow the child and adult to function in a more adaptive manner than would be predicted on the basis of tests measuring general intelligence.

One area of challenge for people with DS about which there is universal agreement is the linguistic system. The typical person with DS has more difficulties with language than would be predicted on the basis of overall cognitive functioning. Verbal memory is a particular deficit. People with DS can not only recall fewer digits in a span than can

people in the general population, but they also can recall fewer digits than intelligence-matched control subjects who do not have DS. The rate of acquiring new vocabulary is slower in DS than in children of similar mental age.

Epileptic seizures may occur at two separate points in the life span of an individual with DS. In infancy, seizures often take the form of sudden jerking movements called 'infantile spasms'. In later life the onset of seizures may herald the decline associated with Alzheimer disease. Since the early description of DS, personality characteristics have included a strong power of imitation, good sense of humor, and a tendency towards obstinacy. As a rule, people with DS appear to be outgoing, affectionate, with social quotients exceeding intelligence quotient (IQ) measures between 4 and 17 years of age. Older age in DS often brings bouts of depression.

LINKS WITH ALZHEIMER DISEASE

Alzheimer disease (AD) is the most commonly recognized form of dementia and is manifested by a progressive and ultimately fatal deterioration in brain function and capacity. From the late 1940s, researchers have found a curious association between DS and AD. Almost every brain examined from individuals with DS over the age of 40 years shows microscopic signs of the disorder. Often the primitive lesions of AD can be seen in brain tissue from children and young adults with DS. Despite the ubiquity of the microscopic signs of AD, not every person with DS develops clinical symptoms of the disorder. Prevalence rates vary widely, but average about 25%. The early symptoms of AD include change in personality, loss of ability to carry out complex daily skills, and (as mentioned above) the onset of epileptic seizures. As the decline progresses, awareness of the environment is lost and the ability to acquire recent memories ceases. In DS the disease may run a fatal course within 5 years. One of the factors imparting a predisposition to AD in DS relates to a gene located on chromosome 21 which is triplicated in DS. This gene is responsible for producing an overabundance of the peptide amyloid. Amyloid deposition in brain appears to have a key role in the pathogenesis of AD. (*See* **Alzheimer Disease**)

TREATMENT AND GENETIC COUNSELING

There is no medical cure for DS but there are many opportunities to prevent complications in the disorder and to provide a nurturing environment for the realization of full potential for people with this syndrome. A signal advance in modern society has been the provision of opportunities for people with DS (and other forms of learning difficulties) to live and work within the community. No longer are people with DS sent to institutions to live their lives apart from society. With increasing vigilance among medical professionals and the general willingness to intervene on behalf of the child with DS, the life span for people with DS has been greatly extended.

Genetic counseling for DS shares many of the same principles that are applied to other genetic conditions. The genetic counselor's role includes:

- interpreting recurrence risk for families where a DS birth has occurred
- assisting other medical professionals in explaining the diagnosis of DS, patient management, and treatment options
- facilitating psychological assessments where indicated for both patient and family members
- providing information to families about support groups.

The recurrence risk for DS is dependent on the genetic form of the disorder. The disclosure of full information on genetic risks often involves 'cytogenetic' testing of the patient and possibly family members. The recurrence risk to a couple with the classical form of trisomy 21 is about 1%, but there is a strong maternal age dependency which may increase this risk and requires explanation for couples engaging in family planning. In the translocation form of DS, the risk is dependent on whether the translocation was inherited by a parent or occurred for the first time in that individual child. A parent who can transmit a chromosome 21 translocation is referred to as a 'balanced translocation carrier'. Such a carrier parent is asymptomatic and has the normal chromosomal complement, except that part or all of one copy of chromosome 21 is attached to another chromosome. In this case the genetic risk varies widely and is dependent upon the chromosome to which the translocated segment of 21 is joined. The genetic risk for the mosaic form of DS depends on the percentage of mosaic cells in the individual as well as the percentage of trisomic cells in the gonadal tissues. Counseling for these rare forms of DS is complicated and always requires the services of a professional genetic counselor.

For families who wish to know whether the fetus being carried has DS, several chemical compounds have been identified in maternal blood that have a predictive value for diagnosis in up to 70% of cases.

These are considered risk factors but are not diagnostic by themselves. More precise diagnostic data may be obtained prenatally by examining the amniotic fluid and determining the actual chromosomal complement of fetal cells. Maternal blood screening is best done at 15–17 weeks of gestation, whereas examination of amniotic fluid (amniocentesis) is generally done between 14 and 18 weeks of gestation. A newer procedure at around 10 weeks of gestation avoids amniocentesis and obtains fetal cells for genetic testing by sampling part of the placenta (chorionic villus biopsy). The complexity of prenatal diagnosis requires a close working relationship between professionals in obstetrics and in genetics. Many clinics specializing in these integrated services are available in modern medical systems.

Early Experience and Cognitive Organization

Introductory article

Barbara Landau, Johns Hopkins University, Baltimore, Maryland, USA

CONTENTS

There is much support for the idea that cognitive development is specialized, with different aspects of knowledge developing under different mechanisms and timelines. Many aspects of mature knowledge can be traced to innate origins. At the same time, variation in early experience due to genetic defects, blindness or deafness can lead to significant reorganization of the developing brain. Thus human cognitive development is constrained by innate potential, but is also affected by experience during early development.

INTRODUCTION

One of the great mysteries of human development is how our knowledge comes to be organized in the way in which it is. Two competing views have quite different answers to this. The nativist view holds that we are born with specific capacities to organize the world in the way that we do. This view can be traced to the thinking of philosophers such as Immanuel Kant and René Descartes. In contrast, the empiricist view holds that experience after birth molds our knowledge. This view is traceable to philosophers such as John Locke and David Hume. The nativist view is supported by the fact that different aspects of our knowledge have quite different forms, and these develop quite early in life without any formal tutoring. Yet some variations in early experience can have profound effects on brain organization, suggesting that there is some flexibility in the way in which the brain and mind organize the world. This article will consider two types of change in early experience. One is due to changes in an individual's genetic endowment, and the other is due to changes in an individual's sensory and perceptual experience.

SPECIALIZATION IN COGNITIVE DOMAINS

When considering the relative roles of innate potential and experience, it is important to understand that different aspects of knowledge have very different types of organization – that is, they are 'specialized' in the sense that the principles which govern one domain of knowledge may be irrelevant or inapplicable to the next domain. For example, our capacity for language allows us to learn language early in life, and to fluently produce and understand even quite complex sentences throughout life. This capacity reflects our knowledge of language, which is a complex, rule-governed system that allows us to produce and comprehend an infinite number of sentences. In contrast, our capacity to move around the world and find our way, to remember the spatial locations of objects, and to read maps, is part of a different system of knowledge. This system allows us to learn the spatial relationships between places in space, and to understand how to get from one place to another, even if we are travelling along novel routes. This is part of our spatial knowledge system, but it is irrelevant to our knowledge of language. Other cognitive domains are specialized as well. For example, our knowledge of number, causality, time and social relationships is governed in all of these cases by rules and representations that are distinctly different from each other.

Examining development under conditions of varying genetic endowment and/or different types of sensory and perceptual experience can shed light on the question of how cognitive specialization emerges. The nativist view would suggest that

there are strong biological constraints on the types of knowledge that humans can develop, and that changes in genetic endowment might have specific, targeted effects on cognition. At the same time, the empiricist view would suggest that changes in sensory or perceptual endowment – such as congenital blindness or deafness – might lead to changes in the way in which the brain's organization supports cognition. Evidence from recent research supports aspects of both views.

WILLIAMS SYNDROME: A GENETIC DISORDER THAT RESULTS IN SELECTIVE COGNITIVE IMPAIRMENT

Recently, cognitive researchers have become interested in Williams syndrome, a relatively rare genetic syndrome (1 in 15 000 live births) which is caused by a microdeletion of material (approximately 20 genes) on chromosome 7. Individuals with Williams syndrome show distinctive physical characteristics and an unusual cognitive profile. In general, these individuals are moderately mentally retarded, with an average IQ of around 60 (where 100 is the average for the general population). However, their retardation is not 'across the board'. Rather, individuals with Williams syndrome show severe impairments in their understanding of spatial relationships, but considerable strength in language ability. Their severe spatial impairments are manifested in a number of ways. One of the clearest examples is that they have extreme difficulty in copying simple figures. Figure 1 shows an example of drawings produced by two 11-year-olds with Williams syndrome, and one drawing produced by a normally developing child who was younger, but who had the same 'mental age' on an intelligence test, and had a roughly average IQ. It can be seen that the individuals with Williams syndrome could easily duplicate the colors in the model, but could not copy the spatial relationships shown there, resulting in a very distorted copy. In contrast, the normally developing child could reproduce both the colors and the spatial organization. The spatial impairment in people with Williams syndrome contrasts strikingly with their strong language capacities, which are demonstrated by a fluent, articulate

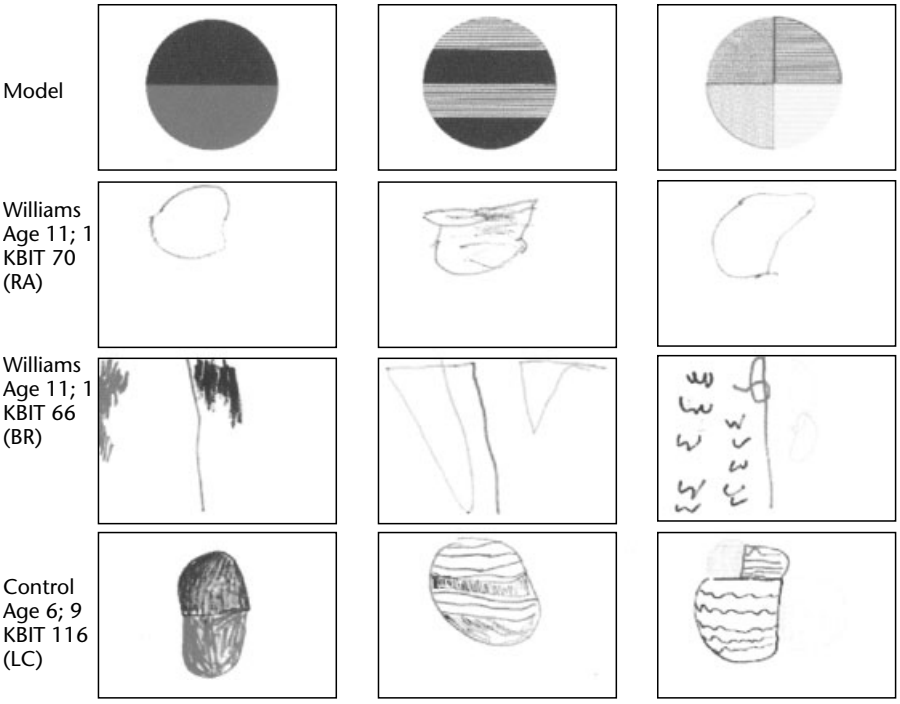

Figure 1. [*Figure is also reproduced in color section.*] Copies made by two 11-year-old individuals with Williams syndrome and a normally developing 6-year-old who was matched for mental age. Each model contains between two and four colors, and these are correctly copied by the children with Williams syndrome as well as by controls. However, there is considerable impairment of the spatial organization of Williams syndrome copies, resulting in unrecognizable configurations. Ages are stated in years and months. KBIT scores are from the Kaufman Brief Intelligence Test, and represent approximate IQ equivalents.

conversational style, relatively high scores on vocabulary tests, and the capacity to produce and understand sentences that are grammatically complex. Individuals with Williams syndrome also tend to be musical, and some people with this syndrome are highly skilled in musical activities such as singing and playing musical instruments. The striking impairment of spatial capacities, coupled with the fact that language appears to be strongly preserved in Williams syndrome, supports the idea that cognitive specialization might ultimately be linked to aspects of genetic endowment.

Researchers are currently asking many questions about the emergence of cognitive specialization in this syndrome. For example, it may be that the spatial impairment is more apparent in some aspects of the spatial knowledge system than in others. Some authors have conjectured that the profile of strengths and weaknesses within spatial cognition may be linked to somewhat unusual organization of the brain in Williams syndrome. One possibility is that the spatial impairment may be limited to certain specific spatial functions that are performed by the brain. The most obvious examples of spatial impairment in people with Williams syndrome are shown when these individuals are asked to copy an existing pattern, either by arranging a set of blocks to copy a pattern, or by drawing a copy of a model, as in Figure 1. However, people with Williams syndrome do not appear to show impaired performance on other spatial tasks. For example, they do not appear to have difficulties in recognizing faces or identifying pictures of objects, even when the objects are presented from very unusual viewpoints, as in Figure 2. In order to identify objects under these types of conditions, it would seem to be necessary to recognize both the parts of the objects and their spatial relationships. Thus this aspect of spatial capacity might be relatively spared in Williams syndrome, even though other aspects of spatial capacity are clearly impaired. Evidence from cases of normal adults who then sustain brain damage (e.g. through strokes) suggests that object recognition and identification may be carried by the brain's 'ventral' stream. The relative strength of object recognition in Williams syndrome may indicate selective sparing of functions carried by this stream. As another example, individuals with Williams syndrome tend to have some difficulty in planning visual–motor acts, such as posting a letter through a mail slot. Yet they have less difficulty when they must simply view the slot and compare its orientation to another sample slot. Again, some authors have conjectured that the relative difficulty in acting on objects, compared with simply perceiving and matching them, could be due to selective impairment of the brain's 'dorsal' stream. Finally, individuals with Williams syndrome perform better than normal children matched for mental age on tests of 'biological motion' perception, in which they perceive a moving animate figure that is shown only by a set of individual dots. Overall, the evidence suggests that there is specialization in the breakdown of spatial cognition in Williams syndrome. This and other hypotheses are currently being actively tested by researchers.

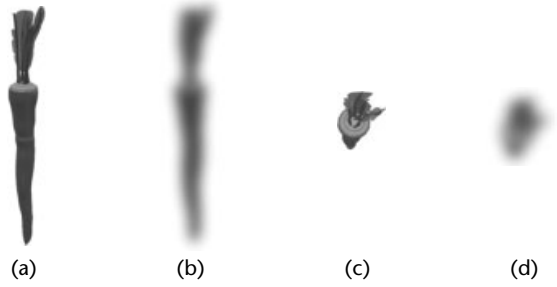

Figure 2. [*Figure is also reproduced in color section.*] These objects are easily recognized and named by children with Williams syndrome, despite the fact that they have profound spatial impairments. The objects are all the same carrot, but vary in whether they are common viewpoints (a and b) or unusual ones (c and d), and also in whether they are clear images (a and c) or blurred ones (b and d).

DOWN SYNDROME: A GENETIC DISORDER THAT SHOWS A MORE GENERAL DECLINE IN COGNITION

In comparison with Williams syndrome, Down syndrome has a very different cognitive profile, again suggesting that cognitive development may be partially under the control of genetic endowment. Down syndrome occurs in roughly 1 in 1000 births, and in the majority of cases it is associated with an additional copy of chromosome 21 (resulting in three rather than two chromosomes at that locus – hence the name 'trisomy 21'). Individuals with Down syndrome tend to have distinctive physical characteristics, although these are different from those in Williams syndrome. Furthermore, there are some gross anatomical differences between the brains of individuals with Down syndrome and those of individuals with Williams syndrome. Finally, the cognitive profile of the two groups is quite different. Individuals with Down syndrome are moderately retarded, but their cognitive profile is relatively even. That is,

they are impaired in various cognitive domains to roughly the same extent, and they do not show the striking profile of strengths and weaknesses that is characteristic of individuals with Williams syndrome.

A number of studies have directly compared the spatial and linguistic capacities of individuals with Down and Williams syndromes. The results of spatial studies show that although both groups are impaired relative to normally developing individuals, people with Williams syndrome perform even more poorly on some spatial tasks than individuals with Down syndrome who have the same IQ. In addition, they may use different types of solutions for the same spatial problems. For example, several reports indicate that individuals with Down syndrome can replicate more global spatial aspects of a model, whereas individuals with Williams syndrome are more likely to replicate accurately the more local aspects of a model – the smaller elements that are put together to make up the overall pattern. It is possible that these different patterns of spatial impairment in Down versus Williams syndrome are due to different types of brain organization and impairment.

The results of language studies show that although neither group performs at a level commensurate with its chronological age (i.e. they are both impaired to some extent), individuals with Williams syndrome outstrip those with Down syndrome who have the same IQ. Moreover, when individuals with Williams syndrome are tested on grammatically complex structures, they tend to do well compared with individuals with Down syndrome. The spontaneous speech of individuals with Down syndrome does not exhibit a large amount of grammatical complexity. For example, longer sentences are primarily produced by stringing together simple phrases with conjunctors such as 'and'. In contrast, individuals with Williams syndrome produce longer sentences that exhibit a considerable degree of grammatical complexity, including relative clauses (e.g. 'The boy that was looking at the man jumped over the fence'). The fact that these can be fluently produced by individuals who are retarded points to the possibility that language capacity may develop rather normally in the case of Williams syndrome. In the case of Down syndrome, the general dampening of linguistic capacity is roughly commensurate with the overall retardation of these individuals. The combination of cases indicates that changes in genetic endowment may have highly specific and targeted consequences for cognitive development.

CONGENITAL BLINDNESS AND DEAFNESS

Sensory deficits such as congenital blindness and deafness may result in reorganization of the brain. There is considerable evidence that knowledge in a variety of domains can develop normally in individuals who are blind or deaf from birth. For example, congenitally blind individuals show the capacity to understand locations in space, to get from one place to another by independent locomotion, and to read haptic or Braille maps. As another example, congenitally deaf individuals acquire manual (signed) languages effortlessly, just as hearing individuals effortlessly acquire spoken languages. In these cases and others, the knowledge that develops is organized in the same manner as in individuals who are sighted or hearing. This indicates that cognitive organization can emerge guided by principles that do not depend on these particular types of sensory or perceptual experience (i.e. seeing or hearing).

However, there is also evidence of flexibility in the way in which the brain accomplishes these cognitive functions. This flexibility is evident from studies of brain activity following sensory or perceptual deprivation. A number of studies have shown that changes in early experience can have a major impact on the organization of the brain's cortex. If an individual is deprived of input from sensory receptors, the cortical areas that are normally activated by those receptors are 'taken over' by other types of input. For example, in adults who have had a limb amputated, the cortical area that used to represent that limb (i.e. be activated by it) now becomes responsive to stimuli from other areas of the body that would normally activate neighboring areas of the cortex. In effect, the areas of cortex that have been 'abandoned' by the amputated limb are commandeered to serve other functions. Other research shows that individuals who have been blind or deaf from birth have brains that are organized somewhat differently from those of individuals who are sighted or hearing. For example, in some research, congenitally blind individuals who perform tasks using the skin and hands show brain activation in areas that are normally 'designated' for vision. In this case, the visual areas are commandeered for touch, and hence the area of cortex dedicated to touch is expanded in these individuals. Other research has shown that congenitally deaf individuals show unusual brain activation patterns when they pay attention to stimuli in their peripheral visual field – that is, outside the central view. Additional evidence

shows that these individuals may be more accurate at detecting these stimuli than hearing individuals. In essence, congenital auditory deprivation appears to lead to a reorganization of the brain in which there are changes in the ways in which visual stimuli are processed.

SUMMARY

Mature knowledge reflects the development of a set of highly complex, differentiated and specialized systems, including language, spatial knowledge, number, causality and other domains. These specialized systems are partly under the control of genetic endowment and partly under the control of variations in experience. The results of genetic deficits are highly specific, with some syndromes targeting specific knowledge systems and other syndromes having more general effects. The results of massive variation in experience, such as congenital blindness or deafness, are some degree of reorganization in the brain, indicating plasticity during early development.

Education, Learning in

Introductory article

Stanton Wortham, University of Pennsylvania, Philadelphia, Pennsylvania, USA

CONTENTS

Learning takes place in many settings, but educational institutions foster both breadth and depth of learning. Different types of teaching make very different assumptions about what learning is.

INTRODUCTION

Theories of learning have been applied most often in educational institutions. The relationship between cognitive science and education has benefited both scientists and practitioners. Scientists have used educational settings to develop and test their theories, and practitioners have used new knowledge about learning to design more effective education.

Broadly conceived, education is the process of continuing the human species. All humans are born immature, without the knowledge and skills they will need to function – without language, without knowing how to use complex tools, and so on. The species continues because adults communicate knowledge and skills to the next generation. This intergenerational transfer allows future generations to build on prior accomplishments.

Thus all humans teach. Whether they realize it or not, all teachers act as if some theory of learning is true. Particular ways of teaching make assumptions about what learning is. Furthermore, theories of learning themselves rest on conceptions of human nature. Different accounts of how people learn assume different things about what people are essentially like.

This article describes three broad theories of learning – together with the conceptions of human nature underlying these theories – and the types of educational practice that have been built on these theories. The article has two purposes. First, it is important to recognize the theories of learning and conceptions of human nature that underlie various types of schooling. The article describes how typical teacher and student behavior makes assumptions about how learning happens. Second, as theories of learning have developed, we have learned that earlier theories were too simple. The article describes how more complex accounts of learning and human nature are needed to guide educational practice.

BEHAVIOR

Theories of learning that focus on behavior are called 'behaviorist'. Behaviorists argue that humans should not consider themselves special. Copernicus showed that the earth was not the center of the solar system, and Darwin showed that humans were not qualitatively different from animals. Behaviorists further puncture our sense of superiority, arguing that humans do not have free will to act as they choose. 'A person does not act upon the world', B. F. Skinner said, 'the world acts upon him.' On this theory, the environment shapes people's behavior through reinforcement. Just as Darwin showed that organisms appear designed by a creator to fit their niche, even though adaptation is in fact a result of random variation and natural selection over time, behaviorists show that humans appear to reflect and choose their actions, while in fact their behavior has been shaped by reinforcement.

To learn, then, is to change one's behavior in response to reinforcement. This account of learning contains three central elements: behaviors by the organism, conditions present in the environment, and consequences that follow from various behaviors. People, like other animals, will generate various behaviors in a new situation. Some of these behaviors will result in positive consequences, while others will not. People learn to respond more often with behaviors that were reinforced positively in a given situation.

Behaviorist Education

On a behaviorist account, teaching is the systematic shaping of a student's behavior. The teacher has control and students are raw material to be shaped.

Teachers arrange reinforcements so that students come to behave as teachers want them to. Scientists have successfully taught pigeons to play ping pong, for instance, by designing a long series of intermediate skills that lead from natural pigeon behavior to ping pong. They reinforce the pigeons for performing each of these intermediate skills, in turn, until the pigeons produce the target behavior. Similarly, teachers of human students should define the target behaviors, design a path of intermediate behaviors from what students can already do, then reinforce students at each step until they produce the target behavior.

Behaviorists have designed 'teaching machines' that dispense rewards as students accomplish prespecified tasks. One famous picture shows a small boy playing a piano, with a candy dispenser on top. Although these pictures now look outdated, many practices in today's schools presuppose a behaviorist account of learning. Discipline systems almost always rely on rewards and punishments to shape students' behavior. Grades are used as reinforcers. And many classroom practices, from worksheets to testing, involve teachers rewarding students for producing desired behavior.

Research in cognitive science from the second half of the twentieth century has shown that behaviorism is not an adequate theory of learning. People often act because they value activities intrinsically, not for external reinforcement. As described in the next section, people also develop complex representations of the world and reflect on their actions in a way that behaviorists denied. Why, then, do students and teachers so often act as if behaviorism were true?

Because it works. If you have control over effective reinforcers, you can shape people's behavior. Behaviorism is not false. It is true, but it is not the whole truth. Under certain circumstances, people do learn just like animals. The question is whether we should create more circumstances that encourage people to learn in this way. Cognitive scientists claim that we should not, because humans have the potential to learn in nonbehaviorist ways, and because students can develop deeper knowledge when encouraged to learn differently.

MIND

Theories of learning that focus on mental representations are called 'cognitivist'. Cognitive approaches to learning see humans as actively making sense of the environment. People develop mental models of the world and act on the basis of these models, not simply in response to reinforcements. When people encounter a new situation, they assimilate it to their own pre-existing models of the world. Learning involves expanding those mental models, in order to make them more accurate.

This account of learning distinguishes between genuine understanding and merely producing the right behavior. People often just parrot the right answer without understanding it, just as pigeons can play ping pong without understanding what they are doing. True learning involves a deeper grasp of the subject matter, such that people's mental models line up with the world. Furthermore, people cannot be forced to learn. True learning requires a change in people's internal models, and learners must change these models themselves.

Cognitive scientists have described various structures and processes that underlie learning. There seem to be some universal constraints, which presuppose people to certain broad types of mental models. Particular domains of knowledge are also organized in distinct ways, to facilitate learning. And individuals sometimes vary in the types of structures that they operate most effectively with. For instance, there are different learning styles – some people learn most effectively through verbal explanations, while others learn more effectively through visual diagrams, and so on.

Cognitivist Education

From this perspective, learners need to develop deeper understandings, not just produce the right behaviors. Deeper understandings cannot be imposed on students, because they must construct their own mental models. So teachers do not shape students, nor do they deliver correct answers. Teachers should develop educational environments that push students to broaden and deepen their own models, thus opening up areas of the world that students have not thought about. After teachers have set up rich educational environments, ones that contain puzzles designed to provoke students to reflect, then they must allow students to explore. Teachers can challenge students, by pointing out contradictions in their beliefs, but students themselves must recognize the puzzles and work to solve them. Teachers can explain, but if students can only repeat a teacher's explanation then they have not truly learned. Students themselves must integrate new experience with their own developing mental models.

Assessment is a bigger challenge for cognitivist educators than for behaviorist ones. Behaviorists pre-define the educational objective, and they assess whether students produce the desired behavior.

Genuine cognitive learning, in contrast, takes place internally. Teachers can infer about students' understandings, but they do not want to encourage rote learning by using simple tests. Instead of assessing whether students get the right answers, cognitivist educators try to assess underlying thought processes by examining how students reached certain answers.

Cognitivist theories of learning are more widely accepted than behaviorist ones. Nonetheless, there is less cognitivist teaching than behaviorist teaching in our schools. This happens partly because cognitivist education is difficult for both teachers and students. Because they are responsible for students' learning, it is hard for teachers to let students pursue their own ideas much of the time. Students also find it easier to write down what the teacher says, instead of developing their own accounts. This sort of resistance can be overcome, and many teachers do successfully encourage students to develop their own deeper understandings. But behaviorist practice has been harder to overcome than behaviorist theory.

SOCIETY

Theories of learning that go beyond mental representations to include social practices are called 'social cognitivist'. Cognitivist learners are autonomous, developing models themselves to make sense of the environment. Recent theories present the learner, instead, as a participant in social activities. Learning, on this account, is a transformation of participation in activity, not primarily the creation of mental models. Instead of simply developing their own representations, people become increasingly competent participants in the intellectual lives of those around them.

From this point of view, people learn as they more competently use tools to facilitate thought and action. Adults incorporate learners into their activity by teaching them how to use certain cognitive tools. Some of these tools are mental, such as mnemonic devices. Others are objects, such as maps. But learners do not have to construct them alone, because these tools have already been developed and can be borrowed from others.

Any theory of learning presupposes a 'unit of analysis'. This is the smallest unit that preserves essential behavior of the whole. In order to study the behavior of water, for example, one must understand the molecular level. Studying hydrogen and oxygen atoms separately will not allow one fully to understand the behavior of water. Similarly, one cannot fully understand learning solely by studying individuals' mental representations. Individual cognitions are essential, as hydrogen atoms are essential to water, but learning itself depends on a larger unit: a social activity, which includes individuals' mental representations, various cognitive tools, and others' knowledge and skill, all of which together allow learning.

Unlike behaviorists, and like cognitivists, social cognitivists describe how cognitive structures and processes mediate between the environment and people's actions. But social cognitivists emphasize that these mediating structures go beyond individuals' mental models to include tools and other aspects of social activities. Although some activities (such as conventional tests) do require individuals to think in isolation with limited tools, a full account of learning must analyze social activities in addition to mental representations.

Social Cognitivist Education

In a social cognitivist approach, both teacher and student are active. Instead of relying primarily on students' own exploration and model-building, the teacher acts as a competent practitioner of the activity being taught and brings tools for students to use. Teachers guide students as they begin to participate in the activity. This guidance allows students to do tasks that they would not be able to perform on their own. Students act like apprentices, at first doing minor parts of the task while observing others, then taking on increasing responsibility.

Teachers should design more naturalistic or 'authentic' activities for students to participate in, where the goal is competent participation in real activity. Many medical schools, for instance, now use 'problem-based learning' – in which groups of beginning students are given real, complex cases and asked to diagnose the problem. They must consult more expert practitioners, do research on relevant topics, and develop alternative diagnoses to present in class. Students thus learn how to participate in the practice of medical diagnosis, and they learn the relevant facts along the way.

From this perspective, testing is unnatural. If students must learn to participate competently in real activities, teachers should not test whether they can solve problems by themselves out of context. And because learning most often involves participating with others to accomplish a task, students should not be tested alone. Students should instead be asked to exhibit their mastery by participating competently in naturalistic activities.

Like behaviorism, pure cognitivism is only partly true. Just as people are often manipulated by reinforcements, people often rely primarily on their own mental models to understand the environment. But if our educational goal is to help young people build on the knowledge and skills that have been developed by previous generations, we should treat them neither as animals to be shaped nor as lone thinkers. We must help them grow into and expand the activities that make us human. This will require educational practices based on more complex accounts of learning.

Emotion

Introductory article

Paula M Niedenthal, National Centre for Scientific Research, Blaise Pascal University, Clermont-Ferrand, France

CONTENTS

Emotions are sets of processes involved in an organism's response to significant, goal-relevant life events. Such processes include expressive behavior, cognitive appraisals, physiological arousal, action tendencies and subjective feelings.

INTRODUCTION

It is difficult to imagine life without emotions. We would feel no joy at successfully accomplishing a task, no sadness at failing an examination, no anger when we witnessed displays of prejudice and discrimination. We would not feel ashamed upon insulting another individual in social interaction. Nevertheless, emotion as a field of study remained firmly ensconced in the realms of philosophy and literature for many centuries. Now of central interest to psychology, the cognitive sciences and the neurosciences, emotion is finally also a topic of empirical investigation. Neuropsychological and psychological investigation shows that it is indeed hard to imagine life without emotions, because emotions are essential for human functioning. Social interaction, decision-making and judgment would be very poor without the capacity to experience emotion. Normal and pathological emotion states are determined and controlled by almost all of the systems of the human body, and emotional states in turn influence the cognitive functions of attention, perception, categorization, memory and judgment.

EMOTIONS AS MULTICOMPONENT PROCESSES

A precise definition of emotion eludes scientists. This is because no single event or process constitutes an emotion. Emotions are sets of processes that involve different components including subjective feelings, but also expressive motor action, cognitive appraisals, physiological arousal, and tendencies to take particular actions. If you see a bear in the forest, a favorite example of the nineteenth-century psychologist William James, you might experience strong physiological arousal, have an urge to run, open your eyes and mouth wide, and feel something that you label as fear. In this example the components are quite coherent and conform to a common emotional experience. However, the different components of emotion can be decoupled. In different situations and across different cultures, social norms influence the expression and experience of emotion. For example, an adult in an industrialized Western country might feel like laughing at a funeral if a funny joke about a priest or a rabbi suddenly comes to mind; however, the person would probably suppress any laughter, avoid smiling, and display some degree of sadness. Such norms are one force that can decouple the multiple components of emotion. In this example the decoupled components are subjective experience and expressive behavior. (*See* **Cultural Psychology**)

Differentiation of the Component Processes: Are There Discrete Emotions?

Although scientists agree that emotions have many components, debate continues about the extent to which there are unique patterns or levels of each component process that correspond to discrete (basic or fundamental) emotions such as sadness, joy or fear.

Facial expression

The component of initial interest and debate was that of facial expression of emotion. Charles Darwin was an early proponent of the idea that facial expressions of emotions serve adaptive

functions – he called them 'serviceable habits' – and have thus evolved as hardwired expressions of discrete subjective states. For example, disgust, Darwin suggested, is associated with a gesture that represents the expulsion of food from the mouth and avoidance of the intake of an odor through the nose, precisely because the function of disgust is to prevent individuals from ingesting dangerous substances. From this evolutionary perspective, facial expressions of emotion should be both distinctive and universal. Indeed, studies of people of different cultures, even those not exposed to Western media, blind children, and infants, suggest that there exist universal displays and recognition of the expressions of at least joy, sadness, fear, anger, disgust, and perhaps surprise. Thus, such facial gestures may be based in innate neural motor programs. However, such a conclusion is still widely debated because each existing demonstration of universality can be criticized on technical grounds. (*See* **Face Perception, Psychology of**; **Face Perception, Neural Basis of**)

Vocalizations

Somewhat less controversial is the study of vocal expression of emotion, also called emotional prosody. Research supports the idea that vocal expression is biologically based and that there is evolutionary continuity of vocal emotion expression. For example, data from studies conducted by behavioral biologists suggest that there are significant similarities in the vocal expression and communication of emotional states across species: angry states are typically expressed by loud, harsh vocalizations, while fear and anxiety are typically associated with high-pitched, shrill vocalizations. Furthermore, human perceivers show wide agreement about the emotions communicated by utterances characterized by specific patterns of physical parameters such as fundamental frequency and pitch.

Autonomic activity

William James, as well as a Danish contemporary named Lange, originally proposed the idea that there are distinctive patterns of autonomic arousal that correspond to discrete emotions. Although this peripheralist position was attacked for over a century, both by scientists who believed that arousal was nonspecific, and by those who believed that the autonomic nervous system responds too slowly to subserve discrete emotional states, research suggests that some physiological parameters do differentiate some pairs of emotion. Sadness and fear differ in their patterns of heart rate, for example. Other studies show that fear is characterized by increases in heart rate, contractility of the heart musculature and respiration rate, which together mobilize a flight response, while anger is characterized by a rise in diastolic blood pressure and in peripheral resistance, which together mobilize a fight response. (*See* **Autonomic Nervous System**)

Subjective experience

Despite intuition to the contrary, some emotion theorists do not believe that emotional states are differentiated as discrete categories (happiness, sadness, disgust) of subjective experience. Rather, they believe that the conscious experience of emotion can be accurately characterized by two underlying psychological dimensions. Early in the last century these dimensions were referred to as pleasantness–unpleasantness and excitement–depression, although now the dimensions are often termed 'valence' (positive–negative) and 'activation' (high–low). In the dimensional view, for instance, the emotion that is called fear can be described psychologically as a state that is negative in valence and high in activation. One answer to the question of whether subjective experience is differentiated in terms of a few dimensions or whether it is categorical, is to say that it depends on the person. Research suggests that some individuals do indeed experience their emotional states in terms of a few simple dimensions ('I feel good') while others make finer, categorical distinctions among states ('I feel joyful'; 'I feel proud').

THEORIES OF EMOTION

Theories of emotion are precise statements about the causes of an emotion, the order in which emotional processes unfold, and how the different components of emotion interact. Although within each category several different versions can be discerned, there are currently two major categories of emotion theory. These are evolutionary theories and cognitive appraisal theories. Depending upon which approach is adopted by a scientist, the methods for producing and measuring an emotion in the laboratory, the types of emotions under scrutiny, the way in emotions are thought to be elicited and regulated and the application of the research findings may be quite different.

Evolutionary Theories

The evolutionary approach to emotion is based in part on the thinking of Charles Darwin and begins with the assumption that emotions are biologically

based and functional. In considering the evolution of emotion, Darwin focused largely on his idea that facial expressions of emotion are remnants of serviceable habits. In addition, he argued for an adaptive signaling function of facial expression: that is, facial expressions allow members of the same species to know the subjective experience of the expresser, and therefore the emotional significance of the situation, as well as the expresser's likely actions. In a more general way, the evolutionary perspective assumes that emotions motivate adaptive action, such as the tendency to flee when fearful and the tendency to fight when angry. The problems of adaptation thought to be associated with specific emotions are finding and consuming food and drink, locating shelter, seeking support from other members of the same species, being social, satisfying curiosity, appraising sexual partners, nurturing offspring, and escaping dangerous situations. From a biological perspective, then, emotions are responses that have evolved to motivate individuals to successfully pass on their genes to offspring. The three types of evidence cited in support of an evolutionary approach to emotion are: (1) blind children produce recognizable facial expressions of the basic emotions; (2) human facial expressions such as smiling have homologs in chimpanzee expressions; and (3) there are cross-cultural similarities in the antecedents of emotion. (*See* **Aggression and Defense, Neurohormonal Mechanisms of**; **Cultural Differences in Causal Attribution**; **Evolutionary Psychology: Theoretical Foundations**)

The implications of this approach are that there are biologically based systems that subserve emotions, in a discrete way. There also exist biologically relevant 'signal stimuli' that recruit specific emotional reactions and adaptive response tendencies in situations that are significant to the person for phylogenetic or ontogenetic reasons. At the behavioral level, emotional phenomena are displayed as action or motor tendencies. They thus recruit metabolic processes related to arousal and behavioral energetics. Such processes can be subjected to scientific investigation through psychophysiological indices such as cardiovascular and electrodermal responses. (*See* **Emotion, Neural Basis of**)

Cognitive Appraisal Theories

If the evolutionary approach links emotions to biological adaptation in the distant past, appraisal theories of emotion link emotions to 'higher level', cognitive processes of evaluation of meaning, causal attribution, and assessment of coping capabilities. The main principle of appraisal theories is that emotions are elicited and differentiated by individuals' evaluation of the significance or meaning of an object or event for themselves and their current goals on a number of dimensions or criteria. A classic demonstration of the role of appraisal in differentiating (although not eliciting) emotion was a study conducted by psychologists Schachter and Singer in the 1960s. These psychologists proposed that individuals sometimes experience physiological arousal that does not have a known cause. The arousal motivates individuals to explain the cause and nature of the arousal, which as consequence gives rise to a discrete emotional state. In their study the researchers injected participants with adrenaline (epinephrine), which enhances arousal, or with saline, a placebo which causes no physiological change. They then informed some of the participants injected with adrenaline to expect an increase in arousal; other participants were left uninformed about these effects. Later, when the adrenaline had taken effect for those who had received it, all participants were placed in a situation in which they interacted with a confederate of the researcher who acted in either a euphoric or an angry manner. Subsequent assessment of participants' emotions showed that those who had received adrenaline and were uninformed about the accompanying arousal – but not those participants who received placebo or who had an expectation of arousal – reported feeling the same emotions as those expressed by the confederate. That is, participants who experienced unexplained arousal sought an explanation in their environment and this appraisal determined their precise emotional state.

It is no longer widely believed that emotions are the products of unexplained arousal shaped by reference to events in the surrounding environment. However, modern cognitive appraisal theories do hold that discrete emotions result from processes of evaluation of significant events and of attributions of the causes of those events. In particular, whether unconsciously or consciously, individuals assess the degree to which events facilitate or impede their goals, whether they are pleasant or unpleasant, whether they are controllable or not, and whether they are novel or familiar. Depending upon the result of this appraisal, a discrete emotion is evoked. Tables 1 and 2 summarize examples of appraisal theories and the profiles that in theory give rise to certain emotions.

The implications of appraisal theories are that emotions do not unfold in a hardwired way in response to certain situations or objects, but that

Table 1. Comparison of the appraisal criteria postulated by different theorists

the emotional significance of the events and objects depends upon the goals and the coping capacities of each individual. Thus, appraisal theory can comfortably predict that one person will respond to the same stimulus with fear while a second will respond with anger. Emotions are differentiated and can be associated with different physiological processes and facial expressions in this view, but

the antecedent of the emotion – the specific profile of appraisal – determines which discrete emotion is experienced.

COGNITIVE REPRESENTATION OF EMOTION

Individuals do not only experience emotions, they also verbally label emotions, represent their ideas of what emotions are as concepts, and can reflect on and remember their emotional feelings.

Emotion Labels

Subjective experience of emotion is largely revealed to scientists through emotion words. In the English language there are between 500 and 2000 words that refer more or less to emotions (e.g. shame), affective or valenced states (e.g. tranquility), and cognitive–affective states (e.g. vengeance). In Malay there are about 230 emotion words, and in Ifaluk there are only about 50. Clearly, then, although there is enormous cultural variation in the number of words individuals use to talk about emotions, they talk about emotions in all cultures. The basic categories of words, despite important differences, show general consistency across culture. (*See* **Cultural Psychology**)

The dimensional analysis of the meaning of emotion words usually reveals the same bipolar structure as does an analysis of individuals' ratings of their subjective emotional states. That is, the meaning of the labels are organized around the two dimensions of valence and activation or arousal. More specifically, a circular representation of emotion words, a circumplex structure, is typically observed. Figure 1 illustrates this structure, showing the position of the basic or discrete emotions as well as other affective states. The circumplex shows that individuals make fine-grained distinctions among emotion words in their reference to pleasantness and level of arousal.

Emotion Prototypes

The categories that emotion labels refer to share many properties in common with categories of concrete objects such as animals, vehicles and furniture, as well as more abstract concepts such as personality disorders, negotiation strategies and scientific theories. First, the defining characteristics of the categories vary in their diagnosticity, or probability of being present in any given episode of an emotion. For instance, individuals know that the experience of anger might almost always include the feeling of the face growing hot or the muscles being tense, but only sometimes the action

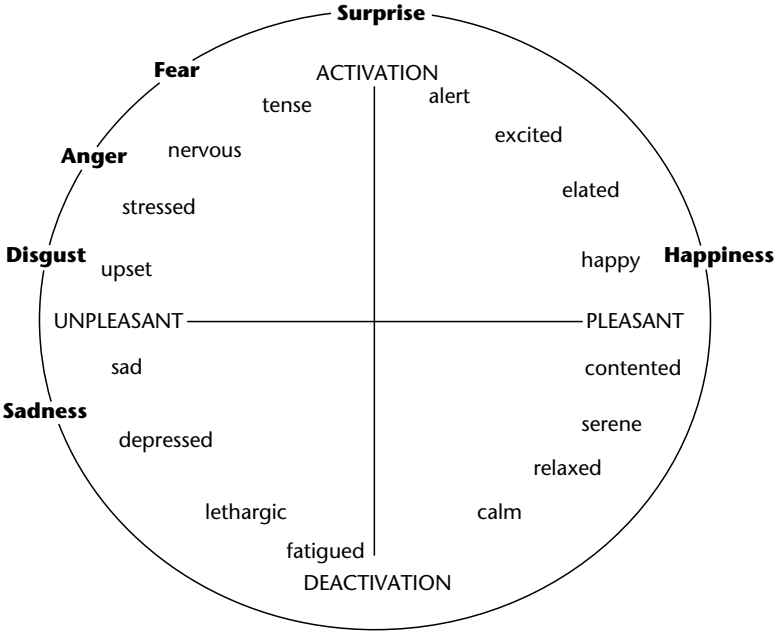

Figure 1. The circumplex structure of affective meaning that results from the multidimensional scaling of judgments of similarity between emotion words. The outer circle shows where several prototypical emotions fall. From Feldman Barrett L and Russell JA (1998) Independence and bipolarity in the structure of affect. *Journal of Personality and Social Psychology* **74**: 967–984.

of striking out. Second, membership in the categories is a matter of degree, and is not 'all or none'. Thus, a good example of feeling fear is a situation in which you see a bear and run away, heart pounding and mouth open to scream. But being on a carnival ride or jumping off a high diving board, with all the physiological and subjective experiences these entail, may be less good examples of fear. The best examples of each emotion are the central or prototypic examples of the categories, while the others are considered borderline or less prototypic examples. Finally, each category of emotion contains a script for the ordering and patterning of events involved in that emotion. Individuals are able to describe the antecedent events, the behavioral reactions to those events and the physiological and expressive responses involved in a way that preserves the temporal and spatial structure of a prototypic emotion episode. (*See* **Conceptual Representations in Psychology**; **Schemas in Psychology**)

Representation of Emotional States

Emotional feelings and experiences themselves are also represented in memory. Individuals can remember what emotions feel like and even reproduce aspects of the feelings if they retrieve memories of past episodes. It has been proposed that emotional states, perhaps the discrete emotions, are represented as informational units in an associative network in memory. In such associative network models the informational units are proposed to be linked to memories of the experience of the emotion and to memories for times when these emotions were induced. The existence of mental associations between a representation of the feeling of emotion and memories and perhaps the semantic categories of knowledge about the emotion has important consequences for understanding the processing of information during emotional states. (*See* **Memory Models**; **Spreading-activation Networks**)

EMOTION–COGNITION INTERACTION

Emotional states, and indeed emotional traits such as depression and anxiety, influence the manner in which individuals process information. Such states and traits can affect the allocation of attention, the efficiency of perceptual encoding, the retrieval of memories from long-term memory, the learning of new information, decision-making and judgment, as well as the organization of conceptual material in memory. (*See* **Affective Disorders: Depression and Mania**; **Depression**)

Emotion and the Content of Cognition

The associative network model makes a specific prediction concerning the influence of emotion in information processing, which is reminiscent of expressions such as, 'She was so happy that she saw the world through rose-colored glasses.' According to the model, emotional states activate the unit of information representing that state in long-term memory. Through passive diffusion of activation, other information that has been associated with or causal to that same emotional state becomes activated too, and then influences the ease and efficiency with which new information is perceived and stored. The consequence of such activation is the facilitated processing of emotion-congruent information. For example, in a happy state an individual will allocate attention to and rapidly encode smiling faces, people he or she likes, and words or phrases with positive meanings. One study also showed that individuals in happy states who were watching a happy expression gradually disappear from a face of another person, perceived the expression to still convey happiness for a significantly longer time – even when almost completely neutral – than did individuals in a sad state. This means that the happy individuals were particularly efficient at detecting signs of a happy expression that was ambiguously neutral. Other research has shown that, while in a happy state, individuals are also better able to learn and retrieve information associated with happiness. Finally, the judgments of individuals in happy states tend to be optimistic rather than pessimistic in nature. In a sense, emotions mobilize the entire cognitive system to process information that is relevant to that state. (*See* **Priming**)

Emotion and Information-processing Strategies

Emotions also influence the actual cognitive processes that are employed in judgment and decision-making: that is, the structure of those processes. When individuals are in positive emotional states they process information less deeply, in a simple, heuristic way. This does not mean that they cannot make careful judgments or that they think poorly, only that they tend to use short cuts for solving problems and may sacrifice attention to detail. The same appears also to be true for individuals who are in states of anger. On the other hand, sadness is associated with a more careful, less schematic type of processing. Individuals who are sad are likely to scrutinize information and to engage in

more systematic processing of that information. Research has shown, for example, that individuals in happy and angry states are more likely to base their judgments of the defendant in a hypothetical legal trial on racial stereotypes, than are individuals in sad or neutral states, who based their judgments more on the presented legal evidence.

There are a number of reasons why emotions are associated with more or less systematic styles of information processing. First, different emotions have different information values to the individuals experiencing them: happiness tends to indicate that the environment is safe and that all is going well; sadness indicates that there is a problem to be solved and that all is not going well; and anger suggests that fast action must be taken to solve a problem. Thus, happiness and anger have different signal values that nevertheless may result in the same tendency to process rapidly and in less detail. Sadness signals that careful attention to details of the environment is required. Second, happy states exert a high degree of cognitive load. Because happy states are associated with more information in memory – probably because individuals are on average happy more often than they are sad, angry or fearful – many different ideas come to mind during those states. The rush of associations can inhibit the ability to process additional incoming information in detail. In contrast, sad states, which are associated with less information stored in memory, at least among nondepressed individuals, tend not to trigger as many associations and tend therefore not to overload the system. Consequently individuals in sad states seem to have more capacity to process information in a systematic way. Third, different emotions have different motivational properties. Individuals who are feeling happy or angry may not be motivated to distract themselves from or otherwise change those states by processing new information in a systematic way. They protect their emotional states from change, albeit for different reasons. Individuals in nonclinical sad states, on the other hand, are often motivated to distract themselves from the sadness or engage in other mood regulation strategies. They are thus more likely to systematically process incoming information.

Emotion and Conceptual Organization

Finally, emotional states influence the way information is organized in memory, and therefore the content and structure of concepts. Natural categories in the environment are revealed by perceptual similarity among their members: it is easy to learn the category of birds because most examples of that category (most birds) have physical properties in common. Concepts, the representation of categories in memory, are therefore grounded in perceptual similarity. They are also organized theories that individuals possess about the origins and functioning of objects and events. However, during emotional states concepts may be organized somewhat differently. Rather than representing categories of things that belong together because they look alike or conform to a common theory of cause and effect, concepts may temporarily represent groups of objects and events that have elicited the same emotional state. For example, individuals are more likely during emotional states, compared with neutral states, to see emotional equivalence among events and objects, and group them together as being 'the same kind of thing', if they evoked the same emotion. (*See* **Conceptual Representations in Psychology**; **Concept Learning and Categorization: Models**)

REGULATION AND SUPPRESSION OF EMOTION

Emotion regulation includes processes that individuals use to influence whether they have an emotion, which emotions they experience and do not experience, the conditions under which they experience emotion, and how they express such states. Although Western cultures seem ambivalent about the need to regulate emotions, as conveyed in the conflicting expressions 'He who keeps a cool head prevails' versus 'Let your feelings be your guide', it is clear that individuals in all cultures attempt to control, alter, augment and suppress at least some emotions. Anthropologists and psychologists have observed specific social and cultural rules for doing so.

Emotion regulatory strategies are important to understand because they are fundamental to personality functioning and adjustment, and to psychological and physical health. Major depressive disorder, for example, is characterized by a deficit in experience of positive emotion and a surplus of processing negative emotions and negative information. Chronic hostility and anger inhibition are associated with hypertension and coronary heart disease. Emotion inhibition or suppression may enhance minor illnesses and accelerate the progression of major illness such as cancer.

Processes of Emotion Regulation

Given the multicomponent nature of emotions, it is not surprising that there are many different

processes involved in the regulation of emotional states, and that these processes operate more or less on physiological, expressive, and experiential aspects of the emotion.

Antecedent-focused regulation involves regulation strategies that are mobilized in the service of avoiding or enhancing emotions in an anticipatory way. Potentially emotion-arousing situations or stimuli can be avoided or approached, aspects of the situations can be selectively attended to or ignored, and, as suggested by appraisal theories of emotions, situations can be (re)evaluated in ways that augment or diminish the probability of specific emotions.

Response-focused regulation involves attempts to alter emotional states once they have been elicited. Representative strategies include the suppression or enhancement of expressive and behavioral components of the emotion, and distraction of conscious attention away from the subjective experience of the emotional state to other events internal or external to the individual, such as distracting thoughts and stimuli, respectively. An example of the regulation of an expressive component of emotion as a means to regulate emotional state is the voluntary manipulation of facial expression of emotion. This is the deployment of the adage for people who are depressed to 'Put on a happy face', for example, in order to feel happier. Putting on a happy face may indeed regulate emotional experience through a number of different mechanisms. First, it may alter the social environment such that more positive experiences are possible. In addition, self-perceptual processes – noticing that one is smiling – may lead individuals to believe that indeed they are happy and to realize this belief. Finally, several facial feedback theories of emotion also hold that facial expression of emotions actually feed back through physiological systems to influence subjective state. Specifically, the strategic use of facial musculature may alter other neurochemical processes involved in emotion.

Effects of Different Regulation Strategies

Emotion regulation strategies are differentially effective and have different costs and benefits over time. Of particular interest has been comparison of reappraisal of negative situations compared with the suppression of negative expressive behavior and feelings. Research has generally demonstrated that reappraisal can diminish the subjective experience and expressive aspects of an emotion. Of course, reappraisal of some negative situations is quite difficult in the first place. Suppression of emotional expression and behavior may often (or even always) be possible. However, suppression is associated with increases in sympathetic nervous system activation, and thus can be a physiologically costly strategy. It is probably for this reason that individuals who habitually suppress negative emotions tend also to suffer both minor and more permanent health consequences.

Environmental Psychology

Introductory article

Stephen Kaplan, University of Michigan, Ann Arbor, Michigan, USA

CONTENTS

In the context of evolution and environment, human information processing has many connections with preference and motivation, with far-reaching implications for the possibilities of enhancing human effectiveness.

INTRODUCTION

If we think of an environment as a pattern of information, then environmental psychology and cognitive science have much to learn from each other. Computer scientists have provided a useful concept, the 'software environment', which connects these disciplines. When dealing with a new software program one faces a pattern of information that is only a small piece of the total collection of information that makes up the program. Yet to be comfortable with the program and make good use of its capabilities one has to build some sort of mental map of the whole program. This example gives a fairly good idea of what constitutes an environment from an informational perspective.

The environment that early humans faced was not, of course, a software environment, but a physical environment: if they had not been able to master that environment, their future development as a species would not have been possible. To understand environmental psychology from a cognitive point of view it is necessary to consider these two quite different environments: the one in which humans evolved, and the one that humans now inhabit.

THE ENVIRONMENT AS A SOURCE OF INFORMATION

The ancestors of the human species were originally tree dwellers. As latecomers to the savanna, humans adopted a life at the ecological margins, scavenging where they could, taking advantage of opportunities wherever possible, and getting away from predators before it was too late. The story of human evolution is the story of how a creature with limited physical assets managed to survive by its wits, by developing powerful and ingenious ways of dealing with environmental information.

Information Processing for Survival

The typical early human was home-based yet hunted a vast territory (probably about 250 square kilometers), in which one could easily get lost, so that a good memory for spatial information was essential. In addition to spatial knowledge, several other information-processing capabilities would have been essential to a creature surviving at the ecological margins: recognition, prediction, evaluation, and action.

Quick recognition of important objects in the environment, along with a capacity to discern the essence of what is happening, to get to the gist of things, would have been imperative. Quick recognition of objects is no small challenge (one that is still very difficult for computers). Interpretation of a scene is even more difficult, as it involves both the set of important objects and their spatial configuration.

Still, quick recognition is not sufficient. It is necessary not only to understand the present situation, but to anticipate what might happen next. Thus, prediction is a vital aspect of information processing.

Even recognition and prediction are not enough. One must evaluate whether the current situation and what might come next are likely to have good or bad consequences. And one must do so quickly, so that one can act before one is overtaken by events. Reviewing many similar events that have happened before, and pondering whether or not one would want them to be repeated, are often

unaffordable luxuries. There must be a way to translate many different experiences into a quick and simple mandate for action.

The Cognitive Map

How can an animal with only a modest brain store so much spatial knowledge economically? The 'cognitive map' (some sort of durable mental model of the environment) provides a possible explanation. The capacity to recognize, think about and remember objects has been studied extensively. Considerable evidence suggests that experience leads to internal representations in the human mind, which stand for things in the world. These mental units make possible quick and confident recognition of objects despite the enormous variability in how they are experienced.

There is also evidence that people tend to associate things that occur near to one another in time; in other words, they readily form mental sequences that connect the representations of things that were experienced at about the same time. It is useful to think of these sequences as composed of 'nodes' (the representations of the objects) and 'paths' (the associations between them).

Sequences are necessary to cognitive maps, but not sufficient. What is needed is some way to integrate them into a coherent model of the environment. Suppose, for example, that there is a particular internal representation that stands for a landmark, such as the campus bell tower. Any sequence one experiences during one's walks on campus that include the bell tower will lead to the activation of this representation. Thus various routes will share this common node. Imagine, for example, that one is new on campus and only knows two routes: the 'weekday' pattern, from dorm to bell tower to classroom building, and the 'weekend' pattern, which includes the sequence from stadium to bell tower to cafeteria. With the knowledge of these two sequences, even if one has never traversed it, one also knows the route from dorm to bell tower to cafeteria. The cognitive map, therefore, is not a long list of separate sequences but a network of interlocking paths whose integration is due to their common elements.

Such an integration of nodes and sequences provides an economical way to store relevant information while ignoring much unnecessary detail. This cognitive map or mental model would have been a great help in avoiding getting lost, but it accomplishes much more than that. The capacity to form networks about the structure of the environment is likely to have served our distant ancestors even before the development of language. For example, early hunters, because of their limited weapons, had to attack potential prey from close proximity. In addition to spatial knowledge, they therefore needed considerable knowledge of prey species, including the capacity to recognize important signs and to interpret and predict behavior. The cognitive map is well suited to these challenges as well. The capacity to anticipate possible futures, and to recognize distinctive configurations and what they lead to, is called 'lookahead'. It is what enables people to use mental models to try out possible alternatives and ascertain possible consequences before making a decision. Given its antiquity, as well as its flexibility and generality, the cognitive map may in fact constitute a general-purpose way of storing knowledge that underlies much of what modern humans know and do.

INFLUENCES OF ENVIRONMENT ON AFFECT AND COGNITION

The importance of the cognitive map to the survival of early humans points to another issue, often neglected in cognitive science. Imagine an individual who finds being frequently confused or lost a satisfactory state of affairs. One can be reasonably sure that such an individual could not have been our ancestor. Indeed, although little note is taken of this fact in most current research and theory, modern humans, presumably like our ancestors, have strong negative feelings about being confused and, by contrast, find being knowledgeable and competent most enjoyable. Far from being totally separate domains, cognition and emotion (or affect, as it is sometimes called) are necessarily intimately linked. Strong feelings apply not only to the adequacy of our knowledge: they are also associated with the environments in which we feel competent or confused.

Preference and the Variables that Predict It

Experts trained to design landscapes consider form, line, color, and texture to be the essential elements of beauty in the landscape. However useful these concepts may be to the designer, an important component of what people like in the landscape is, of course, content. Trees, water, and smooth places to walk play an important role. There are, however, other properties of the preferred landscape that are about information rather than content. Two categories of informational factors have been identified: understanding (making sense of a setting

and expecting that one could venture into it without getting lost), and exploration (having much to look at and the possibility of learning more as one ventures into the setting).

In a sense these two informational categories are in opposition to each other. What one already understands, while providing safety, may not offer opportunities for new learning; and a place that offers new learning opportunities might also be a place where one can get lost. Not surprisingly, environments where both learning and staying oriented are possible are strongly preferred.

Together, the often competing forces of understanding and exploration provide a solution to an important problem. As a knowledge-based organism, the human must be pulled towards opportunities for learning, for acquiring new information. Thus, when one is in a highly familiar environment the support for understanding is likely to be high, so one's choice of direction will be influenced by the path that offers greater opportunity to learn. At the same time, it is important that the organism not be pulled too far from what it understands. If its survival depends on information, it is dangerous to move too deeply into unfamiliar territory where it is not clear what to do or how to interpret events. The strong preference for exploration and understanding together leads the organism to seek new information without getting too far from what it knows and can handle.

Affect and the Environment

Pleasure and pain are often triggered by actual situations. The lookahead capability of cognitive maps, however, also enables us to experience pleasure and pain with respect to events that have not yet happened. For example, if one dislikes public speaking, having to make a presentation two weeks from now can create great pain. In this case the painful event is a prediction, not a reality. Similarly, the expectation of a holiday can give one pleasure long before one departs.

What makes the human reaction to environments associated with pain and pleasure particularly interesting is the subtlety of the environmental dimensions that are coded for pleasure or pain. People readily respond with strong negative reactions when their abilities to understand or explore the environment are blocked, when they are made to look foolish or experience harm to their sense of self, or when they feel incompetent or helpless. Human competence depends on the capacity to process information effectively. An environment that makes this difficult therefore lowers competence and, in turn, safety. Thus, it is adaptive to experience pain in such environments, leading one to quickly leave the situation and avoid it in the future. Correspondingly, environments that support people's information-processing needs enhance competence and confidence, and are experienced as pleasurable.

STRESS AND MENTAL FATIGUE

While pleasure and pain are powerful forces for moving individuals away from 'bad' environments and towards 'good' ones, they are less helpful for dealing with information within an environment. The environment is highly complex. Most of what is in one's field of view at any one time is of little or no relevance to one's purposes. To function effectively in a vast sea of stimulation, selection is essential. Humans have a variety of mechanisms for selection; one of the most important of these is attention.

Of the several kinds of attention, two are particularly important to understanding the human–environment relationship. 'Fascination' refers to a kind of attention that is automatic. A fascinating stimulus is one that is hard not to attend to. In evolutionary times, what was fascinating was what was important for human purposes, so that the problem of what to attend to was often solved automatically and effortlessly. In the modern world, many factors, such as advertising and the media in general, have utilized our capacity for fascination to so great a degree that, rather than supporting one's purposes, it often serves the purposes of others. A fascinating stimulus that is irrelevant to one's purposes is a distraction. When distractions are many, it is necessary to employ a different kind of attention, called 'directed attention', to maintain one's focus on what is important.

As we have seen, recognition depends on a process whereby patterns in the environment activate corresponding mental structures. There is, however, a limit to how many such structures can be active at once ($5 +/- 2$, assuming that the patterns are well learned). If what uses up this precious limited capacity is just whatever is biggest or brightest or most fascinating in the environment, what goes on in the mind will be determined by the environment and not by one's purposes. An all-too-frequent consequence is that one's mental activity will be dominated by someone else's purposes. Even when environmental patterns do support a purpose that an individual is committed to, that support is not necessarily enduring. A change in

environmental configuration might present a new opportunity that fits some other purpose better. Thus, if one has no way of fending off distraction, environmental variability can undermine the persistence that is essential to effective goal-directed behavior. Some means of escaping from environmental control is necessary. Directed attention provides the mechanism for achieving this. This achievement, however, comes at a cost: directed attention requires effort and is subject to fatigue. Not surprisingly, the very contexts that require its use – resisting distraction, making sense of confusing situations, maintaining one's focus when what is important is not particularly interesting – are the very contexts that lead to such mental fatigue.

As fatigue increases one may eventually become aware of one's declining effectiveness, and this can cause stress. Stress can itself serve as a severe distraction, resulting in heavy demands on directed attention. Thus, although stress and fatigue are distinct, they often occur at the same time.

Environments that lead to mental fatigue or stress reduce confidence and competence while simultaneously increasing the sense of urgency and concern for self-preservation. One would hardly expect people to be helpful or responsive under such circumstances. In other words, environments that undermine competence and confidence will be unlikely to bring out the best in people.

USING THE ENVIRONMENT TO IMPROVE EFFECTIVENESS

The task of influencing one's own behavior is often achieved more readily by an indirect approach than by a direct one. Since people are responsive to environmental factors, arranging the environment to support appropriate behavior can be a particularly effective strategy. In addition, it does not call upon willpower, which depends on the same resource necessary for directed attention.

The attentional resource is perhaps the most important of the cognitive factors that one can do something about. Since mental fatigue is an ever-present threat and a serious handicap, ways to keep it under control and to recover from it are important interventions. Recent discoveries in environmental psychology are relevant here. Research on 'restorative environments' points to the importance of spending time in settings where fascination is readily available and where directed attention is little needed. Natural environments have been shown to serve this function particularly well. A related strategy is to make the everyday environment less costly. Such strategies as reducing distractions and avoiding noisy settings can protect directed attention from unnecessary demand. The focus on the attentional resource, which recasts the way one looks at one's environment, can have beneficial effects.

Both at the personal level and on a larger scale, strategies for achieving these benefits call for many small experiments to determine what works. In the individual case, 'know thyself' here takes on a more tangible meaning, as well as a greater urgency. The solutions, however, must go beyond the individual. People who are stressed and fatigued are not ideal neighbors. They contribute little to safety, stability, and civility. The pervasiveness of unreasonable behavior is one of the plagues of the modern world. Environments more responsive to human needs might help to temper this unfortunate trend.

Episodic Memory, Computational Models of

Intermediate article

Kenneth A Norman, University of Colorado, Boulder, Colorado, USA

CONTENTS

Computational models of episodic memory constitute mechanistically explicit theories of how we recall previously experienced events, and how we recognize stimuli as having been encountered previously. Because these models concretely specify the algorithms that govern recall and recognition, researchers can run computer simulations of these models to explore how (according to a particular model) different manipulations will affect recall and recognition performance.

INTRODUCTION

Episodic memory refers to our ability to remember specific, previously experienced events: we can *recall* (i.e. mentally re-create) previously experienced events, and we can *recognize* a stimulus as having been encountered previously. From a computational standpoint, the unifying feature of episodic memory tests is the need to isolate the memory trace corresponding to the to-be-remembered (*target*) event. Recall tests ask subjects to isolate the target event's memory trace in order to retrieve some missing detail, and recognition tests ask subjects to assess whether the target event is actually stored in memory. On both recall and recognition tests, good performance is contingent on the system's ability to screen out the effects of non-target memory traces. (*See* **Memory, Long-term**)

Computational models of episodic memory can be divided into two categories: *abstract* and *biological*. Abstract models make claims about the 'mental algorithms' that support recall and recognition judgments, without addressing how these algorithms might be implemented in the brain. The primary goal of these models is to account for challenging patterns of behavioral recall and recognition data from list learning paradigms (where stimuli are presented as part of a well-defined 'study episode'; then, subjects are asked to recall specific events from the study episode, or to discriminate between stimuli that were and were not presented during that episode). Biological models, like abstract models, make claims about the computations that support recall and recognition judgments; the main difference is that they also make specific claims about how the brain gives rise to these computations. This brain-model mapping provides an extra source of constraints on the model's behavior. (*See* **Memory Models**)

ABSTRACT MODELS

Abstract *global matching* memory models take a unified approach to recognition and recall. There are several different global matching models; this article will focus on a single, representative model, MINERVA 2 (Hintzman, 1988); see Clark and Gronlund (1996) for an explanation of differences between the various models. MINERVA 2 (M2) represents each study list item as a vector where each element equals 1, −1, or 0. Each element corresponds to a particular feature that may or may not be present in that item; a 1 value indicates that the feature is present, a −1 value indicates that the feature is absent, and a 0 value indicates that the feature value is unknown. Thus, the vectors corresponding to different items will overlap (i.e. have the same value for a particular vector element) to the extent that they consist of the same features. M2 posits that the vectors corresponding to different studied items are stored separately in memory (but see Murdock (1993) for an example of an abstract model that posits that memory traces are stored in a composite fashion; Murdock's TODAM model stores items by adding together vectors corresponding to different items). When an item is presented at test, M2 computes how well the test item vector matches all of the different vectors stored in memory. On recognition tests, M2 sums together all of these individual match scores to get a 'global match' (*familiarity*) score; recognition decisions are made by comparing familiarity scores to a criterion

value, i.e. respond 'studied' if an item's familiarity score exceeds the criterion value, respond 'nonstudied' otherwise. M2 implements recall by computing a weighted average of all of the items stored in memory, where each item is weighted by its match to the test probe. Thus, M2 generates a *vector* output on recall tests and a *scalar* output on recognition tests, but both recall and recognition depend on the same underlying match computation. (*See* **Memory Models**)

How Match is Computed

In global match models like M2, the match computation weights multiple matches to the same trace more highly than the same total number of feature matches, spread across multiple memory traces (e.g. a test cue that matches two features of one item yields a higher familiarity signal than a test cue that matches one feature each of two items). Put another way: the match computation is sensitive to whether the features of the test probe were studied together (vs. separately). M2's match computation achieves this *sensitivity to conjunctions* by first computing the dot product of the cue vector and each memory trace vector (this gives the proportion of matching features minus the proportion of mismatching features for each memory trace) and then cubing the dot product score for each trace; finally, M2 adds together the cubed match scores to get the familiarity score for that cue. This algorithm yields sensitivity to conjunctions insofar as matches spread across multiple stored traces are combined in an additive fashion, but – because of the cube rule – multiple matches to a single trace are combined in a positively accelerated fashion.

Sensitivity to conjunctions ensures that one strong match outweighs the effects of several weak matches. Given the fact that different episodes share features to some extent, it is inevitable that test probes will match at least one feature from several memory traces other than the target trace. In models that lack sensitivity to conjunctions, these small matches – in aggregate – would swamp the one large match score associated with the target trace. Figure 1 illustrates how sensitivity to conjunctions (implemented using the cube rule) helps reduce interference in M2.

Modeling Interference Data

List length effects

While sensitivity to conjunctions minimizes interference caused by low amounts of cue-trace overlap, there is no way to completely eliminate interference caused by higher amounts of cue-trace overlap. There will always be non-target memory traces that, by chance, match the test probe strongly; these strong, spurious matches add noise to the global match signal and degrade performance. All global matching models predict that adding new items to the list (increasing *list length*) will impair both recognition and recall, by increasing the odds that a strong (but spurious) match will occur. In keeping with this prediction,

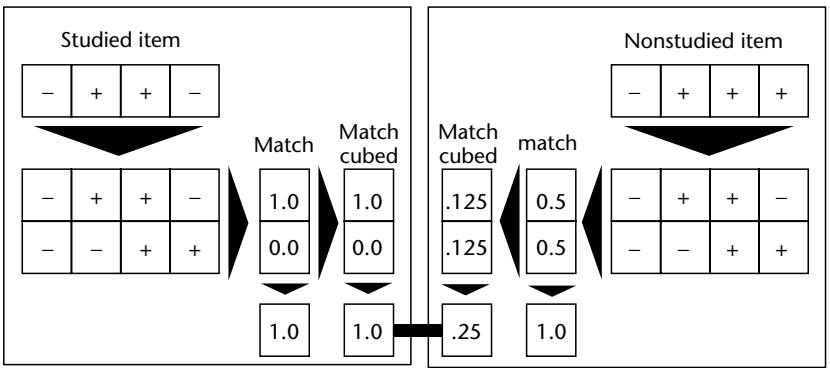

Figure 1. Illustration of how MINERVA 2 (M2) computes global match. For each of the two traces stored in memory, M2 computes a match value = (number of matching features – number of mismatching features)/(total number of nonzero features); then, M2 cubes these match values and adds them together to get a familiarity score for that cue. In this example, if match values are summed prior to cubing, the summed match values are equivalent for the studied item and the nonstudied item. However, if match values are summed after cubing, the studied item generates a much larger summed match score than the nonstudied item. Cubing benefits discrimination by minimizing the effect of weak (partial) matches on the summed match score, relative to the effect of more complete matches.

a very large number of studies have obtained list length effects for recognition and recall, although it is becoming clear that list length effects are not always obtained for recognition (see Dennis and Humphreys (2001) for discussion of this issue). (*See* **Catastrophic Forgetting in Connectionist Networks**)

Modeling the null list strength effect

One finding that global match models initially failed to predict is the null list strength effect (LSE) for recognition: Ratcliff *et al*. (1990) found that strengthening some list items, by presenting them repeatedly or for a longer duration, does not impair recognition of other (non-strengthened) list items. In models like M2, strengthening is operationalized by storing extra copies of an item to memory, or by increasing the probability of successful feature encoding. Both of these manipulations increase the global match score triggered by the strengthened item (thereby allowing the model to accommodate the finding that strengthening an item improves memory for that item). However, strengthening an item's memory trace also increases the mean and variance of the global match signal triggered by *other* items (intuitively: random, spurious match between the test probe and memory trace X has a larger effect on the global match signal when X is *strong* vs. when X is *weak*); this increase in variance leads to decreased recognition performance.

Researchers have been working from 1990 to the present to modify global matching models so they can accommodate the null recognition LSE obtained by Ratcliff *et al*. (1990). One promising approach to modeling the null LSE has been to posit that *differentiation* occurs as a consequence of strengthening (Shiffrin *et al*., 1990); the gist of differentiation is that as participants acquire experience with an item, the item's representation becomes increasingly refined, making it less likely that it will spuriously match some other item at test.

One example of an abstract model that incorporates differentiation is the REM model described by Shiffrin and Steyvers (1997) (see McClelland and Chappell (1998) for a similar model). REM uses a 'match' rule, based on Bayesian statistics, that computes the odds that the test probe and the stored trace are the *exact same item*. With this rule, a small amount of mismatch can have a very large effect; if you are certain that a memory trace contains a particular feature, and you are certain that the test probe does *not* contain that feature, the match value will be zero. In REM, strengthening a memory trace increases the number of encoded features; strong traces are less likely to trigger a spurious match because they are more likely to contain features that mismatch the test probe. Figure 2 provides a simple illustration of how strengthening reduces spurious matches in models like REM.

Single-process vs. dual-process approaches

An important feature of abstract global match models is that they attempt to explain recognition performance entirely in terms of the scalar familiarity signal. This *single-process* approach contrasts with *dual-process* theories of recognition, which posit that both familiarity and recall contribute to recognition performance (i.e. items can be called 'old' because they trigger a nonspecific feeling of familiarity, or because the subject specifically recalls some detail from when the item was studied). Furthermore, the most prevalent dual-process theory (Jacoby *et al*., 1997) posits that the operating characteristics of familiarity and recall are qualitatively distinct; according to this theory, familiarity is a signal-detection process (i.e. studied-item and lure familiarity are both normally distributed, and the two distributions overlap extensively) but recall is a high-threshold process (i.e. recall is all-or-none; studied items are sometimes called 'old' based on recall, but lure items are never called 'old' based on recall). Note that recall can be applied to recognition in abstract models like M2 (e.g. by cuing with the test item and comparing the recalled vector to the test item – if they match above a certain threshold, say 'old'). However, recall-based recognition and familiarity-based recognition have very similar operating characteristics in abstract models, because they are based on the same underlying match computation; as such, adding a recall process typically does not affect these models' recognition predictions. The only time that adding recall affects these models' performance is on recognition tests where some kind of content has to be retrieved (e.g. an exclusion test, where subjects have to say 'old' to studied words from one list and 'new' to studied words from another list). Also, some models derive different predictions for recall and familiarity based on the assumption that subjects cue memory differently when they are trying to recall items, i.e. they are more likely to incorporate context into the retrieval cue (Shiffrin *et al*., 1990); however, this is not a difference between recall and familiarity *per se*.

It would be possible to build an abstract model that uses different match rules for recall and familiarity-based recognition, in keeping with the idea that these systems have distinct operating

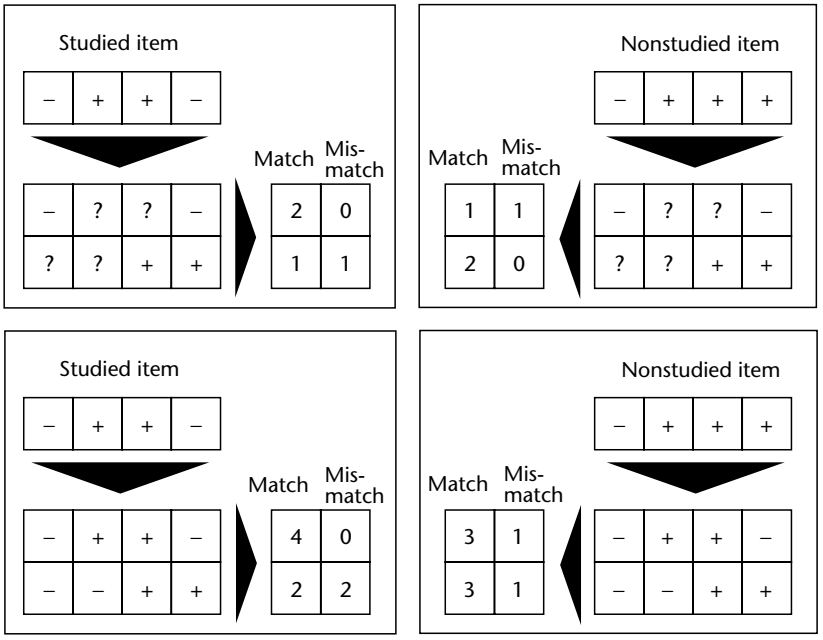

Figure 2. Illustration of how strengthening – operationalized as more complete feature encoding – can reduce spurious matches. Question marks indicate features that were not encoded at study. Prior to strengthening (upper two panels), the studied item and the nonstudied item match stored traces equally well; for both items, there is one trace that appears to match the test cue, i.e. there are some matching features, and no mismatching features. After strengthening (lower two panels), it is apparent that the nonstudied item does not exactly match either of the stored traces.

characteristics. This has not occurred because, once recall and familiarity are allowed to use different match rules, it is unclear how to constrain these (separate) systems based purely on behavioral data. Extant techniques for measuring the separate contributions of recall and familiarity to behavioral recognition performance are controversial because they rely on assumptions about the properties of recall and familiarity that cannot be tested empirically (e.g. that recall and familiarity are stochastically independent; for more on these techniques, see Jacoby *et al.*, 1997).

BIOLOGICAL MODELS

One way to further constrain dual-process models is to incorporate information about how recall and familiarity are computed in the brain. Biological models of episodic memory, like abstract models, try to account for the widest possible range of behavioral findings; however, unlike abstract models, biological models incorporate explicit claims about how the brain gives rise to recognition. Biological models of episodic memory have focused largely on the hippocampus, because neuropsychological data unequivocally indicate that the hippocampus is necessary for recall.

Modeling Hippocampal Contributions to Episodic Memory

Over the past decade, several researchers have developed biologically detailed computational models of the hippocampus, with the goal of explaining how the hippocampus contributes to episodic memory (Norman and O'Reilly, in press; Hasselmo and Wyble, 1997). The aforementioned models all view the hippocampus as a machine that is specialized for rapidly storing patterns of cortical activity ('episodes') in a manner that minimizes interference and allows for *pattern completion*: subsequent recall of entire stored patterns in response to partial cues. Furthermore, these models make similar – albeit not identical – claims about how different hippocampal substructures contribute to this process. This article will focus on the Norman and O'Reilly Complementary Learning Systems (CLS) neural network model, which has a hippocampal component (described in this section) and a cortical component (described in the next section); a schematic diagram of the CLS hippocampal network is shown in Figure 3. (*See* **Hippocampus**)

In the CLS model, the hippocampal network binds together sets of co-occurring neocortical

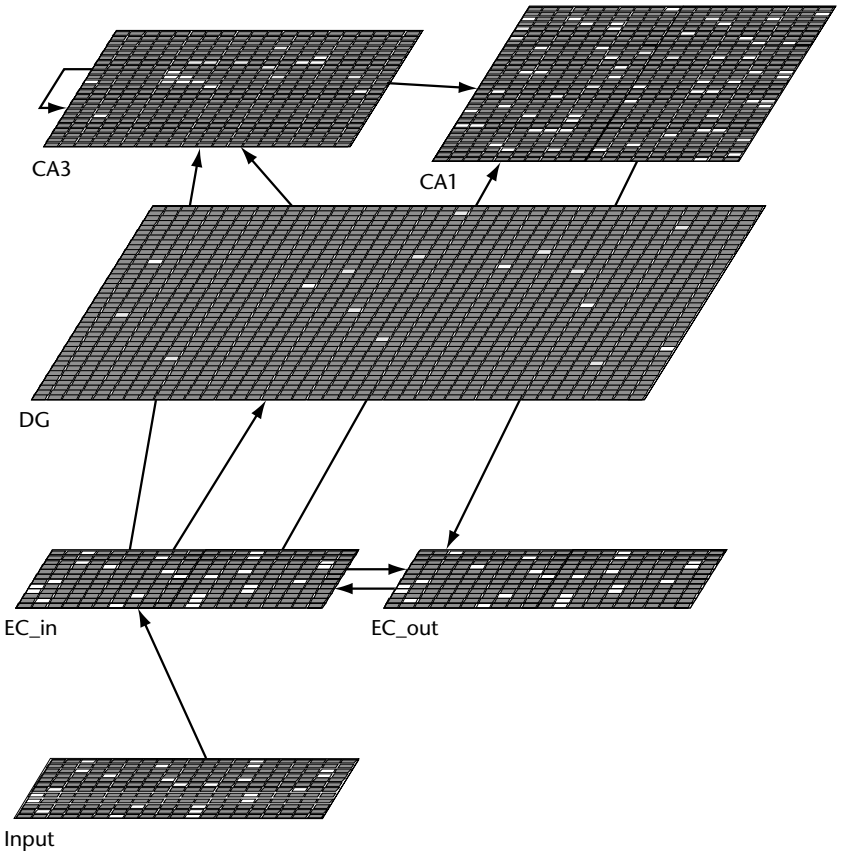

Figure 3. Diagram of the CLS hippocampal network. The hippocampal network links input patterns in entorhinal cortex (EC) to relatively non-overlapping (*pattern-separated*) sets of units in region CA3; recurrent connections in CA3 bind together all of the units involved in representing a particular EC pattern; the CA3 representation is linked back to EC via region CA1. Learning in the CA3 recurrent connections, and in projections linking EC to CA3 and CA3 to CA1, makes it possible to recall entire stored EC patterns based on partial cues. The dentate gyrus (DG) serves to facilitate pattern separation in region CA3; see O'Reilly and McClelland (1994) for details.

features (corresponding to a particular episode) by linking co-active units in entorhinal cortex (EC – the neocortical region that serves as a gateway to the hippocampus) to a cluster of units in region CA3 of the hippocampus; these CA3 units serve as the hippocampal representation of the episode. Recurrent connections between active CA3 units are strengthened. To allow for recall, active CA3 units are linked back to the original pattern of cortical activity via region CA1. Learning in the model occurs according to a Hebbian rule whereby connections between units are strengthened if both the sending and receiving units are active, and connections are weakened if the receiving unit is active but the sending unit is not.

At test, when a partial version of a stored EC pattern is presented to the hippocampal model, the model is capable of reactivating the entire CA3 pattern corresponding to that item because of learning that occurred at study; activation then spreads from the item's CA3 back to the item's EC representation (via CA1). In this manner, the hippocampus manages to retrieve a complete version of the EC pattern in response to a partial cue.

To minimize interference between episodes, the hippocampus has a built-in bias to assign relatively non-overlapping (*pattern separated*) CA3 representations to different episodes. Pattern separation occurs because hippocampal units are sensitive to conjunctions of neocortical features; given two neocortical patterns with 50% feature overlap, the probability that a particular conjunction of features will be present in both patterns is much less than 50% (see O'Reilly and McClelland (1994) for a much more detailed treatment of pattern separation in the hippocampus, and for discussion of the role of the dentate gyrus in facilitating pattern separation). The hippocampal model is sensitive to conjunctions because it uses *sparse* representations (where this sparseness is enforced by inhibitory

competition); in the model, a given input pattern only activates about 4% of the units in CA3. Inhibitory competition forces units to compete to represent input patterns, and units that are sensitive to multiple features of a given input pattern (i.e. feature conjunctions) are more likely to win the competition than units that are only sensitive to single input features.

A key property of neural network models is that some degree of structural interference between memory traces at storage is inevitable, assuming that there is overlap between memory traces (i.e. different items activate the same units). Whenever there is overlap, sensitivity to features that are shared across items increases, but sensitivity to features that are unique to specific items decreases. Pattern separation mechanisms in the hippocampus reduce structural interference (effectively preventing *catastrophic interference*, where studying new items totally wipes out stored memory traces) but do not eliminate interference entirely. The view that degradation is inevitable contrasts strongly with models like MINERVA 2 and REM, which posit that memory traces with overlapping features can be stored separately, with no structural degradation (but do not explain how this could come about). (*See* **Catastrophic Forgetting in Connectionist Networks**)

The raw output of the CLS hippocampal model is a vector comprising recalled information. Norman and O'Reilly (in press) apply the model to recognition by comparing the output vector (recall) to the input vector. If recalled information matches the test probe, this constitutes evidence that the test probe was studied; if recalled information mismatches the test probe, this is evidence that the test probe was not studied; specifically, Norman and O'Reilly compute a recall score equal to the number of matching features minus the number of mismatching features. While the hippocampal model shows good recognition discrimination in standard list-learning paradigms, there are several findings in the recognition literature that the hippocampal model, taken by itself, cannot explain. For example, the hippocampal model tends to underpredict false recognition. Because of pattern separation, test cues have to overlap strongly with studied patterns in order to activate the CA3 representations of these studied patterns (thereby triggering recall); as such, the hippocampal model predicts that nonstudied lure items should not trigger any recall, unless they are highly similar to studied items. This prediction conflicts with the finding that false recognition rates are typically well above zero in list-learning experiments.

Modeling Neocortical Contributions to Episodic Memory

One way to accommodate these issues with the hippocampal model is to argue that the hippocampus is not the only structure that contributes to recognition memory. Consistent with this view, neuropsychological data indicate that *medial temporal neocortex* (MTLC) also contributes to recognition – patients with hippocampal damage but spared MTLC perform well above chance on recognition tests. Norman and O'Reilly (in press) have also constructed a neural network model of MTLC to explore how this structure contributes to recognition memory. In keeping with the complementary learning systems view set forth by McClelland *et al*. (1995), Norman and O'Reilly posit that the primary function of neocortex (including MTLC) is to integrate across episodes to learn about the statistical structure of the environment. In contrast to the hippocampal model, which is biased to assign distinct representations to episodes and uses a large learning rate (thereby allowing it to quickly memorize individual episodes), the MTLC model assigns overlapping representations to similar episodes (thereby allowing it to represent what these episodes have in common) and uses a relatively small learning rate.

A schematic diagram of the MTLC model is shown in Figure 4. Because cortex uses a small

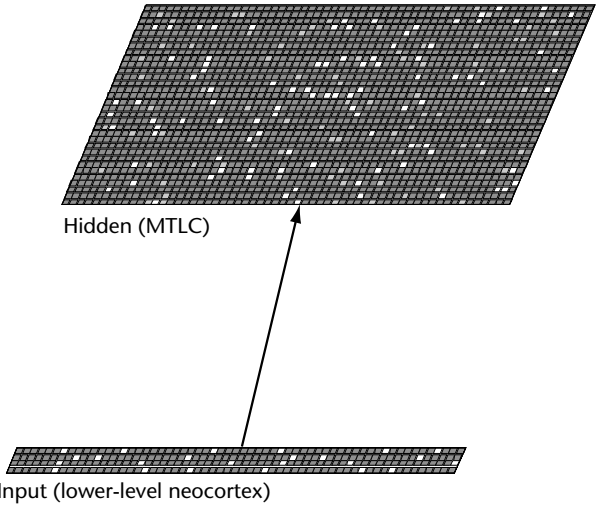

Figure 4. Diagram of the CLS cortical network. The cortical network consists of two layers, an input layer (corresponding to 'lower' cortical regions that represent basic features of input patterns) and a hidden layer (corresponding to MTLC). Units in the hidden layer compete to encode (via Hebbian learning) regularities that are present in the input layer.

learning rate, it is not capable of pattern completion (recall) following limited exposure to a stimulus. However, it is possible to extract a scalar signal from the MTLC model that reflects stimulus familiarity. In the MTLC model, as items are presented repeatedly, their representations in MTLC become *sharper*: novel stimuli weakly activate a large number of MTLC units, whereas familiar (previously presented) stimuli strongly activate a relatively small number of units. Sharpening occurs because Hebbian learning specifically tunes some MTLC units to represent the stimulus. When a stimulus is first presented, some MTLC units, by chance, will respond more strongly to the stimulus than other units; these units get tuned by Hebbian learning to respond even more strongly to the item the next time it is presented; and these strongly active units start to inhibit units that are less strongly active. To index representational sharpness – and through this, stimulus familiarity – we measure the average activity of the MTLC units that win the competition to represent the stimulus. Because there is more overlap between representations in MTLC than in the hippocampus, the MTLC signal has very different operating characteristics than the hippocampal recall signal. Whereas lures rarely trigger hippocampal recall, Norman and O'Reilly (in press) showed that the MTLC signal tracks, in a graded fashion, how similar the test probe is to studied items.

Some Predictions of the CLS Model

Effects of hippocampal lesions

Because the CLS model maps clearly onto the brain, it is possible to use the model to address neuroscientific data in addition to (purely) behavioral data. For example, the model makes predictions about how different kinds of medial temporal lesions will affect episodic memory. One prediction is that hippocampal lesions should impair performance on yes–no recognition tests with *related lures* (i.e. lures that are similar to specific studied items) more so than on tests with *unrelated lures*. When lures are not highly similar to studied items, both systems (MTLC and hippocampus) discriminate well, but when lures are similar to studied items the hippocampus outperforms MTLC because of its ability to assign distinct representations to similar stimuli, and its ability to reject lures when they trigger recall that *mismatches* the test probe. For evidence in support of this prediction see Holdstock *et al*. (in press).

Interference: a challenge for biological models

While the biological approach to episodic memory modeling has led to new insights into episodic memory (and the brain basis thereof), this approach faces several challenges. One major challenge is accounting for the effects of *interference* (e.g. list length, list strength) on recognition and recall. As discussed above, biological models generally predict some degree of structural interference between memory traces at study, i.e. learning about one item degrades the memory traces associated with other items. Several researchers have questioned whether models that posit structural interference at storage could account for the null list strength effect on recognition sensitivity, because of this pervasive tendency towards trace degradation. However, Norman and O'Reilly (in press) showed that biologically realistic neural network models with overlapping representations are, in fact, capable of accommodating the null list strength finding. The CLS cortical model predicts a null list strength effect for recognition sensitivity, given low-to-moderate levels of input pattern overlap, because (initially) the model's responding to lures decreases as much as its responding to studied items as a function of interference; as such, the distance between the studied-item and lure-item familiarity distributions stays relatively constant, and discriminability does not decrease.

Importantly, the CLS model also predicts that list strength effects should be obtained for the hippocampal recall process. In the hippocampal model, interference degrades the model's ability to recall studied items, and recall of lures is typically near zero (and thus can not decrease); because of this floor effect on lure recall, interference has the effect of pushing together the studied-item and lure-item recall distributions, leading to decreased discriminability. For evidence in support of the CLS model's list strength predictions, see Norman (in press).

SUMMARY

Abstract episodic memory models like M2 provide an elegant account, at the algorithmic level, of our ability to recall and recognize specific events from our personal past. These models posit that recall and familiarity rely on the same 'match' rule and thus have similar operating characteristics. A potential weakness of abstract models is that they do not consider the *neural plausibility* of these algorithms; it is very difficult to see how features

of some abstract models (e.g. the total absence of structural interference between traces at study in M2 and REM) could be implemented in the brain.

Recently developed biological episodic memory models seek to remedy this by establishing a clear isomorphism between parts of the model and parts of the brain that have been implicated in episodic memory (e.g. in neuropsychological studies). The Norman and O'Reilly CLS model posits that recall and familiarity have different operating characteristics, insofar as they rely on distinct neural structures – the hippocampus and medial temporal neocortex – that differ in their architecture and connectivity. The hippocampus is more sensitive to feature conjunctions than cortex, which in turn leads to less overlap between representations. Low overlap makes it possible for the hippocampus to rapidly memorize patterns without catastrophic interference (although interference still occurs), and it also decreases the probability of false recognition, relative to what occurs in cortex. Event-related Potentials and Mental Chronometry

Introductory article

Edward L Wilding, Cardiff University, Cardiff, Wales, UK
Jane E Herron, Cardiff University, Cardiff, Wales, UK

CONTENTS

Mental chronometry is the label that has been given to the use of reaction times to identify and characterize the stages of human information processing that occur between a stimulus and a response. Event-related potentials (ERPs) are also suited to this, since they index in real time the brain processes that reflect successive stages of human information processing.

INTRODUCTION

Cognitive scientists study and attempt to explain the workings of a complex information-processing system, namely the human brain. One particularly influential concept in this endeavor has been the computer metaphor, which incorporates the view that human cognition can be understood by comparison with the ways in which computers process information. Consideration of the limitations and operating characteristics of computers yields several features that might also be true of the human information-processing system. For example, information is often processed in a series of stages, at least some of those stages have capacity limitations, and each processing stage takes time to complete.

The challenge for cognitive psychologists is to develop appropriate models that describe these information-processing stages, and then to test the models in experiments. There are several approaches that can be taken in pursuit of this goal. These include (1) the implementation of computational models that mimic the way in which the system might work, (2) the study of individuals with selective brain damage who have deficits at particular information-processing stages, and (3) the use of reaction times, measures of accuracy, and/or online measures of brain activity to test and generate predictions of a model. It is a subset of this third approach – which can be defined as *mental chronometry* – that will be the focus of the rest of this article.

MENTAL CHRONOMETRY

The term *mental chronometry* was introduced in the late 1970s to describe (primarily) the use of reaction-time measures to gain a better understanding of the structure, function, and dynamics of the human information-processing system (often referred to as the *cognitive architecture*). The main idea is that differences between reaction times that are obtained in different tasks can be employed to determine the dynamics of human information processing, and to infer the presence or absence of certain processing stages, as well as the way in which those processing stages work.

One set of tasks that has been widely used in order to investigate human information processing involves systematically manipulating the relationship between the types of stimuli that are presented and the types of responses that are to be made to them. One reason for doing this is to investigate the operation of two stages that intervene between a stimulus and a response. These stages are *stimulus discrimination* and *response selection*. The idea is that by designing tasks which challenge these processing stages in different ways, and by using reaction times as a measure of performance, it will be possible to determine some of the characteristics of these two stages.

Imagine, for example, that three tasks all involve presentation of a series of pictures one at a time, and that each picture is either a blue circle or a red circle. Each task differs in what you know about the picture that will be presented next and/or in the

rules with regard to when you should and should not respond by pressing a key. The different requirements are described briefly below.

Task Structure

- *Task 1 (simple reaction time)*. You know ahead of time that the circle will always be blue. All you have to do is to respond as quickly as possible by pressing a key when the blue circle appears.
- *Task 2 (choice reaction time)*. You do not know what color of circle will be presented in each trial. You must respond as quickly as possible with the appropriate hand (e.g., left for blue, right for red) when the circle appears.
- *Task 3 (go/no-go)*. This is the same as for task 2, except that you must respond to red circles (go trials) and make no response to blue circles (no-go trials).

Comparison of the reaction times in these three tasks allows estimates to be made of the time courses of stimulus discrimination and response selection. Consider the differences between tasks 1 and 2. Only the latter requires you to determine the color of the circle and to map the color on to the appropriate response, because in task 1 you know ahead of time which hand to respond with. Thus any difference in reaction time between these tasks probably reflects a combination of the time taken for stimulus discrimination *plus* the time taken for response selection.

Now consider tasks 1 and 3. In this case, the primary disparity is the requirement for stimulus discrimination in task 3 only, while in both cases the response selection requirement is the same – there is only one response to make. Triangulating the reaction times in the three experiments thus provides a means of estimating separately the times that are taken for stimulus discrimination and for response selection.

LIMITATIONS OF REACTION-TIME MEASURES

The example described in the previous section gives some idea of how reaction times can be used to investigate characteristics of the cognitive architecture. This particular approach has been termed the *subtraction method* because it relies on a comparison of the differences between reaction times that are obtained in tasks which are assumed to differ in terms of the particular information-processing stages that they challenge. The principal limitation of the use of reaction times to study the time course of cognitive processes stems from the fact that it is reasonable to assume that multiple, possibly temporally overlapping, processing stages intervene between a stimulus and a response. Reaction times provide only an estimate of the total time that is taken to progress between stimulus and response. The concern that a particular experimental manipulation does not isolate the stage or stages of interest is one that is difficult to dispense with altogether. Indeed, much of the discussion of the appropriate framework within which to employ reaction times optimally in the study of human information processing reflects these concerns.

The ideal measure of the processing stages that intervene between stimulus and response would be one that can track *in real time* the progression of the cognitive operations that are engaged between these two points. Examining the way in which these measures of particular cognitive operations change as a result of cognitive challenges would then allow more precise claims about the time course and the architecture of the human information-processing system than is available from reaction-time measures alone. The acquisition of event-related potentials (ERPs) is one approach that could potentially bridge the gap between stimulus and response.

EVENT-RELATED POTENTIALS (ERPS) AND MENTAL CHRONOMETRY

Information transmission in the brain is achieved by means of electrical signals. These signals can be recorded from electrodes that are placed on the scalp. There are several types of such recordings, including *event-related potentials (ERPs)*, which are small changes in short segments of the ongoing electrical activity of the brain, revealed by averaging across several segments of the same type. ERPs can track changes in brain activity on a millisecond-by-millisecond basis, and by starting recording precisely when a stimulus (e.g., a red circle) is presented, ERPs may provide insights into the processing stages that commence with stimulus presentation.

ERPs are typically recorded from multiple sites on the head, and the activity reflecting the operation of different cognitive processes is detectable at different sites. Of most relevance to mental chronometry is the fact that an ERP recorded from a single site can be regarded as a graph that plots changes in brain electrical activity over time. Each graph consists of a series of positive and negative deflections, and these can be thought of as reflecting the different processing stages that are set in train by a stimulus. (*See* **Visual Evoked Potentials**)

One line of psychological inquiry involves identification of the cognitive processes that are indexed by particular deflections. For at least some of these there is a degree of consensus as to which information-processing operations they reflect, and this is important if ERPs are to be used as a tool to complement the information about human information processing that is provided by reaction-time studies. The core assumption of the ERP approach to mental chronometry is that inferences about cognitive architecture can be made by observing the way in which these positive and negative deflections vary across different psychological tasks.

There are at least two ways in which ERP deflections can vary across tasks. First, the amplitude (or size) of a deflection can change. This is generally taken to mean that the cognitive process indexed by that deflection is active to a greater extent in the task where the deflection is largest. Second, the time after a stimulus at which a deflection is largest (the *peak latency*) can differ. In this case, it is assumed that the time course of the cognitive process that is indexed by the deflection of interest differs across tasks. In some cases, amplitude and latency changes can occur together, while in others only one of the two will change. The following example gives more substance to this abstract characterization, and is concerned with changes in the amplitude of deflections only.

THE LATERALIZED READINESS POTENTIAL (LRP)

Some ERP deflections are given names that describe, at least in part, the psychological processes that they index, and the lateralized readiness potential (LRP) is one example of this. The LRP is considered to reflect preparatory motor processes, and can therefore be used as an index of covert preparation for movement. The LRP, as the label implies, is larger over the left or the right hemisphere of the brain depending on which hand the participant is preparing to respond with. The LRP is largest over the hemisphere opposite the hand with which the participant is preparing to respond. The LRP is typically evident in the electrical record during the period immediately before a response is made. The presence of a measurable LRP is a very strong indication that a participant is preparing to make a response.

In studies of mental chronometry, measurements of the LRP have been used to determine what sources of information influence the selection of a particular motor response in cognitive tasks. This question is interesting because it is concerned with the way in which the response-selection system works. According to one account, response selection begins only after complete evaluation of a stimulus has occurred. However, according to an alternative account, partial information can be sufficient to influence response selection. The experiment described below provides an example of how it might be possible to determine which of these competing accounts is correct.

Consider a variant of the go/no-go task described earlier. In that task, the stimuli were either red or blue, and the requirement was to respond to red stimuli only. In this new task, the stimuli are again either red or blue, and in addition they are either the letter N or the letter M. Crossing all possible combinations of colors and letters means that there are four different stimuli. In this task, the requirement is to respond to a red M only. The question is whether a larger LRP is observed for the red N than for the two blue stimuli. Observation of the LRP for the red N but not for either of the blue stimuli would indicate that color information has privileged access to the response-selection process, since color provides only partial information about the appropriate response in that trial. It would be almost as if the system was making an educated guess about the likely response, since knowing the color increases the probability that a response is required (since only two of the four stimuli are red), but it does not provide all of the information that is necessary for a response to be made or withheld.

There are a number of studies in which the LRP has been measured and it has been demonstrated that certain types of partial information influence response selection, while others do not. Findings such as this are important for our understanding of cognitive architecture – they tell us something about the way in which the system works – and they have important practical implications as well, since there are circumstances in which it would be undesirable to provide partial information that might influence response selection. Imagine, for example, that the use of partial information will lead to an increased likelihood of a response error (in the above example this would be a response to a red N). In safety-critical environments such as a cockpit, pilots have to distinguish quickly between multiple competing stimuli, some of which are more important than others. It is desirable to use stimuli that minimize errors in this environment, and of course optimal stimulus design will be

guided by fundamental psychological knowledge of the way in which human response selection works.

CONCLUSION

Mental chronometry is the label that has been given to the use of reaction times to study the dynamics and structure of cognitive architecture. ERPs index (with millisecond resolution) some of the cognitive processes that are involved in the gap between the presentation of a stimulus and a motor response. Because of this characteristic they are well suited to providing information about cognitive architecture which complements, and in some cases might extend, that which can be obtained by using reaction times. CONTENTS

Executive control is involved in the operation of processes supporting various prefrontal functions such as set shifting, working memory and long-term memory.

INTRODUCTION

The frontal cortex comprises one-third of the human brain; it is the structure that enables us to engage in higher cognitive functions such as planning and problem-solving. What are the processes that serve as building blocks for these higher cognitive functions, and how are these implemented in the frontal cortex?

Patients with prefrontal damage show a characteristic deficit in the ability to construct mental plans of action ('schemas') and to execute them. This deficit can be objectified by several neuropsychological tests. It is most apparent in tests that require internal programming of new behavior. The ability to plan, which depends on executive function, is severely curtailed in many patients with prefrontal cortical damage.

The Tower of London Test is considered to be a test of the ability to plan and is used on patients with prefrontal cortical damage (Figure 1). The test material consists of a board with three vertical sticks fixed on it and three wooden rings of different colors made to slide up and down on them. The sticks are of different lengths, so that the first can accommodate the three rings on top of one another, the second two rings, and the third only one. From an initial position of the rings on the sticks (for example, red over green on the long stick, blue on the middle stick), the person completing the test is instructed to move one ring at a time from stick to stick in a prescribed number of moves, and achieve a certain order (for example, green over blue over red on the long stick in five moves). The test requires planning a series of subgoals in order to attain the ultimate goal; the participant must anticipate and visualize not only that goal but also the steps leading to it in the proper sequence. Patients with prefrontal cortical damage were found to be severely impaired in performing this test, suggesting that the prefrontal cortex exerts executive function.

ANATOMY OF THE PREFRONTAL CORTEX

The prefrontal cortex is located on the anterior pole of the brain (Figure 2). Its increase in size with phylogenetic development can be inferred from the study of brains of existing animals as well as from paleoneurological data. It is most apparent in the primate order based on cytoarchitectonic calculations, forming 29% of the total cortex in humans, 17% in chimpanzees, 11.5% in gibbons and macaques, and 8.5% in lemurs. For dogs and cats, the figures are 7% and 3.5% respectively. Thus, the greater magnitude of the human prefrontal cortex in relation to other cortical regions has been considered to indicate that this cortex is the substrate for neural activity of higher cognitive functions, which, as a result of phylogenetic differentiation, has become a distinctive part of the evolutionary patrimony of our species.

With regard to studying the neural bases of cognition, a key question is the delineation of the cortical areas in which changes in neuronal activity occur during specific aspects of cognitive processing. The aim of delineating the cortical areas is to achieve an understanding of the cortical and subcortical networks that underlie different cognitive processes, and to specify the contribution of each cerebral area to the functional network in which it is involved.

To divide the prefrontal cortex into areas, the prefrontal cortex of the human and the monkey

has been studied anatomically. The brain was sectioned in the coronal plane and stained for cytoarchitectonic and myeloarchitectonic analysis. One of the well-known cytoarchitectonic maps of the prefrontal cortex is provided in Figure 3. The prefrontal cortex is divided anatomically into three major regions: dorsolateral, orbital and medial. In the case of the human prefrontal cortex, these regions are outlined as follows. The dorsolateral cortex is the lateral aspect of the prefrontal cortex and comprises areas 8, 9, 10, and 46. The orbitofrontal cortex is the ventral aspect of the prefrontal cortex and it mainly comprises areas 11 and 13. The medial prefrontal cortex comprises parts of areas 8 through 10, and areas 12, 24 and 32. Damage in each of these three regions tends to be associated with a characteristic syndrome or cluster of symptoms.

NEUROPSYCHOLOGY

Studies of lesions of the prefrontal cortex caused by disease or trauma provide helpful insights into the functions of this structure, even though the lesions occur unpredictably and without experimental logic. The neuropsychological effects of prefrontal cortical damage vary greatly depending on the location and the extent of that damage.

Damage to the major prefrontal region generally results in one of three different syndromes. The dorsolateral damage syndrome is characterized mainly by difficulties in focusing and sustaining attention, lack of initiative and decision-making, inability to form plans and execute them, poor working memory and low verbal fluency. All these disorders are more common and conspicuous if the left dorsolateral cortex is involved than if the lesion is on the right hemisphere. A common result of dorsolateral damage is the deficit in working memory, i.e. the memory of information used for prospective motor or mental action. The orbital damage syndrome is mainly marked by impulsivity, hypermotility, distractibility, instinctual disinhibition, irritability, euphoria, perseveration and lack of moral restraint. The medial/anterior cingulate syndrome is mainly distinguished by a lack of initiative, hypokinesia or akinesia, apathy and mutism.

A prefrontal cortex deficit can be detected using a variety of tests, including the Wisconsin Card Sorting Test (WCST). This test requires the categorization of sensory (visual) items according to a temporally changing principle (Figure 4). Patients with dorsolateral lesions in the prefrontal cortex are unable to perform the task flexibly. At the start of the test, the participant is shown four 'target' cards on a table, each with a different printed design: one red triangle, two green stars, three yellow crosses and four blue circles. The participant is given a deck of cards differing in the number, color and shape of the items they depict, and instructed to sort the cards and place them, one

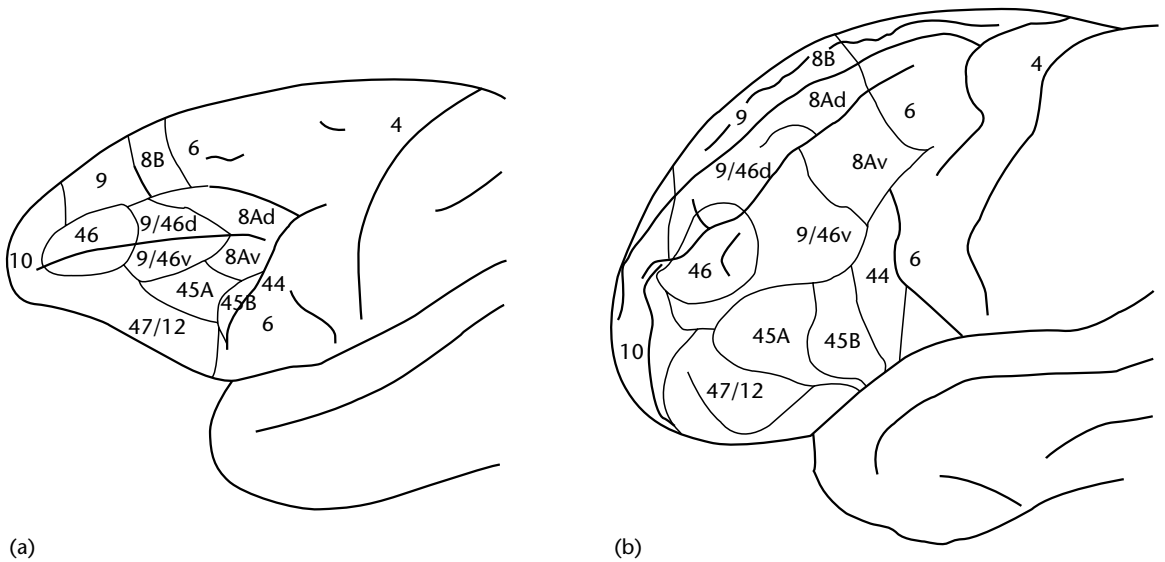

Figure 3. Cytoarchitectonic map of the lateral surface of the frontal lobe of human (a) and macaque monkey (b). d, dorsal; v, ventral. Modified from Petrides and Pandya (1994).

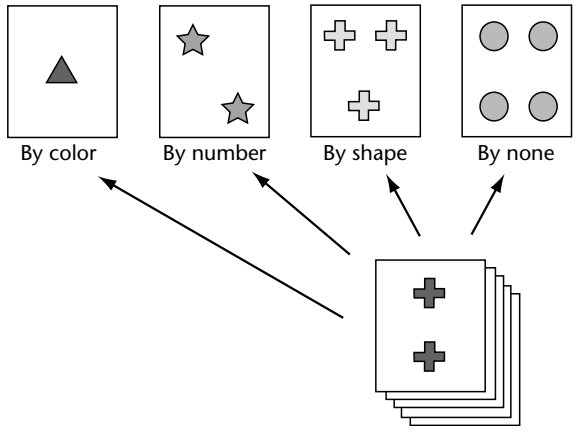

Figure 4. [*Figure is also reproduced in color section.*] The Wisconsin Card Sorting Test. Modified from Milner (1964).

at a time, under the target cards. After each card placement, the tester simply tells the participant whether the choice is correct or not (according to a tacit matching principle – number, color, or shape – determined by the tester). After a succession of correct choices, the tester, again tacitly, changes the matching principle, and the participant must guess that new principle and make subsequent choices according to it. After a succession of correct choices the principle changes again, and so on.

In order to perform the WCST correctly, the person taking the test must not only adapt to a new principle but also reject an old one. Thus, the WCST tests not only short-term memory but also the ability to withstand interference from inopportune memories. It also tests the ability to plan actions and to carry them out. All these functions can be impaired in the prefrontal syndrome, and it is probably for this reason that performance on the WCST may be poor as a result of dorsolateral lesions.

The prefrontal syndrome varies presumably depending on the region most affected. In particular, the dorsolateral syndrome can be summarized as the failure of executive functioning.

NEUROIMAGING

Computerized scanning and tomographic methods allow the visualization of changes in regional blood flow and metabolism related to neuronal activity. Thus, neuroimaging provides indirect records of the global neuron discharge in various regions of the brain simultaneously: that is, a functional map of the brain.

Recent imaging studies of the prefrontal cortex have focused on working memory, a system used for temporary storage and manipulation of information. The system is divided into two general components: short-term storage and a set of 'executive processes'. Short-term storage involves active maintenance of a limited amount of information for a matter of seconds; it is a necessary component of many higher cognitive functions and is mediated in part by the prefrontal cortex. Executive processes

are implemented by the prefrontal cortex as well. Although executive processes often operate on the contents of short-term storage, the two components of working memory can be dissociated: there are neurological patients who have intact short-term storage but have defective executive processes, and vice versa.

Storage Processes and the Prefrontal Cortex

Many neuroimaging studies are founded on Baddeley's model of working memory, which posits separate storage buffers for verbal and visuospatial information. Baddeley further argued that verbal storage could be subclassified into a phonological buffer for short-term maintenance of phonological information and a subvocal rehearsal process that refreshes the contents of the buffer. Here we examine evidence on each aspect of this model with respect to the prefrontal cortex.

Some evidence about storage mechanisms was obtained by positron emission tomography and functional magnetic resonance imaging studies using 'two-back' and 'three-back' tasks. In the two-back task, participants viewed a sequence of single letters presented at intervals of a few seconds; for each letter they had to decide whether it was identical to the letter that appeared two items back in the sequence. The experiment used two different controls. In one, participants were presented with a sequence of letters but only had to decide whether each letter matched a single target letter. Subtracting this control from the two-back condition identified many areas of activation known to be involved in item recognition tasks, including the left frontal speech regions and the parietal area. The second control required participants to rehearse each letter silently. Subtracting this rehearsal control from the two-back task should have removed much of the rehearsal circuitry since rehearsal is needed in both tasks; indeed, in this subtraction, neither Broca's area nor the premotor area remained active. Hence, this experiment isolated a frontal rehearsal circuit. Frontal regions that no doubt evolved for the purpose of spoken language appear to be recruited to keep verbal information active in working memory.

Research on nonverbal working memory has been influenced by physiological work with nonhuman primates. Single-cell recordings performed while monkeys engaged in spatial-storage tasks have identified 'spatial memory' cells in the dorsolateral prefrontal cortex (which is usually considered to include areas 46 and 9). These cells selectively fire during a delay period and are position-specific. Recordings performed while monkeys engaged in object-storage tasks have identified delay-sensitive 'object memory' cells in the prefrontal cortex.

Executive Processes and the Prefrontal Cortex

Most researchers concur that executive processes are mediated by the prefrontal cortex and are involved in the regulation of processes operating on the contents of working memory. Although there is a lack of consensus about the taxonomy of executive processes, there is some agreement that they include:

- focusing attention on relevant information and processes, and inhibiting irrelevant ones (attention and inhibition);
- scheduling processes in complex tasks, which require the switching of focused attention between tasks (task management);
- planning a sequence of subtasks to accomplish some goal (planning);
- updating and checking the contents of working memory to determine the next step in a sequential task (monitoring);
- coding representations in working memory for time and place of appearance (coding).

Performance of tasks manifesting each of these processes is known to be selectively impaired in patients with prefrontal damage. Of these five executive processes noted, the first two appear to be the most elementary and the most interrelated; for these reasons, we focus on task management.

A canonical case of task management arises when patients are required to perform a dual task. For example, they may be presented with a series of numbers and have to add 3 to the first number and subtract 3 from the second, and so on through successive trials. Both tasks require some nonautomatic or 'controlled' processes, and a critical aspect of task management is switching from one controlled process to another.

A magnetic resonance imaging study has examined dual-task performance. In one task, participants had to decide whether each word presented in a series named an instance of the category 'vegetable'; in the other task, participants had to decide whether two visual displays differed only by a matter of rotation; in the dual-task condition, the patients had to perform the categorization and rotation tasks concurrently. Only the dual-task condition activated prefrontal areas, including

dorsolateral prefrontal cortex (BA 46) and the anterior cingulate.

Neuroimaging studies of humans show that storage and executive processes are the major functions of the prefrontal cortex. The distribution between short-term storage and executive processes appears to be a major organizational principle of the prefrontal cortex. Neuroimaging analysis of executive processes is quite recent, and must lead to clear dissociations between processes.

STUDY OF PREFRONTAL CORTEX IN ANIMALS

The role of the prefrontal cortex has also been studied in nonhuman primates in lesional and physiological studies.

Lesions in the prefrontal cortex elicit characteristic behavioral abnormalities. The dorsal and lateral prefrontal surfaces of the cortex are primarily involved in cognitive aspects of behavior; the rest of the prefrontal cortex, medial and ventral, appears to be mostly involved in affective and motivational functions, as well as in the inhibitory control of external and internal influences that interfere with purposive behavior. The ability of monkeys with lesions in the prefrontal cortex to perform an analogue of human neuropsychological tests such as the WCST is also impaired.

Neurophysiological studies of monkeys that have explored the neural basis of cognitive control indicate that the prefrontal cortex has a role in operating nodal points, where neural circuits integrate currently available or memorized information to generate the information necessary to perform an action. Subsequent reports provide insight as to how the processes of information retrieval and integration are actually carried out in the prefrontal cortex. The prefrontal cortex performs the following functions: retrieval of sensory information to meet behavioral demands; executive control of memory retrieval from sites of long-term storage; active maintenance of either sensory or memory information; and integration or manipulation of the retrieved or stored information for subsequent use.

Sensory Information Retrieval

Prefrontal neurons reflect learned associative relationships between goal-relevant elements – they show conjunctive tuning for learned associations between cues, voluntary actions and rewards. Prefrontal neurons even show tuning for complex, behavior-guiding rules. Thus they may help form neuron ensembles that represent the regularities across experiences that describe the principles needed to achieve a particular goal in a particular situation.

Many lateral prefrontal cortex neurons reflect these learned associations. For example, most lateral prefrontal cortex neurons were found to reflect the association between a cue and a reward. A given neuron might be activated by a cue, but only when it signalled 'reward'. In contrast, another neuron might be activated only by a cue that signalled 'no reward'. Similarly, lateral prefrontal cortex neurons can reflect learned associations between a cue and behavior. Monkeys were trained to associate, in different blocks of trials, each of two cue objects with a saccade to the right or left. The activity of lateral prefrontal cortex neurons reflected associations between objects and direction of saccades instructed. Other neurons exhibited activity that reflected the cues or the saccades alone, but these were fewer in number. The prefrontal cortex neurons can reflect learned associations between visual and auditory stimuli.

Storage Processes

Active maintenance of information for subsequent use is an important aspect of the prefrontal cortex function, and its operation has been studied extensively using a variety of working memory tasks. One of the classic signs of the prefrontal cortical damage is increased distractibility: people with such damage seem unable to focus on a task when other, irrelevant events compete for their attention. This may reflect the loss of mechanisms for maintaining goal-relevant information, a process known as 'working memory'. This has been explored in a variety of neurophysiological studies of monkeys.

Many cortical areas seem to have some sort of short-term buffering ability. What sets working memory apart as being more 'cognitive' is that it can retain information over potentially distracting events. The prefrontal cortex neurons particularly have this ability. For example, when monkeys are required to sustain the memory of a sample object for a delay period filled with visual distracters each requiring attention and processing, sustained activity within the prefrontal cortex acts to maintain the sample memory. In contrast, sustained activity in extrastriate visual areas seems to be more easily disrupted by the presence of distracters – following presentation of a distracter, the neural activity in the inferior temporal cortex and posterior parietal cortex no longer reflected the sample object that the monkey has retained in memory.

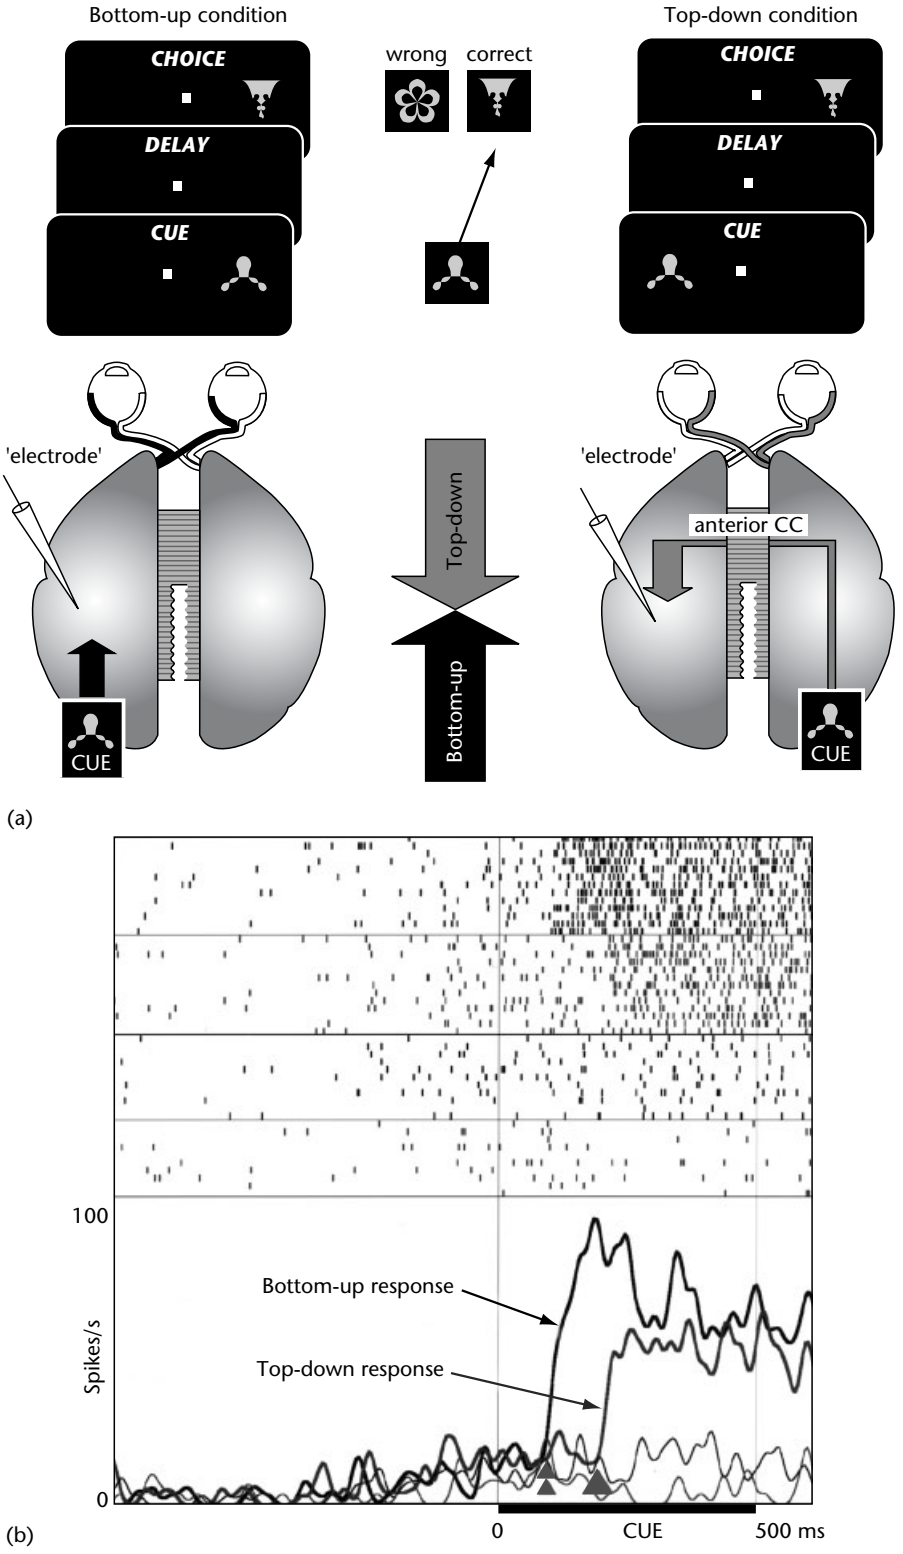

Figure 5. Top-down signal detection. (a) Experimental design; (b) neuronal activity in top-down condition (single inferior temporal cell). Modified from Tomita *et al.* (1999).

Top-down Control

The ability to sustain task information is of little use unless the prefrontal cortex can somehow use it to control processing in other brain systems. The prefrontal cortex activity could exert a 'top down' influence by providing an excitatory signal that biases processing in other brain systems towards task-relevant information. To understand how this may work, let us consider selective visual attention. In the visual system, neurons processing different aspects of the visual scene compete with each other for activation. This is thought to be important for enhancing contrast and separating objects from the background. The neurons that 'win' the competition and remain active are those that incur a higher level of activity. The biased competition model proposes that visual attention exploits this circuitry. In voluntary shifts of attention, a competitive advantage is conferred by excitatory signals that represent the 'to be attended' stimulus. These excitatory signals enhance the activity of neurons in the visual cortex that process that stimulus and, by virtue of mutual inhibition, suppress activity of neurons processing other stimuli. This concept of excitatory bias signals that resolve local competition can be extended from visual attention to cognitive control in general.

Several studies have indicated that the prefrontal cortex exerts a top-down influence over other neocortical regions. Deactivation of the lateral prefrontal cortex attenuates the activity of extrastriate neurons in response to a behaviorally relevant cue. Top-down signals originating from the prefrontal cortex have been shown to be required to activate (recall) a long-term memory stored in the inferior temporal cortex. In the absence of 'bottom up' visual inputs, single inferior temporal neurons were activated by the top-down signal, which conveyed information on semantic categorization imposed by visual stimulus–stimulus association (Figure 5). Performance on a task was severely impaired with the loss of the top-down signal. Thus, feedback projections from the prefrontal cortex to the posterior association cortex appear to have executive control of voluntary recall.

Other indicative evidence was obtained from investigations into the respective roles of the prefrontal cortex and inferior temporal cortex in working memory. Monkeys were trained to hold a sample object 'in mind' while they viewed a sequence of objects. They were required to respond when the sample was repeated and to ignore other irrelevant object repetitions. As noted above, sustained activity in the prefrontal but not in the inferior temporal cortex maintained the sample memory across intervening stimuli. However, many inferior temporal neurons showed an enhancement of their neuronal responses to the sample repetition but not to irrelevant repetitions. This indicated that sustained activity in the prefrontal cortex with respect to the sample might have enhanced responses to its repetition in the inferior temporal cortex.

Because task representations in the prefrontal cortex include disparate information, the excitatory signals from this area could be involved in selecting particular sensory inputs (attention), memories (recall) or motor outputs (response selection).

These neurophysiological studies of nonhuman primates show that the prefrontal cortex may be essential for implementing task information, particularly in situations when familiar sets of behaviors need to be flexibly combined into a coherent sequence. In addition, the prefrontal cortex is required to activate long-term visual memories stored in the temporal lobe. The prefrontal cortex could retain links to stored representations that allow it to bring visual memories and other task knowledge 'online' when required.

SUMMARY

One of the greatest mysteries in cognitive neuroscience is cognitive control and the neuronal mechanism mediating it. The prefrontal cortex is involved in many higher cognitive functions, most typically executive control. Lesions to the prefrontal cortex of humans and nonhuman primates cause the failure of executive functioning. Neuroimaging studies of humans show that storage and executive processes are the major functions of the prefrontal cortex. Neurophysiological studies in monkeys indicate that the prefrontal cortex has a role in the extraction of behavioral significance from sensory cues and the storage and retrieval of mnemonic information.

Expertise

Introductory article

Andreas C Lehmann, School of Music, Würzburg, Germany
K Anders Ericsson, Florida State University, Tallahassee, Florida, USA

CONTENTS

Expertise refers to the cognitive, perceptual-motor, and physiological mechanisms that allow experts to attain consistently superior levels of performance on representative activities in their domains.

EXPERTISE AND EXPERT PERFORMANCE

In everyday terminology, experts are individuals, such as medical doctors, accountants, teachers and scientists, who have first been certified as professionals after extended training and then have gained substantial experience in their specialty. More recently, the term has been expanded to describe any highly skilled performer who consistently exhibits superior achievement after instruction and extended experience in a domain such as one of the arts (e.g. music, painting, writing), a sport (e.g. swimming, soccer, golf) or a game (e.g. chess, Othello, bridge). The general concept of expertise is based on the hypothesis that experts in the different domains will acquire their superior performance according to similar learning principles and that the general structure of the acquired mechanisms will be similar in domains with similar demands on performance.

The main task for researchers of expertise is to explain how some individuals attain the highest levels of achievement in a domain, and why so few reach such levels. Expert performance in many domains looks effortless, and one is thus led to believe that experts excel in general basic characteristics, such as intelligence, memory, speed, and flexibility. It has been assumed traditionally that such characteristics are impossible to train and thus are determined to a large degree by genetic factors (nature). Everyone agrees, however, that experts must acquire at least some necessary domain-specific knowledge and skill (nurture). Without denying the possibility of effects of genetic factors, research in expertise tends to emphasize the importance of knowledge and acquired skills.

Sir Francis Galton, a pioneer in the study of excellence in nineteenth-century England, claimed that instruction and training were beneficial, even necessary, and associated with large initial improvements in performance. However, he also maintained that the upper bound of individuals' performance was fixed by hereditary factors. This view is still common among many researchers and practitioners in some domains. Thus, proponents of this view are still searching for innate talent and measuring basic capacities of memory, perception, and thinking, that would allow them to successfully predict future outstanding performance in children and untrained adults. Today, over a century later, we can safely say that efforts to measure individual differences in basic capacities have not succeeded in predicting which individuals would eventually attain expert performance. For example, when athletes or other experts are tested in the laboratory on how fast they can respond to the onset of a light (simple reaction time), they are not systematically faster than other people. The amazing speed of tennis players' actions is thus not due to superior speed of neural impulses, and we have to assume that returning a fast tennis serve reflects an acquired ability to respond rapidly in specific types of situations.

Domain-specific superiority of experts is very noticeable for cognitive abilities. Chess masters can recall nearly all the 24 chess pieces in a typical chess arrangement after a quick glance, whereas beginners in chess can recall only around four pieces. The experts' ability to recall more chess pieces is, however, restricted to representative (or typical) chess positions in which the expert can meaningfully encode the relations between the chess pieces. When random arrangements of chess pieces are presented, the large recall advantage of the experts over the novices is virtually eliminated.

The major differences between experts and less proficient individuals nearly always reflect specific adaptations acquired by the experts during their lengthy training. This holds true for many anatomical and physiological characteristics of athletes, such as the size of their muscles and bones and the flexibility of joints, and for the increased range of mobility of the limbs in ballet dancers and musicians. Some of these attributes, such as structural changes in the brains of musicians, are even correlated with the early onset of training. Other adaptations – for example, the growth of muscles and thickening of the bones of tennis players (restricted to the arm holding the racket), or the optimization of metabolism of runners (for particular running speeds and different lengths of races) – are so specific that (self)-selection of individuals in those domains appears unlikely. Finally, many physiological adaptations, such as the heart size of endurance runners, have been shown to revert to the normal values once the athletes stop training, which would be expected only for acquired and not for innate characteristics. However, there is at least one exceptional attribute – height – where genetic factors are known to control the development of body size. Above-average height constitutes an advantage in attaining the highest levels in some sports such as basketball, but is a disadvantage in other sports such as gymnastics.

The occurrence of expert achievement in similar domains across several generations in some famous families is frequently cited as proof for the genetic transmission (high heritability) of special talents. However, this can be questioned since the early instruction of children by parents and access to networks and specialized training seem to offer plausible alternative accounts. So far, studies on experts have been unable to document any convincing evidence for significant heritability of expert levels of achievement.

EXPERTISE AS ACQUIRED KNOWLEDGE AND SKILL

Organized Knowledge as a Base for Expertise

Our understanding of expertise was advanced primarily by comparing the thought processes of experts while exhibiting their superior performance with the thoughts of less accomplished individuals (or even novices) performing the same tasks. In his 1940s pioneering study, researcher Adrian de Groot wanted to explain why world-class players generated consistently better chess moves than less skilled players after only a brief exposure to the chess position. He instructed chess players in each group to think aloud while they selected their next moves for a given chess position. The transcriptions of these reports (think-aloud protocols) revealed that in an initial phase all chess players were quickly generating promising moves while examining the organization and structure of the presented chess position. Next, the chess players spent minutes evaluating these potential moves by searching and planning and discovered often even better moves. Neither de Groot nor other researchers found that world-class players differed from less skilled chess players with regard to basic intelligence or to speed of their planning. The rapid speed of move generation indicated that the superior moves were directly retrieved from knowledge of similar chess positions in memory.

According to Simon and Chase's theory of expertise, the essential factor is the accumulation of increasingly complex patterns that allow experts to maintain access to their vast body of knowledge and experience. The same mechanisms were proposed to explain the efficient problem-solving and decision-making of experts in physics, medicine, and business. Hence, the superior ability of experts to reason was found to be specific to domain-related material and thus depended directly on their large body of knowledge and experience. Viewing expertise in terms of superior knowledge led investigators in artificial intelligence to interview experts in order to extract the necessary relevant knowledge and decision rules for building computer programs (expert systems) that were designed to reproduce the experts' behavior.

Challenges to the Knowledge-based View of Expertise

Paradoxically, individuals recognized as domain experts because of their lengthy training and experience do not always exhibit consistently superior performance compared with less experienced individuals and sometimes even complete amateurs. For example, professional stockbrokers do not consistently select better investments than statistical models and amateurs, or even random picks. Impressive dissociations between the level of expertise (indicated by the amount of schooling and experience) and performance have been demonstrated in medical diagnosis of common diseases, treatment with psychotherapy, auditing, and many types of expert decision-making and forecasting.

Why does extended experience not always lead to improvements in performance? It is well known

that when persons are introduced to an activity, their gains in performance are initially large, but once an acceptable level of performance is reached, the behavior of individuals tends to become stable and automated with no further improvements of performance. For example, the vast majority of amateur musicians and recreational athletes in golf and tennis remain at a stable level of performance for years and decades despite their regular involvement in relevant activities. Therefore, it is necessary to distinguish individuals who are customarily labeled 'experts' because of their extended experience, training and reputation, from true 'expert performers' who exhibit consistently superior performance.

Superior Achievement as a Prerequisite for Expert Performance

If we restrict expertise to reproducible expert performance, then the first step is to design tasks that can reliably measure the associated superior performance under standardized conditions. In sports, athletes compete under fair conditions, when they run the 100 m dash or swim 200 m freestyle. Competitions in music and ice skating rely on panels of judges to rate performance. In chess and tennis, the best performers are identified by tournaments where winners advance. In most domains procedures have evolved to evaluate and measure performance in order to identify individuals with superior performance.

The Necessity for Experience, Instruction, and Practice

The development of expert performance requires extensive experience, and it progresses gradually without sudden increases in performance level over extended periods. This is true for the development of adult experts and even for child prodigies. Most expert performers continue to improve their performance long into adulthood, and attain their peak performances in vigorous sports typically at age 25–35 years, and much later for achievements in the arts and sciences. Simon and Chase showed that it takes at least 10 years of training and experience in chess even for the most talented individuals to reach an international level after the start of their engagement in the domain. This 10-year rule has since been shown to apply to most other domains, even in swimming and music where children start practice as early as age 4 or 5 years. Extended experience is thus necessary but not sufficient to attain high levels of performance. If mere experience does not automatically change individuals' behavior, what does?

When our actions and activities run smoothly, a change in the structure of performance is generally not necessary and hence would not be expected. Individuals tend to think that their performance in a given area is 'good enough', and mistakes occur only for very rare or difficult behavior or decisions. For example, a tennis player might have problems with a particular backhand volley, but the need for this stroke during recreational play might occur rarely and unpredictably. In these typical circumstances more experience would not necessarily be associated with improvement of the stroke. However, the problem could be remedied with some precise suggestions by a coach and subsequent practice. The coach would perhaps start with preparatory exercises and work up to difficult and unpredictable exchanges, provide enough challenge and repetitions, and eventually incorporate the strokes in regular training matches.

This optimal type of training activity has been called 'deliberate practice', and its sole purpose is to improve performance effectively. Note that the particular activities that constitute deliberate practice will vary from domain to domain and differ with the level of attained skill. Recreational athletes and amateurs rarely engage in deliberate practice, although they realize that deliberate practice would improve their performance. Since engaging in a domain activity is usually motivated by inherent enjoyment (play) or external rewards (work), most individuals shy away from activities that are more effortful or less enjoyable than the regular activity. Consequently, regular recreational activities and work lack the prerequisites of deliberate practice that are essential for efficient improvement, namely specific goals for training, feedback, and opportunities for gradual improvement through repetition. Engagement in deliberate practice appears to be imperative for individuals to develop the mechanisms for reaching the highest levels of performance.

Over time, experts in domains of expertise have extracted and accumulated a body of organized experience in the form of knowledge and skills that can be effectively transmitted by teachers to students with developed practice techniques. For example, in the Middle Ages it was believed that 50 years were required to master the known forms of mathematics, whereas today students acquire comparable knowledge in highly organized form during their high-school years. Similarly, improved training allows serious amateurs in sports events such as running or swimming to reach levels of performance attained only by elite performers

earlier in the twentieth century. Instead of having to rediscover items of knowledge and ways of practicing or learning, individuals can be given instruction to master and even surpass the established levels of attainment.

The need for specialized instruction and deliberate practice has been recognized. In many domains master teachers and coaches instruct and supervise promising individuals and design their practice from a very young age. The core assumption of deliberate practice is that expert performance is acquired gradually and that effective improvement of the student's performance depends on the teacher's ability to isolate a sequence of simple training tasks that the student can then successively master by repetition with feedback and instruction. The individual training tasks have to be difficult enough to lie slightly outside the student's current range of skills so that the student concentrates on critical aspects and gradually refines performance through repetition in response to feedback. This requirement of focused attention on individual task components differentiates deliberate practice from both mindless drill and playful engagement.

Successful expert performers in different domains share some biographical characteristics, and Bloom and his colleagues have developed a schematic model of the phases of skill acquisition (Figure 1). Often, future experts start training with teachers at young ages after a brief period of playful interaction with the domain (phase I). Their initial formal training (phase II) consists of short training units of about 15–20 min per day, and often a parent supervises practice and helps the child to concentrate. With increasing age, domain-related activities, especially deliberate practice, occupy more and more room in the daily lives of future expert performers, until at the end of adolescence their commitment to the domain is essentially full-time (phase III). During this phase, increases in performance go hand in hand with the acquisition of the cognitive mechanisms that mediate the superior performance (see below). Bloom found that to reach an international level of achievement, the performers – almost without exception – had been trained by excellent teachers who either were international level experts themselves or had successfully trained students to reach international levels.

At some point the experts start their professional career (phase IV). During this last phase the elite performers strive to make eminent contributions to the domain, which could constitute the setting of new world records in sports, publishing scientific discoveries, or making major creative contributions to the arts.

By using diaries and other methods to study how expert musicians spent their daily lives throughout the different phases, Ericsson and his colleagues demonstrated the importance of deliberate practice for attaining expert performance. They investigated three groups of experts differing in their level of attained musical performance. Based on retrospective estimates of past practice times, the researchers calculated the number of hours of deliberate practice accumulated by the different groups of musicians (Figure 2), and found that the better musicians had spent more time in deliberate practice during their development. By the age of 20 years, the best piano players had spent over 10 000 h in practice compared with only around 2000 h for typical amateur pianists of the same age. A number of subsequent studies in chess, sports, and music have confirmed the relationship between the level of attained performance and amount or quality of deliberate practice.

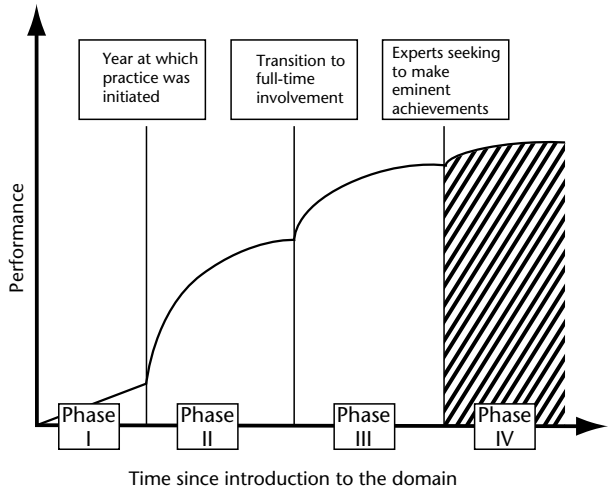

Figure 1. Bloom's three phases of acquisition of expert performance, followed by a qualitatively different fourth phase during which experts attempt to go beyond the available knowledge in the domain. EXPERT PERFORMANCE

The extended period of deliberate practice enables expert performers to acquire complex mental mechanisms that mediate superior performance in their domains. These same mental mechanisms allow them to become their own teachers, which in turn permits them to continue learning and

improving their performance for their entire professional career.

Cognitive Mechanisms Underlying Captured Expert Performance

In most domains it is possible to identify the representative tasks and cognitive mechanisms that capture the essence of that expertise. For example, the essence of chess expertise is the consistent ability to select the best move on the chessboard. Hence, following de Groot's paradigm, we can present different chess players with the same series of unfamiliar chess positions and ask them to think aloud as they select the best move (Figure 3(a)). By analyzing the think-aloud protocols, we can scientifically investigate the cognitive processes that differentiate the experts' performances from those of less skilled players.

In chess, analyses of such think-aloud protocols reveal that chess experts rapidly encode the chess position and access adequate moves from memory. However, chess experts will then spend several minutes evaluating these potential moves by planning out the consequences for each of them. The ability to predict the consequences a particular chess move would have several moves ahead requires extensive working memory. Chess players acquire memory skills that allow them to store information about planned chess positions in long-term working memory (LTWM). The proficiency of LTWM increases slowly as a function of chess skill and can account for increases in the ability to plan, as well as the previously discussed increased memory for briefly presented chess positions. Although chess players can often select appropriate moves very early in the decision process, with additional time the quality of the selected moves will increase for all levels of chess players. Thus, at higher levels of performance, experts have acquired the ability to mentally represent relevant information. Chess masters, for instance, have perfected their mental representations of the chess positions to the point where they can play chess blindfolded.

Mental representations have been shown to play a central role in all domains where it has been possible to capture expert performance with laboratory tasks. For example, medical expertise can be captured by presenting doctors with information about challenging medical cases and asking them to reach a diagnosis (Figure 3(b)). From analyses of protocols of medical experts and students thinking aloud while diagnosing patients, it is known that the experts have acquired a superior LTWM with a better representation of the relevant clinical information. As a result, to arrive at the correct diagnosis medical experts are able to plan and reason about the many relevant symptoms.

In domains of perceptual-motor activity, acquired mental representations allow experts to anticipate upcoming events. For example, the best predictor of individuals' keyboard typing speed is not the basic speed of their finger movements but how far they look ahead. By planning ahead, expert typists can anticipate future keystrokes and thus move fingers to their positions ahead of time rather than rush their fingers. Similarly, the rapid reactions of athletes, such as hockey goalkeepers, baseball hitters, and tennis and football players, have also been found to reflect the ability to anticipate events. The resulting shorter reaction times of experts (compared with less accomplished individuals or novices) for representative tasks are thus not due to an innate speed advantage but to superior anticipation, preparation, and improved perceptual skills.

In many domains, such as music, dance and some sports, the key to expert performance is the acquisition of representations that enable the performer to produce the same movement repeatedly. For example, superior golf players can execute the same putt several times with fewer variations than less skilled golfers; similarly, expert pianists are better able to play the same musical piece several

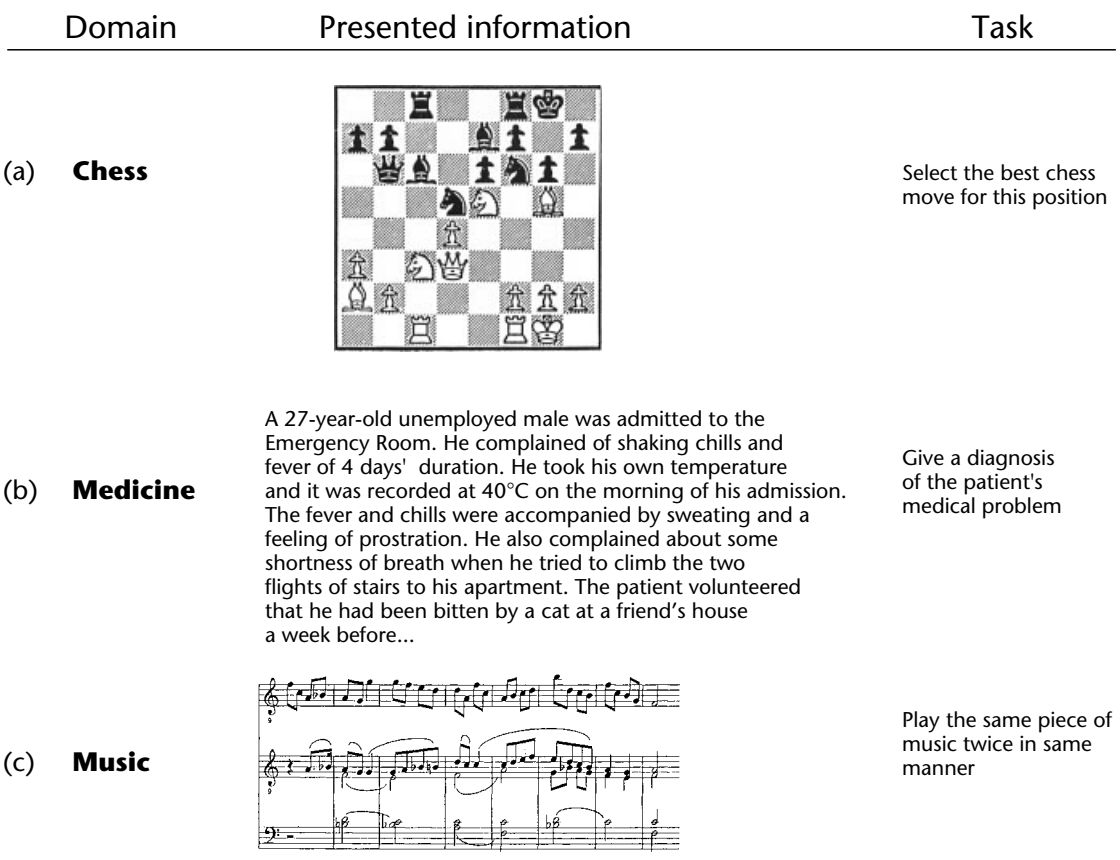

Figure 3. Three examples of laboratory tasks that capture the consistently superior performance of domain experts in chess (a), medicine (b), and music (c). The description of the medical case was taken from the first part of a case report of acute bacterial endocarditis, from 'Inferences in clinical case comprehension' by LD Coughlin and VL Patel, in *Technical Report in Cognitive Research Series*, Center of Medical Education, McGill University, Montreal, Canada, p. 21, 1987. Adapted from Ericsson KA (1998) The scientific study of expert levels of performance: general implications for optimal learning and creativity. *High Ability Studies* **9**: 92. Copyright 1998 by European Council for High Ability.

times in a consistent manner than less skilled pianists (Figure 3(c)).

In sum, the experts' performance is not characterized by reduced cognitive processing and automaticity; rather, experts acquire and refine their mental representations to increase control over their performance.

Importance of Mental Representation for Continued Learning

The experts' ability to mentally represent and manipulate relevant information endows them with the level of control that they need to respond flexibly to changing conditions in real life. Imagine a pianist who has to play a well-entrenched piece under changing acoustical conditions and on different instruments every night, or a tennis player who needs to adapt to different opponents' strengths and weaknesses. In order to maintain a high level of performance despite changes in the environment, the expert needs a flexible and generalizable skill.

Reaching expert performance in a domain does not simply consist of gradually increasing the level of performance, but rather requires the acquisition and the refinement of underlying mental representations, such as being able to image and plan a desired performance, and monitor and evaluate one's own ongoing performance. These are the ultimate goals of instruction, because they make the learner independent of teachers and coaches. In fact, the learner becomes his or her own teacher or coach. This ability to become one's own teacher is important for the development of domain-specific skills at a societal level. As mentioned earlier, the primary objective of experts in later stages of their lives is to make a personal creative contribution to the domain. Before making an innovative contribution to a respective domain, the

performer has to master all the available knowledge and skill; otherwise, he or she would not know when and how to go beyond the current knowledge of performance.

How do experts use their highly developed representations to organize their own training and further improvement in performance? A common method involves studying and analyzing performances and achievements of masters in their respective domains. For example, expert chess players collect books and magazines with published games of chess masters and spend several hours every day playing through those games move by move, trying to predict the next best move the master could have chosen. Any inconsistency between their own prediction and the chess master's actual move is carefully analyzed for oversights in planning and evaluation. In general, this form of study is theoretically interesting because attempting to copy the model behavior of established masters allows performers to gradually refine their own independent representations and expand their body of knowledge. Other domains are likely to require other types of activities that promote further improvements and innovations.

CONCLUSION

The public performance of expert musicians and dancers often appears to be effortless and natural. However, research on expert performance shows that even the most 'talented' individuals need around 10 years and thousands of hours of deliberate practice to attain an international level of performance in their respective domains. Research that has successfully captured expert performance with representative tasks in the laboratory has revealed the complexity and domain specificity of the mental representations and mechanisms that enable superior performance. Once expert performance is understood as the acquisition of an integrated structure of cognitive and physiological adaptations, then the main challenge is to account for how individual domain experts gradually develop their superior performance during decades of deliberate practice.

Eye Movements

Introductory article

Michael K Tanenhaus, University of Rochester, New York, USA

CONTENTS

The organization of the retina requires the eyes to be able to move to alter the fixation of the gaze. These eye movements are closely linked to shifts in attention and have an important role in visual search, perception of scenes, and complex visual tasks.

INTRODUCTION

During everyday tasks involving vision, such as reading a newspaper, looking for the car keys, making a cup of coffee and conversing about objects in the immediate environment, people rapidly shift their gaze to bring task-relevant regions of the visual field into the central area of the fovea, where visual acuity is greatest. These gaze shifts are accomplished by rapid jumping eye movements known as 'saccades'. The pattern and timing of saccades, and the resulting fixations, are one of the most widely used response measures in the cognitive sciences, providing important insights into the mechanisms underlying attention, visual perception, reading, memory, and spoken language processing. Within a fixation, smooth eye movements maintain the stability of the retinal image, compensating for motion on the retina caused by movements of the head, body and moving visual targets.

SACCADES

Saccades are extremely rapid ballistic eye movements. During a saccade, the eye is in motion for 30–60 ms, with the duration of the saccade related to the distance that the eye travels. At peak velocity, the eye can be moving at a rate of 500–1000° per second. During a saccade, sensitivity to visual information is dramatically reduced. Suppression of visual information occurs in part because of masking, and in part because of central inhibition. A saccade is followed by a fixation that typically lasts for 200 ms or more depending upon the task. The minimal latency for planning and executing a saccade is approximately 150 ms when there is no uncertainty about target location. In reading, in visual search, and in other tasks in which there are multiple target locations, saccade latencies are somewhat slower, typically about 200–300 ms.

The brain mechanisms involved in controlling saccades have been intensively studied in recent years. Saccadic control is subserved by both a 'what' system, generated by brainstem cells that show a drop in sustained activity before and during a saccade, and a 'where' system based on spatial coding in neighboring regions. These cells receive inputs from the superior colliculus, which in turn receives primary input from the frontal eye field and posterior parietal cortex.

MEASURING EYE MOVEMENTS

Currently popular methods for monitoring eye movements include measuring infrared corneal and retinal reflections (Purkinje images), video-based pupil monitoring, and search coils attached to a contact lens. Accurate measurement of the 'point of regard' must distinguish between rotation and translation, which is difficult for many systems. Changes introduced by rotation of the eye in its orbit due to a saccade or a smooth eye movement systematically affect the position of the retinal image. However, the position of the image varies with target distance, for the translations introduced by movement of the head. Eye movements differ depending upon whether the head is fixed or not, with more accurate gaze shifts, and faster and more accurate saccades.

Studies of reading with normal-sized text require monitoring eye position with a high degree of accuracy (20 minutes of arc or less). These studies frequently use Purkinje image tracking with the head fixed on a bite bar to minimize translational movement. Studies with action-based tasks increasingly use video-based trackers that monitor

the pupil and the cornea, with independent tracking of the head or compensation for head movement, when stimuli are presented on a screen. Measuring head movement can be bypassed by superimposing fixations on a head-based video record, although this limits analysis to video rates (60 Hz) and requires hand-coding of video records.

EYE MOVEMENTS IN PERCEPTION, COGNITION, AND ACTION

Eye movements are necessary because visual sensitivity differs across the retina. Acuity is greatest in the central portion of the fovea, then markedly declines. The organization of the retina can be viewed as a compromise between the need to maintain sensitivity to visual stimuli across a broad range of the visual field and the requirement for detailed spatial resolution in task-relevant aspects of the visual field. This division of labor also helps restrict most processing to a relevant subset of the visual field, thus reducing the amount of information being made available from the visual environment. However, it also requires an eye movement system to quickly bring new regions of the field into the fovea, and to maintain fixation on the most relevant region of the visual field, for visual guidance in fine motor tasks such as reaching for and grasping an object. These demands suggest a close interleaving of eye movements and attention.

Attention and Eye Movements

Smooth pursuit eye movements are controlled by stimulus motion on the retina; they cannot be voluntarily generated or suppressed. Nonetheless, people cannot easily dissociate attention from the target of a pursuit movement. Participants also make anticipatory and predictive pursuit movements, which can be modulated by cues about the likely direction of an upcoming change in the direction of motion, further suggesting a link between attention and the systems. Dual task studies demonstrate that attention shifts precede a saccade. However, the attentional requirements of saccades are quite modest. People can allocate some resources to nontarget areas without delaying saccades or reducing their accuracy. This makes functional sense: some attentional control over saccades is necessary to prevent irrelevant information from continuously triggering saccades, yet it is important to be able to distribute attention across the visual field, and for saccadic eye movement to be a relatively low-threshold, low-overhead action. (*See* **Visual Attention**)

The claim that shifts of attention and saccadic eye movements are closely coupled also receives strong support from neurophysiological studies in monkeys. Cells in the parietal cortex that are active prior to a saccadic eye movement are also active prior to a shift in attention, even when the monkey is required to maintain fixation. (*See* **Attention, Neural Basis of**)

Visual Search

Influential studies of visual search manipulated the number of distracters in the set and the relationship of the target to the distracters. Detection time was relatively unaffected by set size when a single visual feature, such as color, distinguished the target from the distracters. However, search time was a linear function of set size when the target was distinguished from the distracters by a conjunction of features (e.g., color and orientation). Treisman and colleagues proposed that attention is required to bind features together for object recognition. On the assumption that a linear function is diagnostic of a serial search, the resulting rate of search would implicate several shifts of attention within a single fixation. However, this idea seems increasingly untenable. Parallel search can result in linear effects of set size for conjunction searches; moreover, there is a strong correlation between the number of fixations and target detection time in visual search. It seems increasingly likely that visual search involves parallel evaluation of targets within a fixated region.

Close links between fixation and attention are further supported by studies investigating detection of changes in scenes. (*See* **Visual Scene Perception**; **Change Blindness, Psychology of**)

Perceivers are often remarkably insensitive to changes in scenes, a phenomenon known as 'change blindness'. However, detection of changes to attended objects is quite accurate. In a 'flicker' paradigm in which scenes with changes alternate, changes are detected more reliably if the changed region is fixated prior to a change. When 'saccade-contingent' changes are made to a display during a saccade, perceivers accurately detect a change to a recently fixated target, especially the most recently fixated target. Detection of a change to the target of an ongoing saccade is extremely accurate, suggesting that the fixation has followed a shift in attention to the target object.

Eye Movements in Natural Tasks

The close link between attention and fixations suggests that eye movements should provide an

important window into cognitive processes during complex visual tasks that involve both search and memory. Yarbus showed that the scanning patterns for paintings varied depending upon the viewer's task, and appeared systematically related to the content of the paintings. However, trying to infer underlying mental processes from scan-paths alone is extremely difficult.

Researchers have begun to make considerable progress by measuring eye movements in natural tasks with a well-defined goal structure, such as copying a block pattern or making a cup of tea. Several striking results emerge from these studies. First, gaze is almost exclusively directed to task-relevant objects, such as fixation on an object to provide visual guidance for reaching. Second, fixation is closely time-locked with – and nearly always restricted to – objects relevant to the aspect of the task currently being executed. Third, the information maintained in memory from a fixation appears to be limited and task-specific.

For example, one study monitored eye movements as participants used blocks from a resource area to copy a block pattern from a model into a workspace. Participants typically made two fixations to the model area for each block. They first fixated on a block in the model area, then retrieved a block of the same color from the workspace, and then made a second fixation to the model area before placing the block in its correct location in the workspace. The pattern of fixations suggests that participants were retrieving only color information on the first fixation on the block in the model, returning a second time to retrieve information about its relative position. This strategy is consistent with the hypothesis that fixations are used to gather information 'on the fly', as it is needed for the task at hand, thus reducing the need to build and maintain rich internal memory representations. When task demands require use of richer memory representations, participants make fewer saccades and performance slows.

However, it is important to distinguish between explicit memory representations and implicit measures. (*See* **Memory: Implicit versus Explicit**)

In the block copying task, multiple changes to unattended areas of a display increased fixation duration. Moreover, changes in natural scenes that are not explicitly detected receive longer duration fixations than unchanged regions, suggesting an implicit memory representation. Indeed, some such memory is necessary for coordinating complex actions, including making saccadic eye movements to remembered locations.

Eye Movements in Memory, Imagery, and Other Cognitive Tasks

Eye movement measures have been applied in ingenious ways to shed new empirical light on some classic results and claims. For example, after briefly seeing a chessboard with pieces taken from an actual expert game, chess experts show far better recall than novices. However, the expert advantage is eliminated when the target is a board with randomly placed pieces. Chase and Simon suggested that much of this advantage comes from early perceptual processing. Reingold and colleagues confirmed this hypothesis using a gaze-contingent window paradigm, in which pieces outside a moving window are obscured. During a fixation, chess experts distribute attention across larger spatial regions than novices for chess configurations but not for random piece assignments, confirming Chase and Simon's hypothesis. Spivey and Geng confirmed Hebb's hypothesis that constructing images involves generating saccades. When listening to a story, participants generate patterns of eye movements that reflect the spatial content of the story (e.g., looking upwards when the event takes place high up in a building).

Eye Movements in Reading

Much of our knowledge about linguistic processes in reading comes from the study of eye movements. (*See* **Reading, Psychology of**)

Reading has also served as an important empirical test-bed for evaluating models of oculomotor control and models of perceptual processing during fixation. To a first approximation, readers fixate each word in turn, with each saccade averaging seven to nine characters, and the average fixation taking about 250 ms. The probability that a word will be skipped depends largely on its length. Short function words, such as 'the', 'a', and 'of', are skipped 80% of the time. In a language written from left to right, such as English, more than 80% of fixations are to the right of the previous fixation. Contrary to predictions made by some influential early models of reading, even highly predictable words are typically fixated, though statistically less frequently than less predictable words. Moreover, good readers are not more likely to skip predictable words than poor readers are.

The region of text in which there is some uptake of information during a fixation, sometimes called the 'perceptual span', is asymmetrically centered on the fixation. In English, the span extends

approximately four characters to the left of the character at the center of fixation and 15 characters to the right. In Hebrew, which is written from right to left, the direction of the perceptual span reverses. Estimates of the perceptual span come from studies using different saccade contingent changes of the display. These include creating gaze-contingent windows of various sizes, centered around the fixation, with the text altered outside the window, and making changes to a letter contingent on the saccade crossing a predefined (invisible) boundary. The perceptual span varies with the difficulty of a text, becoming smaller for more difficult texts. Processing difficulty localized to individual words also affects the perceptual span.

Although the perceptual span can include several words, processing seems primarily localized to the word currently being fixated and the upcoming word, with somewhat limited uptake of information from peripheral areas of the span. Fixation duration is strongly affected by linguistic variables. Less common words such as 'viola' receive longer-duration fixations than more common words such as 'piano', with effects spilling over to the next word. Ambiguous words such as 'organ' are fixated for longer than unambiguous words of similar frequency. The ambiguity effect is greatest when alternative meanings are equally frequent.

Fixation duration is also modulated by the preceding context. Increased contextual constraint reduces fixation duration. Moreover, the ambiguity effect for homographs with equally common meanings is eliminated when the preceding context strongly biases one sense. However, there are negligible effects of information from the adjacent right context on the current fixation. Taken together, these results suggest that processing is strongly localized to the word currently being fixated and the upcoming word. As in nonlinguistic visual processing, fixations in reading reflect ongoing cognitive processes and cognitive processes appear to center on the word being fixated. Some information is clearly gleaned from text in the periphery, including information about word length, letter shape, and some phonological information. A striking demonstration of the importance of fixation-based processing in reading comes from contrasting the relatively large disruption that comes from perturbing only the word currently being fixated (i.e., replacing it with a random string of letters) with the less disruptive effect of leaving only that word intact.

As in complex visual processing, the inferences that one can draw about the cognitive processes in reading from patterns of fixations depend strongly on understanding the task. A crucial issue is how the uptake and use of information in the periphery guides upcoming saccades and how use of peripheral information is modulated by the attentional demands of the word that is currently being fixated. Unresolved questions include: (1) to what extent does a shift in attention precede an upcoming saccade? (2) Is the distribution of attention to peripheral information influenced by ongoing processing? (3) To what degree do lexical processes modulate the timing of upcoming saccades?

Eye movements are widely used by psycholinguists investigating sentence processing in reading, especially in testing models of syntactic processing. Locally ambiguous sentences that are eventually resolved in favor of the initially less-preferred structure (e.g., 'From his window, John spied on the girl with the telescope in her lap') result in longer fixations in the disambiguating region ('in her lap') and trigger more regressive eye movements. These 'garden path' effects are modulated by a variety of variables, and are the subject of current theoretical debate. Eye movements in reading also provide insights into the interpretation of referring expression such as the pronouns 'his' and 'her' and the timing of inferences in the comprehension of text. (*See* **Sentence Processing: Mechanisms**; **Sentence Processing**)

Eye Movements and Spoken Language

A rapidly expanding community of psycholinguists are now using eye movements to study both spoken language comprehension and language production. (*See* **Language Comprehension**; **Speech Production**)

The use of eye movements in spoken language comprehension was pioneered by Cooper and later extended by Tanenhaus and colleagues using a task in which participants followed spoken instructions to manipulate objects in a visual workspace. Crucially, eye movements are remarkably time-locked to the unfolding input, with participants looking at objects as they become relevant during the instruction.

Figure 1, summarizing results by Eberhard and her colleagues, shows the pattern of fixations of eye movements to a display containing 8 cards, including 2 five of hearts, one of which is below the eight of clubs and the other below a card of another denomination. In the instruction 'Put the five of hearts that is below the eight of clubs above the two of diamonds,' the referent is disambiguated at the word 'eight'. The pattern of fixations as the instruction unfolds shows that listeners looked at

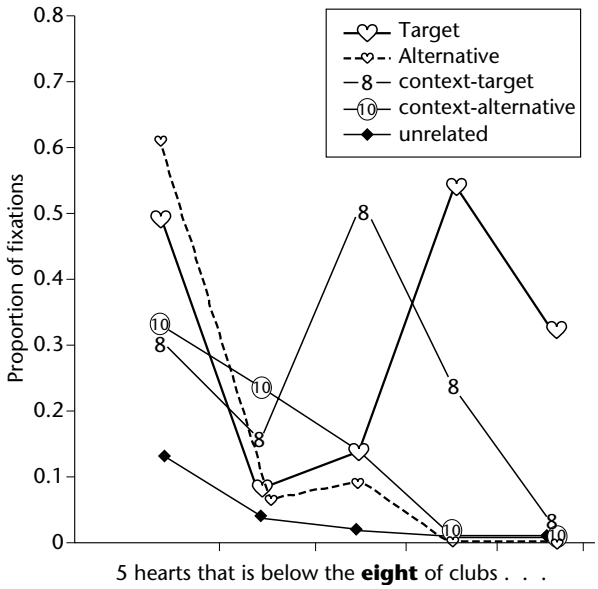

Figure 1.

cards as they became relevant. For example, after 'five of hearts' people were looking at the two potential referents (the five of hearts); at 'below' they were looking at the cards that the fives are beneath (the eight of clubs and/or ten of spades); and at 'eight' they were looking at the eight of clubs.

Fixation patterns are also closely time-locked to utterance generation in language production when speakers describe scenes. Speakers fixate on a referent for approximately 800 ms before beginning to generate the phrase containing its name, shifting their gaze to the next entity to be described in the middle of the previous phrase.

Eye movements are now being used to trace the time course of lexical access, reference resolution, sentence processing in preliterate children, and utterance planning in production, as well as issues in higher-level interactive conversation.

CONCLUSION

The organization of the retina, in particular the presence of the fovea, necessitates that the eyes be able to move to maintain central fixation and shift fixation. These eye movements are closely linked to shifts in attention and have an important role in visual search, perception of scenes, and complex visual tasks. The close coupling of fixations to perception and action allows cognitive scientists to use eye movements as windows in moment-by-moment cognitive processes in vision, problem-solving and in language. Eye movement research on reading and on oculomotor control has flourished for decades. More recently there has been a dramatic increase in the use of eye movements for research in other domains within the cognitive sciences. This trend seems likely to continue as cognitive scientists increasingly turn towards the use of natural tasks that combine perception and action, including language and vision.

CONTENTS

Perceptual information from the human face can be used to determine the identity, sex, race, age, and current mood of an individual. It may serve also as a guide for social interaction, providing us with continually changing feedback about the emotional state of the people with whom we interact.

INTRODUCTION

The number of different faces we must recognize as individuals makes the challenges associated with remembering faces nearly unique in the realm of visual memory. No other class of objects places such stringent requirements on visual memory, and simultaneously calls on human abilities to integrate information into a social context. To recognize and categorize faces, the facial 'features' useful for accomplishing these tasks must be extracted from a moving three-dimensional surface, encoded visually, and represented in memory. Evidence of the importance of face perception to human survival can be seen in the complex network of brain regions specialized for these functions (Haxby *et al*., 2000). (*See* **Face Perception, Neural Basis of**; **Face Cells**)

FACES AS CONFIGURAL OR HOLISTIC UNITS

Human faces can be defined by the universally recognizable configuration of facial features they share. Indeed, newborn infants only a few hours old respond to faces and face-like configurations more than to other visual patterns (Nelson, 2001). Though all faces share the same 'features' arranged in the same basic configuration, we are able to recognize hundreds, if not thousands, of people by their faces. These impressive abilities are thought to drive from our expertise at perceiving and remembering subtle variations in the configuration of the facial features. The reliance of the human perceptual system on configural rather than feature-based information in perceiving faces has been demonstrated using various experimental manipulations aimed at perturbing the configuration of a face or at disrupting our ability to process the configural information in a face. These manipulations include distortion of the relative positions of the mouth, eyes, and nose (Bartlett and Searcy, 1993), inverting a face (Yin, 1969), and altering the vertical alignment of the contours (Young *et al*., 1987). The results of such studies have supported the view that face perception and recognition rely heavily on processing the configural information in faces. The perceptual importance of the facial configuration can be powerfully illustrated using a variation of the face inversion technique. The 'Margaret Thatcher illusion' (Thompson, 1980) illustrates that inverting a face interferes with our ability to detect even an extreme distortion of the configural information in a face (see Figure 1).

FEATURES OF FACES

What are the features of the human face? Although we generally think of the eyes, nose, and mouth as facial features, these elementary facial parts are neither a psychologically valid nor a computationally adequate description of a face. From both a psychological and a computational perspective, the primary function of a facial feature set is to provide a quantification of the information in faces. An effective feature set must therefore retain the information that makes a face uniquely recognizable as an individual and that identifies it categorically (e.g. as male or female). There is still disagreement on what constitutes a good facial feature set. However, computational studies of face recognition, in combination with what is known about the factors that affect human performance, have suggested that the features we use to encode faces may be derived from the statistical structure of the faces we experience.

Figure 1. The 'Margaret Thatcher illusion', so named for the use of the British Prime Minister's face in the original demonstration (Thompson, 1980). The illusion shows that distortions in the configuration of the face, which appear grotesque when the face is viewed upright, are barely noticed when the face is viewed upside down.

FACE SPACE

The theoretical construct of an abstract multidimensional 'face space' has been proposed as a model of human memory for faces (Valentine, 1991). This construct assumes that the human face memory system can be considered metaphorically as a multidimensional space. Each axis of the space represents a feature and individual faces are represented by points in the space. The coordinates of a face in the space, therefore, indicate the feature values of the face. Similarity between pairs of faces is modeled as the distance between the faces in the multidimensional space.

Face space theory was proposed originally to give insight into certain phenomena in human face perception that relate to the importance of facial distinctiveness for recognition. Faces judged as 'distinct' are recognized more accurately than faces judged as 'typical' (Light *et al.*, 1979). In the context of face space theory, the distinctiveness of a face can be measured as its distance from the mean or 'prototype' of the space, or alternatively, as the density of faces around its position in the space. Faces close to the prototype are thought to be more similar to most other faces than faces far from the prototype. These measures have been hypothesized to be indicative of the confusability of the face with other known faces in the space. The face space theory thus provides a useful framework for conceptualizing the similarity relationships among faces and their importance in predicting recognition accuracy.

EIGENVECTOR REPRESENTATIONS

The face space theory of face recognition can be modeled computationally using principal components analysis (PCA) applied to sets of faces. This analysis provides a concrete model of a face space. Principal components (eigenvectors) are derived from the statistical structure of the input faces, and form the 'feature' axes of the space. Eigenvectors can be ordered according to their 'eigenvalues', which measure the proportions of variance that the eigenvectors explain in the data set. An individual face can be expressed as a linear combination of the eigenvectors, where the coefficients are the coordinates that define the position of the face in the space. This interpretation of PCA makes it analogous to the abstract face space theory proposed by Valentine (1991). The eigenvectors comprise a feature set for describing the faces. The coordinates, which define the position of a face in the space, specify feature values for individual faces. It is worth noting that the eigenvalues add to the generic face space model an inherent measure of the importance of individual 'features' for describing faces. (*See* **Pattern Recognition, Statistical**)

PCA has been applied directly to a number of relatively unprocessed image- and surface-based representations of faces. These include raw images, three-dimensional surface representations from laser scanners, and several 'corresponded' or aligned image- and surface-based representations. It is important to note that the eigenvectors that emerge from PCA represent faces according to the same representation as was analyzed. For example, when two-dimensional images of faces are analyzed, the resulting eigenvectors are also two-dimensional images. Therefore, eigenfeatures, or 'eigenfaces', can be displayed visually, alone, or in combination. Recently, corresponded facial codes have emerged as powerful tools for facial synthesis (Blanz and Vetter, 1999). This is because the resulting face space supports continuous 'morphing' between individual faces via simple linear transformations of the coordinates in the face space.

PCA-based codes have been used to model the effects of distinctiveness on recognition memory for faces and have been applied to the analysis of the categorical information specifying the sex, race,

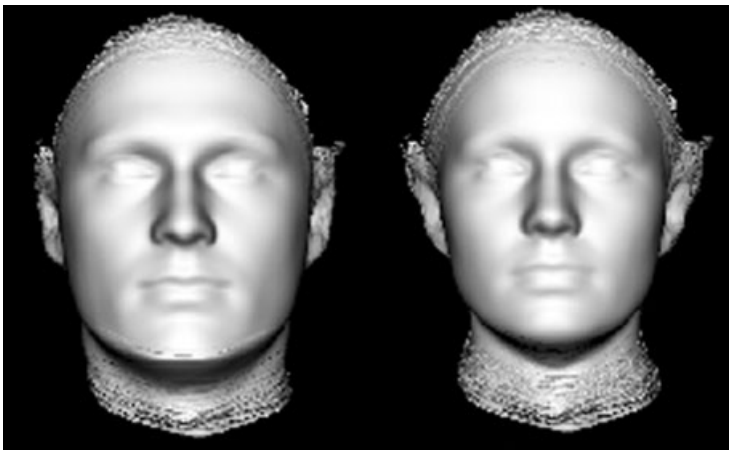

Figure 2. An illustration of the localization of the information that specifies the sex of the face in the PCA code. The first eigenvector captures a global configural contrast between male and female faces. On the left, the first eigenvector is added to the average head. On the right, the first eigenvector is subtracted from the average head.

and expression of a face. The importance of individual eigenvectors for categorization has been assessed by simple neural network algorithms. These networks learn to predict the categorical status of faces using their coordinates in the face space. Several studies have shown that eigenvectors with large eigenvalues tend to encode the categorical information in faces, whereas eigenvectors with smaller eigenvalues tend to encode information about the identity of a face. An example of this principle for sex classification appears in Figure 2. Global configural information about the sex of faces emerges in the eigenvector that explains the largest proportion of variance in the face set (O'Toole *et al*., 1997).

Finally, it is worth noting that the feature sets derived from PCA are dependent on the composition of the set of faces analyzed. This dependence allows the model to simulate specific aspects of human experience and learning in the acquisition of facial features. We will return to this point below when we consider the other-race effect. (*See* **Perceptual Learning**)

MDS REPRESENTATIONS

The abstract face space provides a theoretical framework for understanding human memory for faces, while PCA provides a computational model of this theoretical construct. Multidimensional scaling (MDS) analysis provides data about the psychological validity of the face space theory and about the adequacy of computational implementations of it. Though computationally analogous to PCA, MDS generally refers to the analysis of data produced by human observers. These data comprise similarity judgments between all possible pairs of faces in a set. The resulting human-generated 'distance' measures are used to create a multidimensional map that preserves the psychologically-based similarity relationships among the faces. In this psychological face space, faces are again points in a multidimensional space. The axes are again ordered according to the proportion of variance they explain in the human similarity data; but for most psychological applications, only a small number of axes (usually fewer than four) are retained. Determining the psychological 'features' represented by the axes, however, is a speculative endeavor that involves comparison of faces at opposite ends of the axes.

For many years, MDS has been applied to the analysis of human judgments of face similarity (see Shepherd *et al*. (1981) for the early history of these studies). The early studies were aimed at revealing the basic psychological dimensions underlying human face perception. However, the dimensions of variation that emerged from the analysis were found to depend strongly on the homogeneity of the face set judged by observers. More recently, MDS has been used to focus on more specific questions about the organization of face memory and about the general accord between the assumptions of face space models and the psychological similarity data. MDS analysis of human similarity data has also been used to provide a benchmark for assessing the validity of the computationally-derived face spaces that emerge from different kinds of face input encodings (e.g., two-dimensional image versus three-dimensional surface data).

THE OTHER-RACE EFFECT

The other-race effect for face recognition is the well-known fact that people recognize faces of their own race more accurately than faces of other races (Malpass and Kravitz, 1969). A number of hypotheses have been advanced to explain the other-race effect, including contact with faces of other races, prejudice, and race as a 'feature'. Of these, the 'contact hypothesis' has been investigated most thoroughly. The contact hypothesis assumes that we have more experience with faces of our own race than with faces of other races, and that this experience differential affects the quality of the encoding we make for own- versus other-race faces. An indication of our inability to create distinctive codings for other-race faces is the well-known anecdote 'they all look alike to me'. Studies of the contact hypothesis have related contact with members of other races to the magnitude of the other-race effect. Although these studies have yielded inconsistent results with adult participants, the few studies done with children have yielded more consistent results (Shepherd, 1981). This pattern of findings may indicate the importance of early childhood contact with other-race faces in the acquisition of feature sets, but further experimentation is needed before a firm conclusion can be reached. (*See* **Expertise**)

CONCLUSION

Human face processing relies heavily on the configural information in the face. The face space theory provides a theoretical construct for understanding the organization of human memory for faces. This construct can be modeled computationally with PCA and can be related to empirical data from human observers using MDS. Facial features are unspecified in the original model of Valentine (1991). In the computational framework, features are derived from the statistical structure of the input faces. This kind of analysis can accommodate differences in the experience profiles that individuals have with faces (e.g. experiencing faces of different races in different proportions), and can yield feature sets that are in some senses optimal for the task.

False Memory

Intermediate article

Elizabeth F Loftus, University of Washington, Seattle, Washington, USA

CONTENTS

False memory refers to the experience of thinking that we remember something from our past that did not really happen.

INTRODUCTION

Although memory is one of the most fundamental activities of the human mind, and generally serves us well, it is also true that memory distortion is a fact of life. Portions of what we think we remember are contrary to truth. We sometimes remember the essence of events from the past, but get some of the details wrong. At other times, we remember entire events that were never really experienced by us. Work on memory distortion has not only captured the attention of cognitive psychologists, but has also fascinated physicists and philosophers throughout recorded history. Understanding how we can be tricked by memory is essential for developing ways of avoiding errors, and for resolving memory conflicts in everyday life.

EYEWITNESS TESTIMONY

Thousands of studies have been conducted to determine how people remember accidents, crimes, and other significant events from the past. One popular method of conducting these studies involves simulating what real eyewitnesses might experience. Typically, people are shown simulated crimes or accidents, and are then tested for their memory of the details of these events. So many different factors can affect the accuracy of what a witness remembers, that it has been convenient to divide the factors into three major categories: (1) factors that affect the initial perception or encoding of the event; (2) factors that affect the retention of information in memory; and (3) factors that affect the retrieval of information from the memory system (Loftus, 1979/1996; Wells *et al*., 2000).

Factors Affecting Encoding

When a witness sees a crime, such as an armed robbery, there are some obvious factors that influence the accuracy of the initial perception, such as how good the lighting is or how far away the witness is standing. But there are also some not-so-obvious factors. While it may seem evident that the more time a person has to see the robbery, or the robber's face, the better the memory would be. That's true. But what is not so obvious is that when witnesses try to report how much time they had to look at something, they invariably stretch out those times in their mind. They think they had longer to look than they actually did. In one study people who saw a simulated bank robbery lasting 30 seconds sometimes claimed it lasted for 3 minutes, 5 minutes, or even longer (Loftus *et al*., 1987).

The stress or fright that a witness feels during the robbery can also be a factor. While many people believe that extreme stress leads to an indelible fixation in the mind, in fact the opposite can be true. With highly severe stress, there can be impairments in memory, particularly for the peripheral details of the event. People can focus in on the frightening weapon, and have difficulty remembering the face of the person holding the weapon.

There are a variety of other factors that affect the accuracy of the memory right at the moment a key event occurs. Some have to do with characteristics of the event itself, such as the lighting or duration of the event, or whether a weapon is present. For example, there is a phenomenon called 'weapon focus': when people see a crime involving a weapon, the weapon captures some of their processing attention, and this can result in good memory for the weapon and poorer memory for other details.

Another set of factors concerns characteristics of the witness (such as age, or whether the witness was

under the influence of alcohol, drugs, or other substances). For example, while it might seem obvious that being under the influence of a good deal of alcohol might affect perception and memory, in fact research suggests that as few as two or three drinks can significantly impair the formation of memory. As for the age of a witness, there is now ample evidence that young children have poorer memories than older children and adults, and their memories are more vulnerable to suggestive interviewing and other bad influences (Ceci and Bruck, 1993). At the other end of the age spectrum, research also shows that the elderly sometimes have more trouble forming new memories than do young adults. A selection of further examples are documented in many books devoted solely to the topic of eyewitness testimony (e.g. Cutler and Penrod, 1995; Loftus and Doyle, 1997). In addition, thousands of scientific articles have been published, each devoted to one or more of the various factors.

Factors Affecting Retention

After the event has been witnessed, the memory does not simply sit in the mind waiting to be plucked out. Rather, people are often exposed to new information about the event, and when this postevent information is misleading in some way, people make errors when they later report what they saw. The new information can become incorporated into the recollection, supplementing or altering it, sometimes in dramatic ways.

To show the power of postevent information, researchers have used a simple procedure where witnesses see a simulated accident that, say, involves a car going through a stop sign at an intersection. Later, half receive new misleading information about the event, for example that it was a yield sign. Sometimes the misinformation is presented in the form of a leading question (e.g. 'Did another car pass the red Datsun while it was at the intersection with the yield sign?'); or the misinformation might be embedded in another witness's report to which the original witness is exposed. A separate group of witnesses would not be exposed to any misinformation. Finally, all participants try to recall the original event. When asked about the key details, those given the phony postevent information tend to adopt it as their memory. In the example involving the traffic signs, they claimed that they saw a yield sign. People who had not received the phony information gave much more accurate reports. In some studies, providing misinformation has led to people being half as accurate as they would have been without the misinformation. Distortions in memory from inaccurate postevent information have been found with a wide range of materials. People have recalled nonexistent broken glass and tape recorders, a clean shaven man as having a moustache, and even something as large and conspicuous as a barn in a country scene that contained no buildings at all. The change in report after people are exposed to misinformation is often referred to as the 'misinformation effect'.

A prolonged intellectual debate has occurred over the last few decades about the misinformation effect. Namely, when suggestive information contaminated a person's memory report, did it actually alter the underlying memory traces? Or, did the suggestive information coexist with the original memory traces and under the right circumstances the original might still be accessible? This became known as the debate about the 'permanence of memory' (Loftus and Loftus, 1980). Although this debate continues, what is accepted by virtually all scientists who work in this area is that misinformation can produce profound changes in people's reports of their past experiences.

Factors Affecting Retrieval

A critical stage for an eyewitness is when the person conveys to others what was seen at the original event. This can occur when the witness gives a statement to the police, or tries to identify a culprit from a lineup, or testifies in court. A new set of factors comes into play at this stage. If the witness is asked biased or leading questions, the report can be distorted. Even a simple question like 'Did you see the broken glass?' can lead people to false reporting if there was no broken glass. The use of the definite article 'the' (which implies that there *was* broken glass) is enough to influence what people say. Leading questions can clearly distort what people report. Moreover, there is some evidence that misleading questions can also influence the actual memories.

When witnesses make a memory report, they are often asked for their level of confidence. 'I'm positive that's the guy. I'll never forget that face.' As it turns out, the confidence that a witness expresses is only weakly related to the person's accuracy level. People can be confident, but wrong. Moreover, the level of confidence that a witness expresses can be influenced by feedback that the witness gets (Wells and Bradfield, 1999). If a witness is told 'You picked our suspect', or 'Another witness picked the same guy', or 'The guy's fingerprints were found at the scene', the witness's confidence in her or his memory rises. Confidence can rise, even

when the feedback given is completely inaccurate. Thus confidence itself is malleable, subject to distortion – a kind of false memory of its own.

PLANTING FALSE MEMORIES

It is one thing to see that small details about an event from the past can be distorted, but quite another thing to consider that entire memories can be 'planted' into the mind of people for things that never occurred. Two types of false memory research have been done. One type reveals the creation of a false memory for a word that was never presented, and hundreds of studies of this type have been conducted in part because of the ease of gathering large amounts of data. A second type reveals the creation of false memories of childhood experiences that are far more complex, such as being lost, or being hospitalized, or being injured.

False Memories for Never-seen Words

The paradigm for creating false memories of words is a straightforward laboratory task in which people study lists of related words (e.g. *thread*, *pin*, *eye*, *sewing*, *sharp*, *point*, *prick*, *thimble*, *haystack*, *thorn*, *hurt*, *injection*, *syringe*, *cloth*, and *knitting*). They are all related to a critical lure word that is not presented (*needle*). At a later time, when people have to remember the words that were presented, they frequently falsely recall the critical word. The false recall of the critical lure occurs frequently – as often as half the time or more, and is often at a rate even greater than the recall of actual words that were presented on the list (Roediger and McDermott, 1995).

Because the false word memory studies are so easy to conduct, and large amounts of data can be collected so readily, and the false memory is so reliably produced, the paradigm has been a favorite of memory researchers. Numerous investigators have gone on to learn what they can about memory distortion by ploughing this fertile ground. They have shown, for example, that when people are warned about the problem that a critical nonpresented lure should be avoided, they can reduce the false memory effect somewhat, but the warning does not begin to come close to eliminating the effect.

Individual differences have also been observed in the false word memory paradigm. Older, as opposed to younger, adults have shown a somewhat greater tendency to falsely recall the critical lure. Alzheimer patients show increased false recall. Self-reported episodes of dissociative experiences (e.g. forgetting whether you said something or intended to say it) are connected to increased false recall. And women who have experienced a traumatic event and are suffering from posttraumatic stress disorder (PTSD) have revealed greater false memory for critical lures (Bremner *et al.*, 2000).

Why do people report hearing a word that never occurred? A widely embraced explanation is that while listening to words that are presented (e.g. *thread*, *pin*, *sewing*), the critical lure (*needle*) may come to mind. This might occur consciously, and the person is actually aware of thinking of the lure. Or it might occur unconsciously when an underlying mental representation of the lure is activated. Later, when tested on the lure, the person is confused about whether he or she actually heard it or whether it seems familiar for another reason.

The false memory for words paradigm has been criticized as being artificial, and so different from the kinds of false memories that occur in real-world conditions. Although many researchers believe that the paradigm is a highly valuable one for studying the mental processes that are involved in creating false memories in both laboratory and real-world conditions, it is still useful to explore other memory distortion paradigms and to see whether people can be led to false memories of a more realistic nature.

Planting Childhood Memories

Studies have even shown that more realistic false events can be planted in memory. One example is the research showing that people could be convinced that they had been lost in a shopping mall as children, that they had been upset by the experience, but eventually rescued by an elderly person and reunited with their families. A fairly strong form of suggestion was used in these studies: subjects were 'told' that their parents or older relatives remembered the experience, and the subjects were asked to also remember. In other research using 'parental suggestion', people were led to believe and remember that they had been hospitalized with ear pain, that they had knocked over a punchbowl at a family wedding and spilled punch over the parents of the bride, or that they had been victims of a serious animal attack (Hyman *et al.*, 1995; Loftus, 1997). Real memories and the planted memories differed statistically on a number of dimensions, such as confidence or vividness. Despite the statistical differences when a group of real memories is compared to a group of planted false ones, it was still the case that many of the false memories were vivid and held with confidence and virtually indistinguishable from the real memories

(Porter *et al.*, 1999). Moreover, when people are asked to repeatedly rehearse their false memories, they come to increasingly possess the characteristics of true memories, making the job of distinguishing true from false all that much harder.

The sad fact is that without independent corroboration there is no reliable way at the moment to tell the difference between real memories and ones that are a product of suggestion.

Imagination and False Beliefs

Telling people that a family member has reported a past event is a powerful form of suggestion, so powerful that it has even led people to confess to things that they did not do. But lesser forms of suggestion can also affect past beliefs and memories. When people are led to simply imagine false events they show increased confidence that those events were personally experienced. This confidence-enhancing phenomenon is called 'imagination inflation'. In these imagination inflation studies, people are asked to spend a minute imagining that they had an experience as a child that would have been upsetting if it had occurred. For example, they imagined that they were playing near a window and tripped on something, fell towards the window and broke it with their hand, rendering them cut and bloody. Later on, those who underwent the imagination activity showed enhanced confidence that they had personally experienced breaking a window with their hand. And writing about the contrary-to-truth event can have a similar confidence-boosting effect.

These imagination-type activities can not only make people falsely believe that they had experiences as children, but they can also make people believe that they performed actions a few weeks earlier that they did not perform (Goff and Roediger, 1998). People who imagined doing something multiple times, such as playing drums with toothpicks, frequently falsely claimed that they had actually performed these actions on a specified occasion two weeks earlier.

Some people are more susceptible to imagination inflation than others. For example, people who have self-reported lapses in memory and attention, or people who show better imagery abilities, display more imagination inflation (Heaps and Nash, 1999; Horselenberg *et al.*, 2000).

Why does imagination affect our memory for the past? One explanation is that a simple source confusion error has occurred. When people imagine that they had an experience, there is later on a separation between the content of the information and its source. People remember the content but mistakenly attribute it to the wrong source – they attribute it to their own experience rather than to the imagination activity. The idea that people routinely make source-monitoring errors has a long tradition of study in cognitive psychology outside the area of imagination. People sometimes remember hearing a fact, but misremember who told them that fact. They sometimes remember that they said something to their spouse (e.g. 'remember to buy milk'), but it turns out they only thought about saying that directive, and the spouse comes home empty-handed. (A good discussion of source-monitoring research can be found in Johnson *et al.*, 1993.)

Another explanation for how imagination affects memory is that the imagination activity makes the information seem more familiar. At the time people are asked about an experience, they judge whether it happened to them on the basis of familiarity. Enhanced feelings of familiarity lead them to enhanced confidence that the event was a personal experience (Garry and Polaschek, 2000).

Dreams and False Memory

One commonly used technique in psychotherapy is dream interpretation. Some therapists believe that dreams convey some innermost truth about the past. However, exactly what that truth is appears to depend on the clinician who is doing the interpreting.

Some recent studies have shown that dream interpretation is a powerful way to make people believe that they had experiences in the past that they probably did not have. In this research, subjects reported on various childhood experiences on two separate occasions. Between these two sessions, they went to a clinician who analyzed a dream report. No matter what the person dreamed, the clinician steered them into believing that the dream revealed that they had experienced, before age three, a critical event such as being lost in a public place, or abandoned by their parents, or that they faced a threat to their lives and had to be rescued from that threat. A typical finding is that the dream interpretation led people to believe that they had had the suggested experience. Some of them also went on to develop concrete narrative descriptions of these made-up experiences (Mazzoni *et al.*, 1999).

One of the reasons why this type of suggestion is so effective is that the information is ostensibly coming from an authority figure and it is highly personalized. The clinician is saying, in essence,

'I'm an expert, I've examined your dream, and here's what it means.'

IMPLICATIONS OF FALSE MEMORY RESEARCH

Relevance to the Study of Memory

That memory is constructive is something that psychologists have known for nearly a century. That our memories can fail us because of difficulties that occur at the time information is laid down in memory, or at later times, has been well documented. More recently, the power of suggestion to go beyond simple tinkering with memory, and to lead people to entirely false beliefs about their past, has been shown using a variety of experimental paradigms, such as parental suggestion, imagination, or dream interpretation.

These findings teach us about the rather flimsy curtain that sometimes separates genuine memory from imagination and other processes. We are just beginning to explore how brain activity might help us differentiate real from suggested memories. Studies that explore the activity of the hippocampal and other regions of the brain – using neuroimaging or evoked potentials, for example – are in their infancy but eventually have the potential to help us understand how false memories develop and why they are so often experienced as genuine memories.

Relevance to Legal and Clinical Settings

There are practical implications of memory distortion research to police interrogations, to clinical settings, and to other domains of real-life experience. Police interrogations often involve the strategy of supplying information ostensibly produced by other witnesses. 'Mrs Jones said it happened this way, what do you think?' 'Mrs Jones picked the same person in the lineup.' These are just the kinds of statements that can distort the content of a person's memory, or the confidence with which a memory is expressed. Since judges and juries are influenced by the detail and the confidence of witness testimony, these interventions can improperly affect the outcome of cases. A number of cases of wrongful convictions have recently come to light – individuals who served lengthy prison sentences but who were eventually exonerated by DNA evidence. These cases reveal that faulty memory was a major cause of the wrongful conviction. Fortunately, various government agencies are beginning to appreciate the problems of memory, and to implement procedures that will reduce the mistakes made by witnesses in actual cases (Technical Working Group, 1999).

The finding that memories can be distorted, and even planted entirely, has relevance to the 'repressed memory controversy'. In recent times, numerous psychotherapists have acknowledged the use of hypnosis, guided imagery, imagination exercises, and other memory-focused techniques designed to help patients recover allegedly repressed memories. Self-help books with imagination and writing exercises that encourage counterfactual expression can be having enormous unintended side effects. These techniques have been met with skepticism, precisely because of their ability to lead people to develop false memories. In therapy, there is often pressure brought to bear on patients to comply with a therapist's conceptualization of the patient's difficulties. Good clinical practice demands that therapists appreciate how their treatments work, and what possible side effects those 'treatments' might be having.

Game Theory

Introductory article

David K Levine, University of California, Los Angeles, California, USA

CONTENTS

Game theory is the mathematical study of human interactions described by rules of play and alternative choices.

INTRODUCTION

Situations that economists and mathematicians call 'games' psychologists call 'social situations'. While game theory has applications to 'games' such as poker and chess, it is the social situations that are the core of modern research in game theory. Game theory has two main branches: noncooperative game theory models a social situation by specifying the options, incentives, and information of the 'players' and attempts to determine how they will play; cooperative game theory focuses on the formation of coalitions and studies social situations axiomatically. This article will focus on noncooperative game theory.

Game theory starts from a description of the game. There are two distinct but related ways of describing a game mathematically. The *extensive form* is the most detailed way of describing a game. It describes play by means of a *game tree* that explicitly indicates when players move, which moves are available, and what they know about the moves of other players and nature when they move. Most important, it specifies the *payoffs* that players receive at the end of the game.

STRATEGIES

Fundamental to game theory is the notion of a *strategy*. A strategy is a set of instructions that a player could give to a friend or program on a computer so that the friend or computer could play the game on her behalf. Generally, strategies are contingent responses: in the game of chess, for example, a strategy should specify how to play for every possible arrangement of pieces on the board.

An alternative to the extensive form of game description is the *normal* or *strategic* form. This is less detailed than the extensive form, specifying only the list of strategies available to each player. Since the strategies specify how each player is to play in each circumstance, we can work out from the *strategy profile* specifying each player's strategy what payoff is received by each player. This map from strategy profiles to payoffs is called the normal or strategic form. It is perhaps the most familiar form of a game, and is frequently given in the form of a game matrix.

The matrix shown in Figure 1 is the celebrated *Prisoner's Dilemma* game. In this game the two players are partners in a crime who have been captured by the police. Each suspect is placed in a separate cell, and offered the opportunity to confess to the crime. The rows of the matrix correspond to strategies of the first player; the columns are strategies of the second player. The numbers in the matrix are the payoffs: the first number in each pair is the payoff to the first player, the second the payoff to the second player. Notice that the total payoff to both players is highest if neither confesses, so each receives 5. However, game theory predicts that this will not be the outcome of the game (hence the dilemma). Each player reasons as follows: if the other player does not confess, it is best for me to confess (9 instead of 5). If the other player does confess, it is also best for me to confess (1 instead of 0). So no matter what I think the other player will do, it is best to confess. The theory predicts, therefore, that each player following her own self-interest will result in confessions by both players.

	Player 2		
Player 1		not confess	confess
	not confess	5,5	0,9
	confess	9,0	1,1

Figure 1. Game matrix: 'The Prisoner's Dilemma'.

EQUILIBRIUM

The previous example illustrates the central concept in game theory, that of an *equilibrium*. This is an example of a *dominant strategy* equilibrium: the incentive of each player to confess does not depend on how the other player plays. Dominant strategy is the most persuasive notion of equilibrium known to game theorists. In the experimental laboratory, however, players who play the prisoner's dilemma sometimes cooperate. The view of game theorists is that this does not contradict the theory, so much as reflect the fact that players in the laboratory have concerns besides monetary payoffs. An important current topic of research in game theory is the study of the relationship between monetary payoffs and the *utility* payoffs that reflect players' real incentives for making decisions.

By way of contrast to the prisoner's dilemma, consider the game matrix in Figure 2. This is known as the *Battle of the Sexes* game. The story goes that a husband and wife must agree on how to spend the evening. The husband (player 1) prefers to go to the ballgame (2 instead of 1), and the wife (player 2) to the opera (also 2 instead of 1). However, they prefer agreement to disagreement, so if they disagree both get 0. This game does not admit a dominant strategy equilibrium. If the husband thinks the wife's strategy is to choose the opera, his *best response* is to choose the opera rather than the ballgame (1 instead of 0). Conversely, if he thinks the wife's strategy is to choose the ballgame, his best response is the ballgame (2 instead of 0). While in the prisoner's dilemma the best response does not depend on what the other player is thought to be doing, in the battle of the sexes the best response depends entirely on what the other player is thought to be doing. This is sometimes called a *coordination game* to reflect the fact that each player wants to coordinate with the other player.

For games without dominant strategies the equilibrium notion most widely used by game theorists is that of *Nash equilibrium*. In a Nash equilibrium, each player plays a best response, and correctly anticipates that her opponent will do the same. The battle of the sexes game has two Nash equilibria: both go to the opera, or both go to the ballgame: if each expects the other to go to the opera (ballgame) the best response is to go to the opera (ballgame). By way of contrast, one going to the opera and one to the ballgame is not a Nash equilibrium: since each correctly anticipates that the other is doing the opposite, neither one is playing a best response.

Games with more than one equilibrium pose a dilemma for game theory: how do we or the players know which equilibrium to choose? This question has been a focal point for research in game theory since its inception. Modern theorists incline to the view that equilibrium is arrived at through learning: people have many opportunities to play various games, and through experience learn which is the 'right' equilibrium.

MIXED STRATEGIES

While the battle of the sexes has too many equilibria, what about the game in Figure 3? You may recognize this game as the *Matching Pennies* game. There is, however, a more colorful rendition from Conan Doyle's Sherlock Holmes story *The Last Problem*. Moriarty (player 2) is pursuing Holmes (player 1) by train in order to kill Holmes and save himself. The train stops at Canterbury on the way to Paris. If both get off at Canterbury, Moriarty catches Holmes and wins the game (−1 for Holmes, 1 for Moriarty). Similarly, if both get off at Paris. Conversely, if they get off at different places, Holmes escapes (1 for Holmes and −1 for Moriarty). This is an example of a zero sum game: one player's loss is another player's gain. In the story, Holmes gets off at Canterbury, while Moriarty continues on to Paris. But it is easy to see that this is not a Nash equilibrium: Moriarty should have anticipated that Holmes would get off at Canterbury, and so his best response was to get off also at Canterbury. As Holmes says: 'There are limits, you see, to our friend's intelligence. It would have been a coup-de-maître had he deduced what I would deduce and acted accordingly.' However,

	Player 2		
Player 1		opera	ballgame
	opera	1,2	0,0
	ballgame	0,0	2,1

Figure 2. Game matrix: 'The Battle of the Sexes'.

	Player 2		
Player 1		Canterbury	Paris
	Canterbury	–1,1	1,–1
	Paris	1,–1	–1,1

Figure 3. Game matrix: 'Matching Pennies'.

this game does not have *any* Nash equilibrium: whichever player loses should anticipate losing, and so choose a different strategy.

What do game theorists make of a game without a Nash equilibrium? The answer is that there are more ways to play the game than are represented in the matrix. Instead of simply choosing Canterbury or Paris, a player can flip a coin to decide what to do. This is an example of a random or *mixed strategy*, which simply means a particular way of choosing randomly among the different strategies. It is a mathematical fact, although not an easy one to prove, that every game with a finite number of players and a finite number of strategies has at least one mixed strategy Nash equilibrium. The mixed strategy equilibrium of the matching pennies game is well known: each player should randomize 50–50 between the two alternatives. If Moriarty randomizes 50–50 between Canterbury and Paris, then Holmes has a 50 percent chance of winning and a 50 percent chance of losing, regardless of whether he chooses to get off at Canterbury or at Paris. Since he is indifferent between the two choices, he does not mind flipping a coin to decide between the two, and so there is no better choice than for him to randomize 50–50 himself. Similarly, when Holmes is randomizing 50–50, there is no better choice for Moriarty than to do the same. Each player, correctly anticipating that his opponent will randomize 50–50, can do no better than to do the same. So perhaps Holmes (or Conan Doyle) is not such a clever game theorist after all.

Mixed strategy equilibrium points out an aspect of Nash equilibrium that is often confusing for beginners. Nash equilibrium does not require a positive reason for playing the equilibrium strategy. In matching pennies, Holmes and Moriarty are indifferent: they have no positive reason to randomize 50–50 rather than doing something else. However, it is only an equilibrium if they both happen to randomize 50–50. The central thing to keep in mind is that Nash equilibrium does not attempt to explain why players play the way they do. It merely proposes a way of playing so that no player would have an incentive to play differently. As with the issue of multiple equilibria, theories that provide a positive reason for players to be at equilibrium have been one of the staples of game theory research, and the notion of players learning over time has played a central role in this research.

Gamma Oscillations in Humans

Intermediate article

Catherine Tallon-Baudry, Centre National de la Recherche Scientifique (CNRS), Paris, France
Olivier Bertrand, INSERM, Lyon, France

CONTENTS

Gamma oscillations in human electroencephalographic signals are defined by their frequency range, from 20 Hz up to 100 Hz. Different types of oscillations are related to arousal states, early sensory processes, and neural mechanisms of sensory or cognitive binding by oscillatory synchronization.

INTRODUCTION

The existence of oscillations in the gamma range (20–100 Hz) in human electroencephalographic (EEG) or magnetoencephalographic (MEG) signals was first reported in the 1950s. In the 1990s, interest in these high-frequency activities increased following the proposal that frequency tagging could solve the feature-binding problem (Gray *et al.*, 1989). This problem becomes obvious if one considers the situation when the visual system is confronted with two objects – e.g. a green bar moving upwards and a red one moving downwards. How is the information 'green', coded by one set of neurons, combined with the direction of motion 'up' encoded in a different neural set? How can the system correctly assign the correct color and motion attributes to an object? A possible solution to this problem is that neurons responding to different features of the same object synchronize their discharge on an oscillatory mode. Using different frequencies, distinct cell assemblies could coexist to code simultaneously for different objects (Singer and Gray, 1995). More generally, oscillatory synchrony could provide the necessary link between the multiple areas that are activated in any task, as exemplified in numerous brain imaging studies in humans. It would thus not be dedicated to a particular cognitive process, but could rather be considered as a general neural mechanism that binds together the sensory and cognitive properties of any perceived or recalled object into the experienced entity. (*See* **Binding Problem**; **Neural Oscillations**; **Neural Correlates of Consciousness as State and Trait**; **Neural Correlates of Visual Consciousness**; **Perception, Gestalt Principles of**)

However, very different types of activities having in common a peak in their power spectrum between 20 Hz and 100 Hz have been gathered under the same general appellation of 'gamma oscillations'. They have been studied in various experimental contexts and probably reflect very different mechanisms. So far, only one type of gamma activity ('induced' oscillations) has been repeatedly related to the binding problem.

TYPES OF GAMMA OSCILLATIONS

The different types of gamma oscillations listed below have only one common property: they reflect the synchronization of large neural populations in the gamma frequency range (20–100 Hz). Indeed, scalp EEG or MEG signals always correspond to the collective behavior of neural ensembles. However, the precise anatomical extent of a synchronous activity measured at the scalp level is not readily accessible. (*See* **Electroencephalography (EEG)**)

Spontaneous Gamma Activity and Arousal

The frequency content of the EEG during the sleep–wake cycle changes markedly and indeed is used as a criteria to distinguish between sleep stages. During wakefulness and rapid eye movement (REM) sleep, the EEG power spectrum is shifted towards higher frequencies. In keeping with this classical observation, randomly occurring, spontaneous bursts of 40 Hz activity were shown to appear in the awake and REM sleep states, but not during slow-wave sleep (Llinas and Ribary, 1993). This 'desynchronized' EEG in wakefulness and REM sleep corresponds to a global state of

arousal of the whole brain. It can thus be observed at any recording site, as opposed to gamma responses obtained in response to a stimulus, which show up at the scalp level with a modality-dependent topographical distribution.

The Phase-locked 40 Hz Response: Evoked and Steady-state Responses

Transient averaged evoked potentials (EPs) are obtained by averaging the EEG or MEG signals obtained in response to a stimulus in a series of trials (Figure 1a). Any signal that does not have a strict time relationship with stimulus onset is considered to be 'noise' and tends to disappear in the average. Evoked responses, as they appear in the EPs, are in contrast strictly phase-locked to stimulus onset; they appear in each single trial at the same latency.

Galambos *et al*. (1981) were the first to notice that the series of waves appearing in the first 100 ms following the delivery of an acoustic click could be considered as a sequence of positive and negative peaks separated by approximately 25 ms, thus resembling a sinusoid wave at 40 Hz. This observation led to the definition of the early evoked 40 Hz response, which has been repeatedly observed in both the auditory and visual modalities, in EEG and MEG signals. Like many other EP components, the evoked 40 Hz response is sensitive to the physical parameters of the stimulus, and can be modulated by attention. No conclusive evidence is available yet regarding the nature of this evoked 40 Hz response: it could be a truly oscillatory phenomenon, or reflect a succession of activations of different neural structures that appear by chance at latencies separated by 25 ms at the scalp level. Whether the early gamma response is distinct from the evoked potentials appearing in the same latency range remains unclear.

Steady-state evoked potentials are obtained in response to stimuli presented at a high-frequency rate. They were first observed in the visual modality (Regan, 1968). When a stimulus is presented at frequencies of 30–60 Hz, the evoked response is a nearly pure sinusoid at the stimulus frequency. Large steady-state responses are obtained with a stimulus frequency between 40 Hz and 50 Hz, in both visual and auditory modalities. This finding was first interpreted as the existence of natural resonance frequencies in the brain at around 40 Hz. However, the current prevailing view is that steady-state potentials simply reflect a linear overlap of the early evoked responses to consecutive stimuli (Figure 1c). The steady-state response is a large and stable signal; it can be acquired in a single recording session and readily analyzed in the frequency domain at the driving stimulus frequency. It is therefore considered to be a useful indicator of the functioning of early sensory processes, with applications in both clinical and cognitive research.

Gamma Activities Induced by a Stimulus

As opposed to transient or steady-state evoked responses, induced activities are characterized by a loose temporal relationship to the stimulus (Figure 1a). Induced gamma responses received much attention following the observation of gamma oscillatory synchronization in animals, not phase-locked to the stimulus (Gray *et al*., 1989). Since an induced activity appears with a jitter in latency from one trial to the other, it tends to disappear in the averaged evoked potential. Such activities thus require specific methods to be extracted from EEG or MEG signals. All the methods used so far have in common the transformation of the potential or magnetic field into spectral power prior averaging (Figure 1b). Different techniques, with different time and frequency resolutions, have been successfully applied, such as filtering and rectifying, short-term Fourier transform, or wavelet-based time–frequency decomposition. Using such methods, any noise present in the data (as produced by power supply or screen radiations) tends to show up in the final power average. Other artefacts have physiological sources: muscle activity is picked up in the EEG and can show up in the gamma frequency range. Particular care has thus to be taken to obtain high-quality data. Although a growing number of research groups have been able to record these induced gamma activities, some authors still deny their existence at the scalp level.

INDUCED GAMMA ACTIVITIES

Existence and Characteristics

Induced gamma activities have been observed in different sensory modalities (auditory, somatosensory, visual), before and during movement execution, in various experimental conditions, ranging from a simple auditory detection task to semantic decision tasks. In response to a transient stimulus, an induced gamma-band response usually appears 200–400 ms after stimulus onset. Its frequency is most often between 30 Hz and 40 Hz but it may

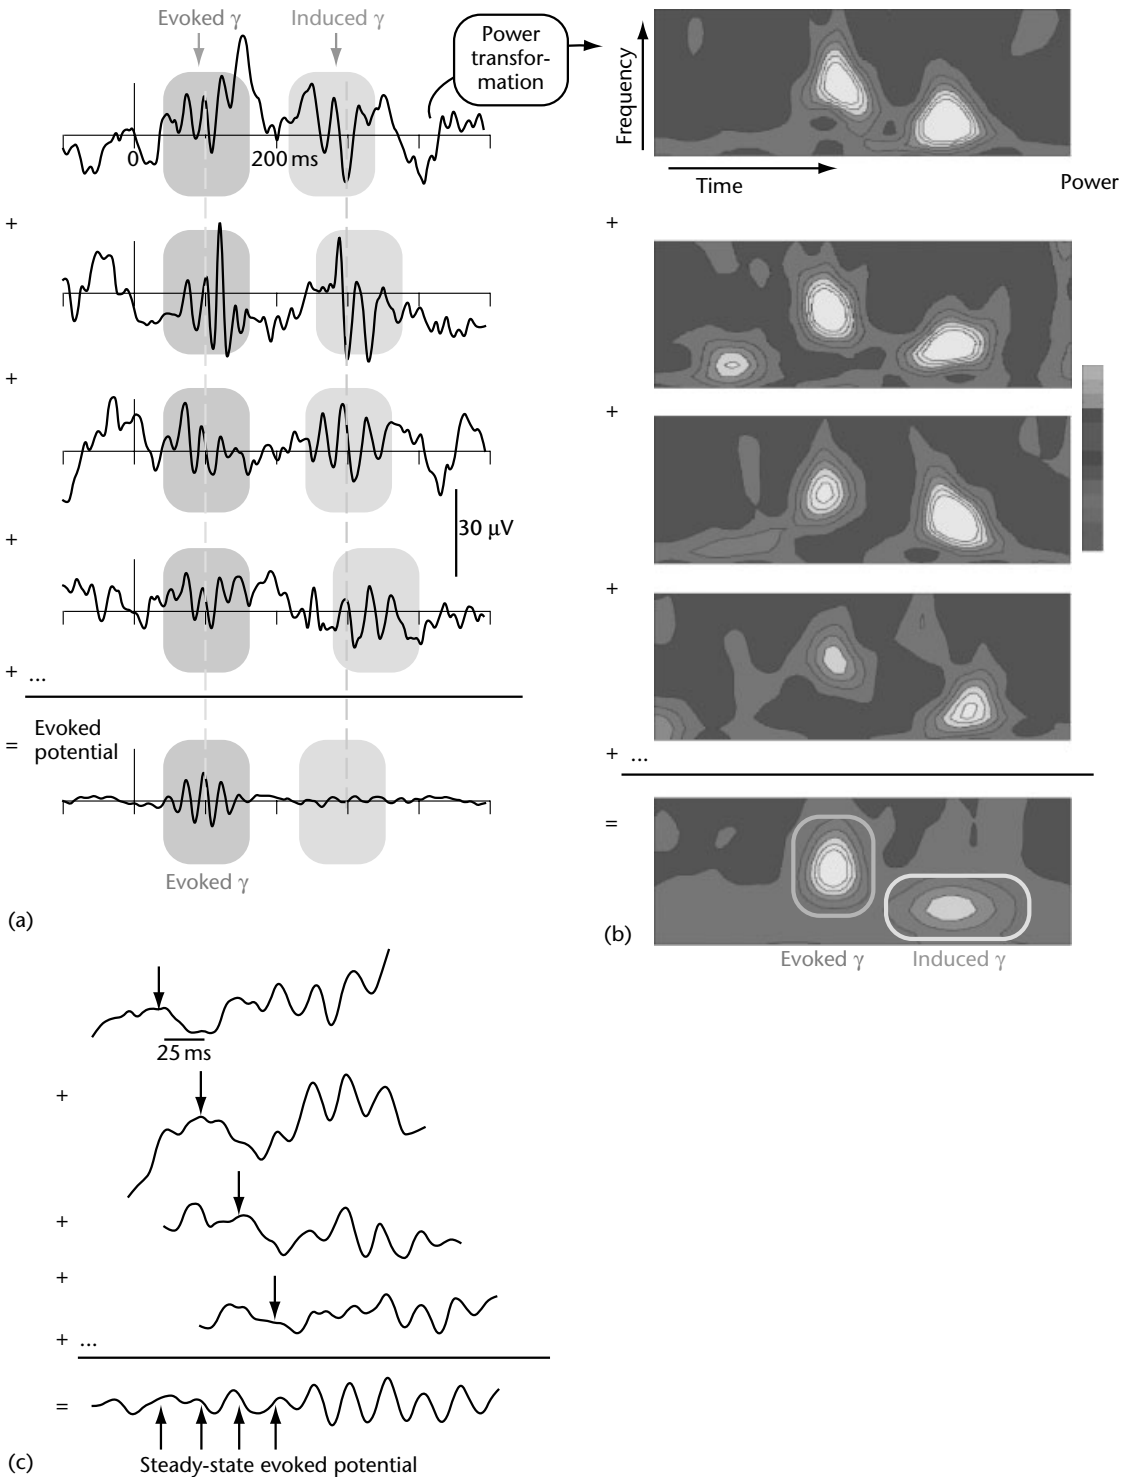

Figure 1. [*Figure is also reproduced in color section.*] The different types of gamma oscillations observed in humans (simulated data). (a) Two bursts of oscillatory activity (shaded) appear in successive single trials obtained in response to a stimulus (stimulus onset at zero latency). The first is evoked: it appears always at the same latency, and thus shows up in the averaged evoked potential (bottom). The second is induced by the stimulus: it appears with a jitter in latency and thus tends to cancel out in the average. (b) Transformation of single trials into power prior averaging. The method depicted here is a wavelet-based time–frequency decomposition of the signal. Both evoked and induced activities show up in the average of these time–frequency plots across single trials (bottom). (c) The steady-state evoked potential could reflect the linear combination of successive early sensory responses, when the stimulus (arrow) is delivered at 40 Hz (Galambos *et al*., 1981).

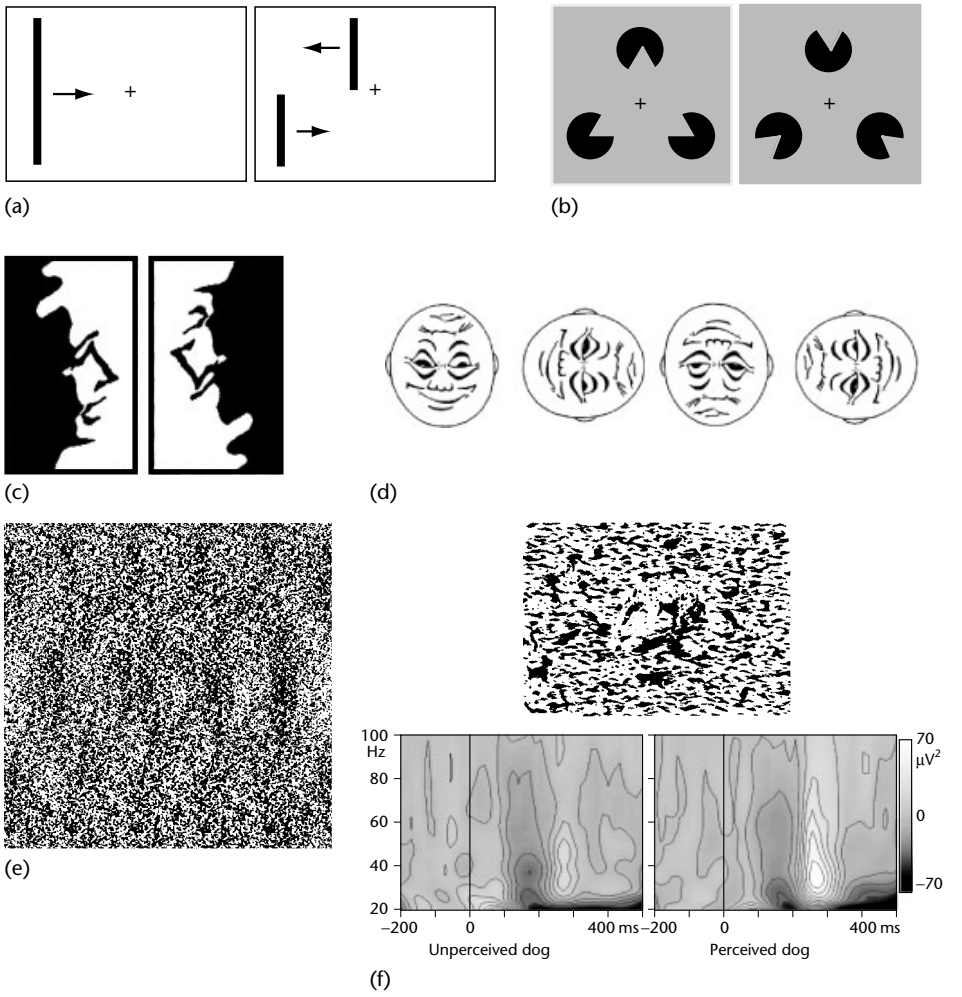

Figure 2. Coherent stimuli giving rise to an occipital increase of induced gamma oscillations. (a,b,c) Coherent object (left) and control, 'non-object' stimulus (right). Multiple objects can sometimes be perceived from the control stimulus. However, if multiple oscillatory assemblies, corresponding to each of these objects, coexist at different frequencies, they should tend to cancel each other in the resulting signal recorded at the scalp level. (d) A continuously rotating stimulus can be perceived as a happy or sad face (vertical orientation). Peaks in gamma activity are observed at these positions only. (e) An occipital increase of gamma oscillations is observed prior the fusion of this autostereogram into a three-dimensional percept. (f) Modified version of the Dalmatian dog picture. Naive observers perceive this stimulus as meaningless blobs on a gray background, and have only a very weak induced gamma response; once trained to perceive the dog hidden in this picture, however, they show a prominent occipital gamma activity. vary from 25 Hz up to 90 Hz. The topography of induced gamma activities is both modality- and task-dependent. This suggests that induced gamma responses reflect the oscillatory synchronization of stimulus- and task-related areas, rather than an unspecific arousal process. For instance, the induced gamma activities that were observed prior to voluntary movement have a scalp distribution

that follows the somatotopic organization of the motor cortex (Pfurtscheller *et al*., 1994). In many of these studies, a relevance of induced gamma activities for sensory or cognitive processes is suggested. However, a more precise functional role of these induced gamma oscillations emerges from studies in the visual modality.

Induced Gamma Oscillations and Coherent Visual Representations

In a series of EEG studies from different groups, it was shown that when the stimulus leads to a coherent percept, a transient increase in the gamma band is observed at occipital leads, compared with meaningless stimuli (Figure 2). In addition, in several of these studies, the coherence of the stimulus was not reflected directly in the classical EPs, nor in the the alpha band (8–12 Hz). Last, variations of gamma power at particular recording sites can be accompanied by episodes of gamma synchronization between electrodes, suggesting that areas wide apart can become synchronized (Rodriguez *et al*., 1999). Altogether, these results provide arguments in favor of a specific role of induced neural synchronization in the gamma range in the integration of visual information into a coherent object representation. Because induced gamma oscillations and evoked potentials in the same latency range do not show the same functional variations, it is likely that these two signals reflect different neural mechanisms.

In addition, induced gamma oscillations also increase when the object representation is not directly triggered by the physical characteristics of the stimulus. A transient increase in gamma power appears when a person has to activate an internal representation of the target to detect it in a picture where it is hidden (Figure 2). Sustained gamma and beta (15–20 Hz) oscillations have also been shown to be present during the rehearsal of an object in short-term memory, both at occipital and frontal sites (Tallon-Baudry *et al*., 1998). This suggests a role of oscillatory neural synchrony in bringing together pieces of information, probably encoded in distinct functional areas, into the meaningful and coherent representation that is perceptually experienced or rehearsed in short-term memory. (*See* **Hebbian Cell Assemblies**; **Neural Development, Models of**)

Finally, following Hebb's concept of cell assembly, neural synchronization in the gamma range could be involved in associative learning: Miltner *et al*. (1999) observed an increase of coherence in the gamma range between occipital and central scalp electrodes in a task involving a conditioned association between a visual and a somatosensory stimulus. (*See* **Hebbian Cell Assemblies**; **Hebb, Donald Olding**)

CONCLUSION

Despite a rapidly growing amount of research, this field of investigation remains controversial. Scalp-recorded gamma oscillations are still sometimes considered to be artefacts. Indeed, EEG signals may be contaminated by muscle activity. However, intracerebral recordings in epileptic patients indisputably show the existence of both within-area and between-area oscillatory synchrony (Fell *et al*., 2001; Tallon-Baudry *et al*., 2001). Finally, the functional interpretation of gamma oscillations suffers from the frequent confusion between the different types of gamma responses.

However, there is converging evidence that induced gamma oscillations are involved in sensory processes, memory rehearsal, visuomotor transformation and learning. This could mean that they are a mere epiphenomenon accompanying any mental activity. Conversely, the variety of experimental situations in which they are encountered suggest that they cannot be correlated with a unique cognitive process, but rather reflect a general neural mechanism used for dynamic binding of activities from the different functional areas activated in sensory and cognitive tasks. This interpretation is in keeping with the theoretical hypothesis of cell assembly synchronization, since scalp-recorded oscillations necessarily reflect a massive neural synchrony. An alternative interpretation is that oscillatory synchrony may serve as an attentional gating mechanism (Fries *et al*., 2001). (*See* **Attention, Neural Basis of**)

To confirm the functional role of induced gamma oscillations, it would be necessary to show that a selective disruption of gamma activity modifies perception or behavior. This could probably be achieved only in studies of freely moving animals. However, it is not clear yet how to relate the gamma oscillations recorded at the scalp level in humans to those observed at a microscopic scale in animal studies.

Gender Differences in Cognition and Educational Performance

Introductory article

Marcia C Linn, University of California, Berkeley, California, USA
Cathy Kessel, University of California, Berkeley, California, USA

CONTENTS

Gender differences in cognitive and educational performance refer to the apparent differences in the cognitive abilities of men and women, especially with respect to spatial and verbal tasks. They have been ascribed to both cultural and biological influences.

HISTORICAL AND CULTURAL INFLUENCES

Meaningful interpretations of gender differences in cognitive and educational performance require a knowledge of the relevant cultural, societal, and historical contexts. In the United States, as in other countries, women's participation in education has indeed been a function of culture and history, as well as economic need and social justice. Women began to gain access to selected institutions of higher education by the late 1800s, although many still believed that study might overtax females by drawing blood away from their ovaries to their brains. Research discredited this belief, but it resonated with popular opinion, patterns of participation in intellectual pursuits, and the images of intellectual women as spinsters. When women started to enroll as undergraduate and graduate students, they tended to earn higher grades than men – a trend that has continued to the present.

Almost a century later, when Title IX came into effect in the United States, most colleges lifted their quotas for women. Now almost every institution of higher education admits both men and women; few professional programs retain gender quotas. As a result, over half of undergraduates are women, and graduation rates of women from high school and college have soared and surpassed those of men. Females comprise an increasing proportion of students in professional schools including medicine, law, and business. National Science Foundation statistics show that almost half of all PhDs are earned by women, and over a third of the doctorates in science and engineering go to women.

The picture is less rosy with regard to employment. Cultural expectations concerning who can succeed, especially in positions of leadership, impact on selection decisions. However, exceptions are widespread. Men have excelled in fields traditionally viewed as feminine, including nursing and office administration, and women have succeeded in endeavors traditionally viewed as male, including conducting orchestras, leading technology companies, and winning intellectual prizes. Nevertheless, progress in these areas has been slow for nontraditional participants, and, in some cases such as computer science, initial gains have subsided.

The subtle but powerful pressures of cultural expectations, giving the work of females less value, are apparent, for example, even at the prestigious Massachusetts Institute of Technology. Female faculty jointly assessed the space they were given, the treatment of their requests for research funds, the assignment of courses, and the assignment of committee responsibilities. Comparing practices across departments revealed systematic and substantial differences in treatment for female compared with male faculty. MIT publicized the discrepancies and remedies in an effort to increase equitable opportunities for women at all institutions. Despite this publicity most other institutions have resisted similar analyses and possible remedies.

Individuals in power may be slow to welcome those who do not resemble themselves. As described, for example by Virginia Valian, individuals who are different from their peers frequently experience difficulties in succeeding and often are more closely scrutinized than their more traditional

peers. These conditions are exacerbated by expectations that tend to place greater responsibility for family and children on females than on males, reducing available female human capital.

Cultural expectations may affect performance as well as selection. The psychological research of Claude Steele and his colleagues has demonstrated how context may make these expectations salient for particular groups. When students of a subgroup that traditionally performs poorly in a given domain are reminded of this fact, they tend to perform poorly on difficult tests; without this reminder, they perform similarly to their peers. These and other findings suggest that cultural expectations permeate all social interactions, including those in research laboratory settings, and may influence outcomes of experimental and classroom studies in subtle and unexpected ways.

Cultural expectations may affect educational participation and performance as well. For example, in 1980 Geoffrey Driver compared the academic performances of students who were white and those of West Indian origin. He found that although they experienced the same general academic program, when tested at age 16, West Indians tended to outperform their English counterparts, English boys tended to outperform English girls – but West Indian girls tended to outperform West Indian boys. A possible explanation is that the West Indian girls assumed a family structure more prevalent in the West Indies in which women are responsible for family subsistence – and were preparing for their futures as primary wage-earners.

Cultural expectations may explain differences in participation found by a Public Policy of California study. In California, middle school girls' course enrollment was greater than boys' for English, foreign language, mathematics, science (except that required for college), social science, but not for computer science courses. The situation was similar for college preparatory high school courses. Female enrollment was greater than that of males – again, except for computer science. This enrollment pattern reverses the earlier gender gap in mathematics and science courses. Moreover, in each ethnic group in the study categories, girls enrolled in more mathematics and science courses than boys. However, gaps were far larger for Filipinos, Hispanics, and African Americans than for whites and non-Filipino Asians.

Cultural expectations and instructional practices may explain the findings of David Byrnes and his colleagues. In contrast with long-standing experience in the United States, no gender gap was found when the SAT was administered to a sample of Chinese high school students. Instructional practices, but perhaps not cultural expectations, may be responsible for a similar result for high school students enrolled in an innovative mathematics course in the United States.

In the past, cultural interpretations of gender differences often followed a deficit model. From this perspective, male behavior was considered normative and desirable, and deviations from this norm were considered deficits. This model also influenced research. Studies looked for differences between males and females and accumulated less successful performances of females to paint a picture of females as having 'deficits'. This deficit model was sometimes elaborated into a compensation model, in which typical male behavior was the norm in 'male' activities, including academic, intellectual, and athletic performance, and female behavior was the norm in activities typed as female, including child care, family relations, and homemaking. These models drew attention away from the large overlap in the distributions of male and female performance in every area, and neglected the rapid improvements that result when barriers to participation or success disappear.

SPATIAL AND VERBAL ABILITIES

Historically, accounts and definitions of human abilities have varied substantially. In the United States at the beginning of the twentieth century, research views of human ability as unitary were reinforced by measures of general ability that yielded a single score. As researchers performed more detailed analyses, they identified more specific and often contextualized abilities. A substantial commercial enterprise in the design, sale, and scoring of tests for these abilities developed.

Some of this proliferation in abilities stemmed from newly available statistical techniques. As factor analysis developed, individual researchers used this technique to distinguish more and more abilities. At the same time, a research program concerning the nature of ability constructs took shape. The identification, statistical properties, and labeling of human ability constructs has continued as an active research area. Researchers seek to distinguish 'traits' that are innate or unresponsive to instruction from achievements that respond to instruction. Good methods for determining whether an ability is inherent or responsive to instruction have been difficult to develop. Sorting out the effects of cultural expectations on human abilities has proven problematic. When cultural

expectations limit opportunity to learn, constructs often appear innate. For example, many assumed there are innate differences in spatial ability only to discover that performance responds to instruction and varies across educational systems. Similar differences in mathematical attainment have narrowed, as Rosenthal observed, 'faster than the gene can travel'. A serious debate about the inherent nature of abilities plays out in each of the areas highlighted in this review.

Spatial Performance

Research on spatial ability has its origins in Francis Galton's work on imagery in the 1880s. Findings concerning gender differences soon followed. Galton found that 'scientific men as a class have feeble powers of visual representation. There is no doubt whatever on the latter point, however it may be accounted for'. G. Stanley Hall reported in his 1891 study, 'The contents of children's minds on entering school', that girls excelled in space concepts and boys in number. Systematic research on this topic began in the 1920s.

Tests of spatial reasoning such as Raven's progressive matrices were viewed as independent of verbal skill. However, using factor analysis to distinguish verbal and nonverbal constructs proved difficult. Raymond Cattell argued that fluid and crystallized ability, although distinct constructs, were correlated factors. Despite these difficulties, by World War II spatial ability measurement played an important role in assessing and assigning army recruits, and measures of spatial ability were used in other career decisions. Eventually, the belief that females had greater difficulty in spatial reasoning was associated with their underrepresentation in mathematics and science.

In 1974, Eleanor Maccoby and Carol Jacklin reviewed all the research on gender differences and concluded that, although performance across tests used to measure spatial ability varied considerably, in general males excelled in spatial tasks. These tests included Raven's progressive matrices, the embedded figures test, and a newly developed measure of speed in mental rotation.

In the late 1970s, Marcia Linn and Anne Petersen extended Maccoby and Jacklin's findings on spatial performance. They sought to distinguish the varied constructs captured under the broad category of spatial ability. They used meta-analysis to group tasks in categories with uniform characteristics and identified three constructs.

First, syntheses of performances on tasks such as embedded figures, paper folding, and Raven's progressive matrices that asked students to reason about figural rather than verbal information revealed virtually no gender differences.

Second, tasks measuring what is often referred to as the *water level task* revealed large gender differences. This task, originally used by Jean Piaget, asks students to predict the level of water in a tilted glass when given information about the water level in an upright glass. Many factors can influence performance, including whether the glass is square or curved, and whether the respondent believes that the glass has just been moved to a new location or has been resting in that new location for some time.

Third, tasks requiring students to mentally rotate two- and three-dimensional objects to a new orientation revealed large differences, primarily in speed. Most respondents obtained the right answer; males responded more rapidly. Some respondents took over twice as long as others, and the studies of strategies for mental rotation showed that some participants mentally rotated an entire object and chose an answer, while others rotated features and repeated the process until the answer was chosen. In these studies, women were more likely than men to use a feature matching approach, and therefore to take longer to respond to mental rotation items. Changing the instructions to encourage rapid responding reduces differences, supporting the idea that a strategy preference is a factor in these differences.

Subsequent research has shown that spatial ability, rather than being an enduring trait, appears quite responsive to instruction and, for instance, multiple strategies can be used to solve most spatial reasoning tasks. For example, Sherry Hsi and Alice Agogino studied spatial reasoning performance among first-year engineering students at a competitive university, a group likely to have been successful in high school mathematics classes. They found large initial differences between males and females on measures of spatial reasoning. Two Saturday morning voluntary training sessions reduced or eliminated these gender differences.

Moreover, in-depth interviews of successful engineers revealed that they rarely used the rotation of whole objects in their work. Instead, most reported that they were likely to rely on descriptive geometry, feature matching, and the rotation of a subset of familiar shapes and forms, rather than using their mental capacities to rotate whole objects. This suggests that success in engineering may not require the use of mental rotation.

Another area where spatial reasoning ability is frequently implicated concerns the interpretation

of maps. Here again, cultural expectations and anecdotal evidence suggest that males are more successful at way-finding, map reading, and map interpretation. Nevertheless, extensive study of young children's ability to find their way in complex settings reveals a fairly systematic result of males being more successful than females. A study of adults found that males were more successful at way-finding and, as with the engineering students, that females improved with training.

All these results underscore the importance of instruction promoting varied spatial abilities. Studies attempting to link spatial ability to activities requiring spatial reasoning such as sports and hobbies have primarily illustrated the complexity of the distinction between opportunity to learn and performance. Scrutiny of the US curriculum, however, reveals little opportunity to learn spatial reasoning. Until recently, elementary mathematics in the United States was almost synonymous with arithmetic. This is followed by a sudden jump to Euclidean geometry in high school and later (often in college) to the geometry concerned in calculus. Curriculum designers consciously chose to reduce or eliminate emphasis on spatial reasoning to be fair to all. This intriguing policy illustrates the role of culture in decision making. It appears that exactly the opposite decision would have been more sensible. By equalizing opportunity to learn, gender differences might have been reduced. Limited instruction and experience with spatial reasoning in the curriculum may exacerbate gender differences.

In summary, in the area of spatial performance, the definition of the construct 'spatial reasoning' has varied substantially. Research shows that the definition of the construct determines the existence and magnitude of gender differences in performance. Moreover, for tasks involving mental rotation where the largest gender differences are found, opportunity to learn as well as instructions to respond rapidly are both important factors in reducing or even eliminating gender differences in performance. Although the connection of the ability to rotate a whole object mentally with performance in mathematics, science, or engineering remains unclear, mental rotation continues to be an object of study.

Verbal Performance

Measures of ability, starting with the Binet measure of intelligence, have generally relied on verbal skills. The Binet test includes vocabulary items as well as comprehension and interpretation items. Tasks such as verbal analogies, opposites, and sentence completion and paragraph comprehension characterize a broad range of items and predominate in widely used tests, including the SAT verbal measure, the Graduate Record Examination verbal measure, and a multitude of achievement tests administered in schools.

Cultural expectations typically include the view that women excel in 'verbal ability', variously defined. This perception is consistent with established findings that on average girls learn to speak and to read earlier than boys. In addition, serious problems with reading are more common among boys than girls; however, individual reports of these difficulties may be affected by cultural expectations. Maccoby and Jacklin reported that differences in verbal ability were well established in their 1974 summary of gender differences. Subsequent meta-analyses conducted by Janet Hyde and Marcia Linn suggest that these differences are very small and vary by the selectivity of the sample as well as the discipline represented in the item.

Differential opportunities to develop specific forms of verbal ability influence performance on verbal measures. Vocabulary items that require the interpretation of word meanings without supplying a context often require students to rely far more on broad verbal experience and test-taking expertise than do more contextualized items such as sentence completion or verbal comprehension tasks. Furthermore, performance on verbal comprehension tasks that strongly rely on information from a specific discipline often display patterns of gender differences compatible with participation in courses from these fields. Because more males than females participate in engineering and physical science courses, passages with physics or engineering content tend to favor males. Similarly, because more females participate in humanities and social sciences, passages from these domains tend to favor females.

Another important consideration in analyzing gender differences in verbal ability concerns the selectivity of the sample. In general, differences in performance between males and females are relatively small when the general population is used but are amplified when selective populations are studied. A very large group of college-bound students take the SAT but this is sample is selective. An interesting pattern of results has emerged over the years in SAT performance. Early measures of verbal ability for this test tended to favor females. However, in the late 1980s, this measure started to favor males. This change in gender differences coincided with an increased reliance on science

passages in the comprehension section. Hyde and Linn demonstrated that when the selective SAT sample was considered, gender differences favoring males were significant, but when a representative group of students were used, these differences disappeared. One might hypothesize that among the selective sample the advantage of specific knowledge about the topics might have a bigger effect on overall differences between males and females. This effect, while still operative, would be very small in a population of individuals when most lacked specific knowledge of the topics.

Recent research calls for viewing verbal ability, verbal performance, and verbal communication skill as nested in the discipline and context where it is used. Ability to write news articles, poetry, short stories, novels, technical manuals, scientific papers, or law briefs depends far more on opportunity to learn, diligence, and motivation than on gender. Viewed through this lens, gender differences play a minor role in verbal performance. By far, the larger differences occur in the age of first speech.

BIOLOGICAL BASIS FOR ABILITY

Belief in a biological basis for gender differences in intellectual performance has motivated numerous research programs. Many studies have examined differences in distributions of ability for males and females. The notion that males are more variable dates back at least to Charles Darwin, who made this generalization from observations and studies of physical characteristics. Scientists sometimes assumed that mental traits were inherited, and would therefore show distributions similar to those of physical traits. Edward Thorndike used this supposition to argue that because 'men differ in intelligence and energy by wider extremes than do women', women should be not educated for professions that required giftedness rather than average ability.

Leta Hollingworth noted that psychologists had variable meanings for 'variability', including: a wider range in distribution of a trait, or the same range with greater frequency in the extremes. Moreover, her large-scale study of neonate measurements did not support any interpretation of 'greater male variability'. Subsequent large-scale studies have reinforced Hollingworth's view that variability between the genders reflects cultural rather than biological factors, and the hypothesis of greater variability has lost currency as an explanation of why 'leadership in the world's affairs … will inevitably belong oftener to men'.

Researchers now use a variety of new, and rapidly advancing methods, for studying the brains of males and females. These include non-invasive measurement of neurotransmitter levels, synaptic strength, number of synapses, and receptor levels as well as postmortem studies comparing the size of various brain areas. Studies often reveal gender differences but no consistent pattern has emerged and new methods often yield findings that contradict prior work. Both small sample sizes and difficulty associating brain functioning with complex performance limit the generalizability of current research. Recent findings offer some insight into the diagnosis and treatment of problems related to brain functioning. For example, when reading performance is measured, men show a higher rate of dyslexia. However, Sally Shaywitz and her colleagues have found that the incidence of dyslexia in brain function appears to be equally distributed by gender. To explain this apparent contradiction, Shaywitz reports evidence that women and men process language in different parts of their brains when reading (men use the right inferior frontal gyrus, women use the left gyrus as well).

ACADEMIC ACHIEVEMENT

As the discussions of spatial and verbal abilities suggest, the distinction between educational attainments in mathematics, science, language and other domains, and spatial and verbal ability has blurred over the past decade. However, it is still a long way from the laboratory to the classroom. Experimental research suggests constraints and draws attention to certain capabilities but does not often yield direct instructional implications. Educational accomplishments depend on opportunity to learn; cultural expectations have a profound impact on who participates and who persists in a variety of fields. Initially, access to education varied by gender, and today gender patterns in enrollment and persistence in courses remain.

The most profound differences in gender, access, and participation are in mathematics and science, where men predominate. In the past 20 years, fields like computer science have gained prominence and importance both in the economy and in academia. After an initial surge, to approximately one-third of the student body, the proportion of women has declined, and today women receive about 12 percent of the computer science PhDs in the United States.

Participation in the natural sciences varies both by field and by nationality. For example, in the United States, equal numbers of women and men

enroll in calculus courses and select mathematics as a college major. By graduate school, according to counts in 1999, women earned over one-third of the mathematics PhDs granted to US citizens by US universities. Since the United States educates a large percentage of graduate students from other countries, when all nationalities are considered only 28 percent of those receiving mathematics PhDs from US universities were women. In contrast to the situation for computer science, both the number and proportion of women receiving PhDs in mathematics has increased. Proportions differ considerably in other fields: women currently earn about 20 percent of PhDs in physics but 40 percent of those granted in biology.

Opportunity to learn effects vary by institution of higher education as well. For example, Marcia Linn and Cathy Kessel found that proportions of bachelor's degrees granted to women from the 'top ten' mathematics departments ranged from 9 to 47 percent. This variability is consistent with research done by Elaine Seymour and Nancy Hewitt. Their analysis of a national sample of 800 000 undergraduates showed that about two-thirds of students who enter college intending to study mathematics or statistics switch to another field. Moreover, 72 percent of the females and 60 percent of the males switched to other fields, but half of the males and two-thirds of the females switched to a field outside of mathematics, science, and technology.

Seymour and Hewitt's more in-depth study of 335 undergraduates in science and engineering at seven institutions suggests an explanation for why men and women switched fields – and moreover, that explanations differed for men and women. Although these undergraduates were considered 'highly qualified' (their SAT-M scores were at least 650), the primary concern of both switchers and persisters was poor teaching: courses were fast-paced, instructors were often unclear, unavailable, and uninspiring, even lecturing by reading from the textbook. Women more than men, however, were repelled by poor instruction. This study suggests that context of instruction rather than 'lack of ability' is a better explanation for students' lack of persistence in science and engineering fields. Possibly reflecting their status as nontraditional students, other motivations for participation – lack of acceptance by male peers, hence lack of opportunity to learn from peers outside of class – contributed to switching.

Other evidence suggests that women may be more often affected by poor instruction, but that improvements advantage all. For example, Marcia Linn and Michael Clancy demonstrated that new computer science courses tend to favor males, contrary to the usual experience of higher female grades. When courses are iteratively refined and improved, they tend to be equally successful in improving the learning and understanding of males and females. In general, when instructors use information from past courses to redesign their instruction to be more responsive to their students, individuals who have been at risk for failure, and groups that have traditionally performed less well, gain more than individuals who are traditional course participants. This finding resonates with the comments of switchers in the Seymour and Hewitt study and that students tend to persist more in nontraditional fields with effective instruction. The pattern of success and persistence also coincides with accounts of success of women who attended all-female colleges in the past.

CONCLUSION

The history of views of gender differences in intellectual ability has responded to changes in research methods. As methods for identifying and assessing gender differences have developed, new interpretations have emerged. Both more powerful tests and new methods for representing results, such as path analysis and meta-analysis, have influenced thinking. Analysis of aspects often categorized as 'noise' in early studies has strengthened the view that opportunity and inclination to learn play a powerful role in measured differences.

The nature of research findings depends on the methods used. The majority of psychological investigations of gender differences tests whether score differences for males and females significantly differ from chance. As the sample size increases and the power of the test increases, the likelihood of concluding that there are statistically significant differences also increases. Measures that tap aspects of broad constructs, such as verbal ability, spatial ability, and school achievement, often yield contradictory results. Synthesis techniques such as meta-analysis make the often unrealistic assumption that the studies replicate each other. In contrast, neurobiological studies with small numbers of women and men offer hints of results to come but are limited by sample size and by complex relationships between indicators and the potential constructs they measure.

In conclusion, the investigation of differences between males and females over the past decade reflects advances in methodological, conceptual, and cultural views of the field. Advances in the understanding of complex behavior have

undermined the once prevalent deficit model and strengthened the belief in opportunity to learn. Changing cultural views of who can succeed in intellectual endeavors have enhanced opportunity and increased the choices available to all students. Most importantly, research on gender differences in intellectual attainment reinforces the importance of effective educational programs and establishes the value of research designed to enhance the learning of students with disparate prior experiences and opportunities.

Generalization

Introductory article

Peter J Urcuioli, Purdue University, West Lafayette, Indiana, USA

CONTENTS

Generalization is the finding that behavior explicitly conditioned to a stimulus also occurs without additional training to other, similar stimuli.

GENERALIZATION IN ANIMAL LEARNING

An adaptive psychological characteristic shared by humans and other animals is that behavior they explicitly learn to certain stimuli or in certain situations will also occur ('generalize') to other stimuli or situations resembling those involved in original learning. This produces considerable behavioral economy by forgoing the necessity of having to learn the same behavior to each and every member in a class of similar stimuli. Thus, learning to speak to certain individuals early in our lives (e.g., our parents) readily generalizes to other people. Likewise, an animal that learns that food is to be found among certain flowers or plants will later search with good effect in different areas containing similar flowers or plants.

Interest in stimulus generalization dates back to Pavlov's pioneering work on classical conditioning. He reported that dogs explicitly conditioned to salivate to a tactile stimulus applied to a certain area of their skin also salivated when that stimulus was applied to other skin areas. When generalization is studied in the context of operant conditioning as popularized by B. F. Skinner, animals are first trained to respond to obtain a reinforcer in the presence of some well-defined stimulus. For instance, a hungry pigeon might be taught to peck a key illuminated by certain wavelength in order to receive food. Afterwards, responding to other, similar stimuli is recorded – for example, pecking is measured to other wavelengths projected onto the key. The typical finding from such a generalization test is that the animal responds to these other ('test') stimuli, but that the frequency or probability with which it responds declines the more different a test stimulus is from the training stimulus. Plotting the frequency or probability of responding as a function of the test stimulus yields a generalization gradient. Typically, the gradient shows most responding occurring to the training stimulus and progressively less responding to stimuli whose characteristics are increasingly discrepant from those of the training stimulus.

Because operant behavior usually occurs in the presence of so-called discriminative stimuli, the generalization test provides a means to assess what features of those stimuli control that behavior. In short, generalization is a measure of stimulus control. Thus, when pigeons learn to peck a key of a certain color, we can determine whether color actually exerts stimulus control over pecking by varying the wavelength of light, and seeing whether or not the rate of pecking changes accordingly. Likewise, since the colored light also has a particular luminance, we can determine whether that characteristic controls pecking by holding wavelength constant and varying its intensity. This procedure of systematically varying some characteristic of a discriminative stimulus during the generalization test has certain advantages over other stimulus control assessments, such as simply removing the feature in question. For instance, if the test stimulus can't be seen (i.e. if its intensity is lowered to zero), observing a lack of responding tells us very little, if anything, about whether behavior is controlled by how bright the stimulus is when it can be seen. The generalization test thus provides relatively more discriminating and comprehensive information than other tests of stimulus control. Over the years, it has been used to demonstrate an impressive range of effective stimuli for animal behavior, from relatively simple stimuli such as color and tonal frequency, to extended stimuli such as the temporal duration of an event, and to relatively complex stimuli such as numerosity and 3-D visual orientation.

Methods for Obtaining and Plotting Generalization Gradients

There are two general methods for assessing generalization of responding around a stimulus signaling reinforcement (an S+). One method involves presenting a single test stimulus to each subject and testing different subjects with different stimuli. This between-subjects assessment obviously requires a large number of subjects in order to measure generalization along an entire stimulus continuum. Consequently, it has been less popular than an alternative, within-subject procedure developed in the 1950s. Here, each subject is exposed to all test stimuli during the generalization test. This procedure has the advantage of requiring fewer subjects to obtain the desired behavioral measures but the disadvantage of requiring a relatively long period of testing in order to obtain response measures to all stimuli in the test range.

With either method, the generalization test is usually conducted in extinction (that is, with responding not reinforced to any stimulus). Testing in extinction avoids possible contamination of the generalization measure that might occur if subjects were to learn (via reinforcement) to respond to every stimulus during the test itself. In addition, the procedure ensures a comparable assessment condition for *all* stimuli, including the formerly reinforced training stimulus. However, testing in extinction runs the risk that the animal will stop responding altogether, especially in a relatively long test, so the animal must be trained to persist despite prolonged periods of nonreinforcement. Persistence is conditioned during training by arranging intermittent reinforcement for responding. For instance, pigeons pecking a particular wavelength of light in training might receive food at variable times averaging only once or twice per minute. Such intermittent reinforcement is a standard feature of within-subject generalization studies. It establishes a steady rate of responding to the training stimulus and, more importantly, allows for a prolonged assessment of generalized responding.

An absolute generalization gradient plots the total number of responses made by a subject or a group of subjects to each test stimulus. The filled symbols in the left panel of Figure 1 show such a gradient as it would appear around a reinforced training (T) stimulus (an S+). Relative gradients, on the other hand, express responding to each test stimulus either as a proportion of responding to the training stimulus or as a proportion of total responding across all test stimuli. The latter measure is plotted in the right panel of Figure 1 using the data from the left panel. Relative gradients are desirable when there are large differences in overall responding across different training conditions or subjects that the researcher wishes to compare.

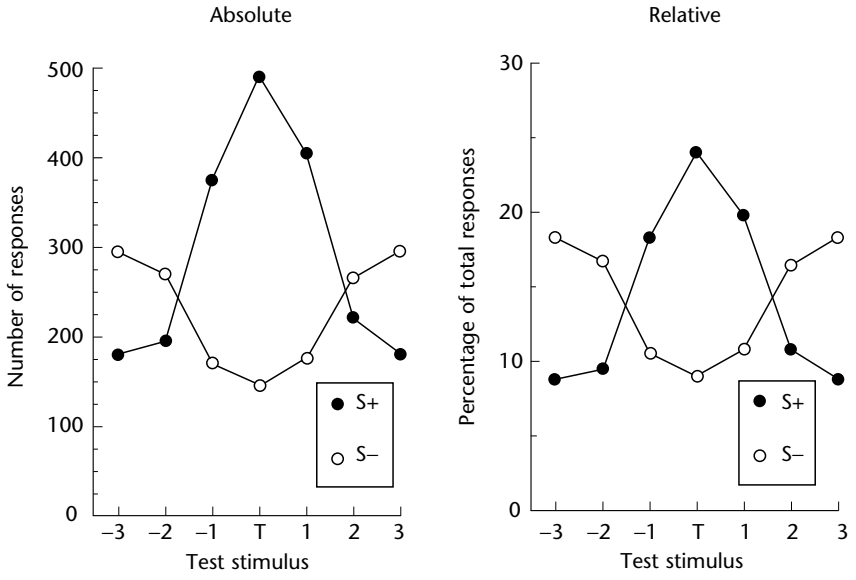

Figure 1. Absolute (left panel) and relative (right panel) generalization gradients around a training (T) stimulus that previously signaled reinforcement for responding (S+; filled symbols) or nonreinforcement for responding (S−; open symbols). Values for the test stimuli represent changes in equal increments above and below the training (T) value.

The Form of the Generalization Gradient

There is no single form to the generalization gradient. Its shape depends upon a variety of factors, such as the nature of training preceding the generalization test, how easy or difficult it is for subjects to distinguish each test stimulus from the training stimulus, whether or not the stimulus characteristics varied during the test do control the animal's behavior, and whether or not other stimuli are present during testing that also control responding.

Excitatory generalization gradients are those obtained by varying some aspect of a stimulus that has been established as a signal for reinforcement (an S+). These gradients generally appear as inverted U-shaped functions with the maximum level of responding at or near the S+, as illustrated by the filled-symbol gradients in Figure 1. Excitatory gradients are also called 'decremental gradients' because of the progressive decrease in responding to stimuli further and further removed from the S+.

Inhibitory generalization gradients are obtained by varying some aspect of a training stimulus that has been established as a signal for nonreinforcement (an S−). Assuming that responding has been concurrently established to an S+, the S− can be viewed as a stimulus that controls 'not responding'. After certain types of training procedures (described more fully later on), varying one of the characteristics of an S− during the generalization test yields a U-shaped gradient with a minimum at the S− value. In other words, an incremental gradient may appear, with the least amount of responding occurring to the stimulus signaling nonreinforcement in training and increasingly greater amounts of responding to test stimuli further and further removed from the S−. Absolute and relative inhibitory gradients are plotted by the open symbols in Figure 1.

Sometimes, the generalization gradient is flat: subjects respond with equal frequency or probability to all values along the test dimension. Flat gradients are difficult to interpret because they can arise for a variety of reasons. For instance, subjects may be perceptually insensitive to the stimulus feature varied during testing. Alternatively, the varied feature may not control behavior even though it is perceptually distinctive because the 'functional' stimulus, the feature that actually controls an animal's behavior, is not what the researcher varies during the generalization test. Finally, a flat gradient may occur despite variation in a functional stimulus because some other 'incidental' feature(s) common to all generalization test stimuli exerts greater control over responding than the varied feature.

An example of the latter situation occurs when pigeons are trained to peck a lighted key for food in the presence of an auditory S+ (e.g. a 1000-Hz tone). When generalization to different tone frequencies is subsequently measured, pigeons peck the lighted key at the same rate independently of the frequency of the tone accompanying it. This flat gradient does not mean that pigeons are deaf or that they cannot distinguish one frequency from another. Rather, the complete generalization of responding across different frequencies occurs because key pecking is controlled to a much greater degree by the lighted key, the stimulus to which pecking is directed. Since the key light accompanies every auditory stimulus presentation during training, it predicts the availability of food just as well as the tone. Moreover, it accompanies every auditory stimulus in the generalization test. Thus, the flat gradient simply reflects the fact that pecking is controlled more by the key light than by the tone.

Explaining Stimulus Generalization and Generalization Gradients

Pavlov believed that generalization from an explicitly trained stimulus to other, similar stimuli reflected a neurophysiological 'spread of effect'. He believed that the training stimulus established a cortical point or region of maximum neural activity and that this focal activity spread decrementally to adjacent cortical regions. Later, researchers using less physiologically oriented language suggested that generalized responding to a test stimulus reflected the degree to which the subject is unable to discriminate that stimulus from the training value. In other words, generalization was thought to be the inverse of discrimination: behavior generalizes from one stimulus to another to the extent that subjects do not distinguish between them. This proposition was not meant to suggest that subjects *could* not make such a differentiation if forced to do so. Rather, the argument was that they *did* not differentiate between certain stimuli in the generalization test.

Contemporary analyses of generalization have combined and refined these ideas into the notion that generalization reflects the number and the nature of the elements that the test stimuli share in common with the training stimulus. According to this view, the training stimulus is an amalgam of

many potentially conditionable elements. Thus, a pigeon that pecks a key of a particular color for food may be controlled in its behavior not only by the dominant wavelength of the S+ but also by its luminance, size, location, etc. Likewise, pecking a lighted key for food in the presence of a particular auditory frequency may establish control by both the tone and the key. During the generalization test, responding to each test stimulus is postulated to be a direct function of the number of conditioned elements it shares with the training stimulus. The greater the number of shared elements, the greater the amount of generalized responding. From this perspective, then, 'failure to discriminate' means that a test stimulus shares many conditioned elements, or a particularly potent element, with the training stimulus, thus generating considerable responding. Conversely, 'discriminating' means that a test stimulus shares few, if any, elements with the S+, thus yielding very little responding.

To illustrate this idea, consider that reinforced responding has been conditioned to an S+ consisting of elements [*a, b, c, d*], and that two generalization test stimuli consist of elements [*b, c, d, e*] and [*c, d, e, f*], respectively. Assuming that each element of the training stimulus gains control over responding, more responding should occur to the first test stimulus than to the second because the first has three elements in common with the training stimulus (viz. [*b, c, d*]) whereas the latter shares only two (viz. [*c, d*]). Similarly, if one element of the S+ is particularly potent – for example, [*a, b, c,* ***D***] – then any test stimulus containing '***D***', for example [*b, c,* ***D***, e] or [*c,* ***D***, *e, f*]), should generate considerable responding. Indeed, if every test stimulus contains a potent [***D***] element, then a flat generalization gradient would be a likely outcome.

DISCRIMINATION LEARNING AND STIMULUS CONTROL

In discrimination training, a stimulus in the presence of which responding is reinforced (an S+) is randomly alternated with another stimulus during which responding is either nonreinforced (an S−) or reinforced less often. In most studies of stimulus generalization, training involves at least an implicit discrimination. For example, pigeons trained to peck a lighted key for food usually encounter brief periods of time during which the key is dark. During these blank intervals separating successive presentations of the key light, food is unavailable (i.e. responding is nonreinforced).

Whether training involves implicit discrimination contingencies such as the periodic absence of S+ or, more commonly, explicit contingencies in which a different stimulus serves as an S−, the effect is a sharpening of the generalization gradient. In other words, the 'fall off' in responding accompanying a change in some feature of S+ is larger than it would be without discrimination training. This means that the animal responds even less to a given test stimulus than it would otherwise. Thus, the peak of an excitatory gradient is more 'pointed' and its slope is steeper after discrimination training than after training with just the S+.

Discrimination training sharpens the generalization gradient because it ensures that the relevant stimulus feature(s) of S+ and S− will exert greater control over responding than irrelevant or incidental features. The strengthening of stimulus control by the relevant features occurs because the discrimination contingencies establish them as better predictors of reinforcement and nonreinforcement than other elements common to both stimuli.

To illustrate the impact of this on the generalization gradient, consider an S+ consisting of elements [*a, b, c, d*] and an S− consisting of elements [*a, d*]. During discrimination training, responding in the presence of the [*a, d*] elements will sometimes yield reinforcement (when S+ is present) and sometimes will not (when S− is present). In other words, these two elements are relatively poor predictors of reinforcement. By contrast, elements [*b, c*] are perfectly correlated with reinforcement and nonreinforcement: when they are present, reinforcement is available; when they are absent, reinforcement is unavailable. Consequently, responding will be more strongly conditioned to the predictive [*b, c*] elements than to the less predictive [*a, d*] elements. A number of studies have shown that stimulus control by less predictive stimuli is relatively weak compared to that of more predictive stimuli. In addition, the control exerted by poorly predictive elements such as [*a, d*] following discrimination training is demonstrably weaker than the control they would exert if they were just as predictive of reinforcement as anything else, as would occur after training with only the S+.

Consider now a single generalization test stimulus consisting of elements [*c, d, e, f*]. In the absence of discrimination training (that is, after training with S+ alone), responding to this test stimulus will occur by virtue of the conditioning accruing to both the [*c*] and [*d*] elements. By contrast, after discrimination training of the sort described above, control by the [*d*] element should be weakened or 'neutralized' leaving only the [*c*] element to control responding. Consequently, less responding will

occur to this test stimulus after discrimination training than after training with only the S+; stated otherwise, the gradient between these two values will be steeper.

Interdimensional Discrimination Training

Interdimensional discrimination training involves reinforcing responding in the presence of a particular stimulus feature but nonreinforcing it when the feature is absent (or vice versa). Such training yields generalization gradients that are much steeper than those obtained when subjects are trained only with the stimulus containing the feature of interest. For example, although pigeons produce flat frequency-generalization gradients when their training consists solely of food-reinforced pecking in the presence of a particular tone, they provide decremental gradients when their training consists of reinforced presentations of the tone (S+) randomly alternated with nonreinforced presentations of the key light without the tone (S−).

With interdimensional discrimination training between tone present (S+) and tone absent (S−), the lighted key alone signals reinforcement only 50 percent of the time. By contrast, the presence versus absence of the tone is perfectly correlated with reinforcement versus nonreinforcement. Not surprisingly, then, responding is predominantly controlled by the auditory stimulus, and this will be evident in the finding that varying one of its attributes (frequency) produces an orderly decrement in responding that would not otherwise occur. Thus, the appearance of a decremental gradient following such training arises in part because the incidental feature common to all of the test stimuli (i.e. the lighted key) has been 'neutralized'.

Interdimensional discrimination training is also used to obtain inhibitory (incremental) gradients. Here, the feature varied during the generalization test is initially established as a signal for *non*reinforcement (an S−); a stimulus minus that feature is concurrently established as a signal for reinforcement (an S+). Because subjects learn to respond only when the feature is absent, the feature-present stimulus (the S−) can be viewed as a stimulus controlling not-responding (or, more precisely, some behavior other than that conditioned to the S+). If 'not-responding' generalizes to stimuli similar to S−, then progressively less 'not-responding' should occur to test stimuli increasingly different from the S−. Generalization of not-responding often translates into a progressive increase in the responses separately conditioned to S+. The result is a U-shaped gradient with a minimum at S−, shown by the open-symbol gradients in Figure 1. The slopes of incremental gradients are often not as steep as those of decremental gradients because not all of the generalized 'not-responding' ends up as the measured responses conditioned to the S+. Some of the generalization ends up in other behavior not recorded by the researcher.

Inhibitory generalization gradients can also be obtained by intermittently reinforcing responding to every stimulus in the generalization test (as opposed to testing in extinction). This resistance-to-reinforcement test is useful because it counteracts any tendency of subjects not to respond to the S− and to any test stimulus containing its negative feature(s). In addition, it raises the overall level of responding during the generalization test, thus avoiding the possibility of flat gradient that could easily arise if subjects rarely respond to any stimulus along the 'negative' test dimension. The incremental or U-shaped gradient obtained in a resistance-to-reinforcement test arises because the S− stimulus is the most 'negative' and, thus, the most resistant to the response-enhancing effects of reinforcement. Test stimuli further removed from S− are progressively less 'negative', and so are progressively less resistant to the effects of reinforcement.

Intradimensional Discrimination Training

Intradimensional discrimination training involves two stimuli both of which lie on the generalization test dimension – for example, two different colors, two different auditory frequencies, or two different line orientations. Both stimuli, in other words, contain the feature varied during the generalization test. During training, responding is typically reinforced in the presence of one stimulus (the S+) and nonreinforced in the presence of the other (the S−). As the preceding discussion suggests, generalization gradients around the S+ from an intradimensional discrimination are sharper than those around the same stimulus trained in isolation (i.e. when subjects learn to respond only to an S+). Sharpening of the gradient under these conditions is hardly surprising considering that subjects have explicitly learned *not* to respond to one value along the test dimension (the S−). Moreover, intradimensional discrimination training should reduce stimulus control by any incidental features common to the S+ and S−. Nonetheless, the post-discrimination gradient (PDG) obtained following

such training frequently exhibits a unique characteristic not anticipated by an analysis of stimulus generalization in terms of common elements or incidental features – a peak shift.

THE PEAK SHIFT

A generalization test following intradimensional discrimination training often reveals a shift in the peak level of responding from S+ to a value further removed from S−. Figure 2 shows an example of a peak-shifted PDG and, for comparison purposes, a gradient obtained after training only with the S+. The peak shift has been observed in many different species: pigeons, rats, horses, goldfish, and humans.

The peak shift was discovered in the course of testing a theoretical account of the phenomenon of transposition. Transposition refers to the finding that after reinforcing responding to, say, the larger of two discriminative stimuli, subjects given a choice between the S+ and an even larger stimulus frequently choose the latter. One theoretical account claims that transposition reflects the algebraic summation of two opposing response tendencies: an excitatory (response-producing) tendency to S+ and an inhibitory tendency to S−. Given that each tendency will generalize to other similar stimuli, yielding an excitatory gradient around S+ and an inhibitory gradient around S−, response strength to any stimulus simply equals the net excitatory and inhibitory tendencies, respectively, at that point. By this account, there is more inhibitory strength at S+ than at stimulus values beyond it because S+ is closer to the S− than more remote values, so more inhibition will generalize to it. This yields a lower net response strength at S+ than at immediately adjacent but more extreme values and, hence, transposition. In addition, it should yield a peak shift – greater responding to values further removed from the S− than the S+ itself in a generalization test.

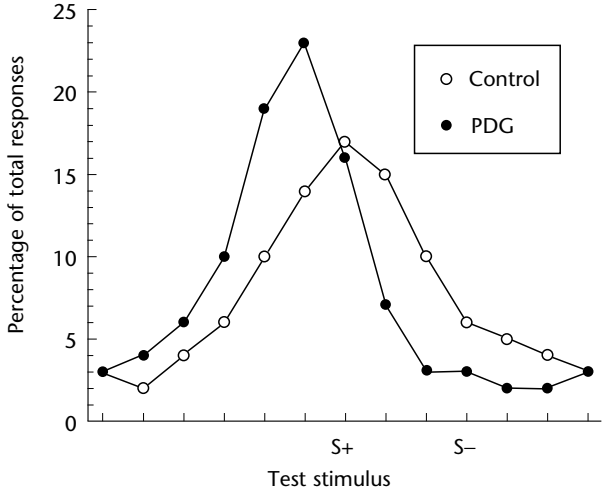

Figure 2. Relative generalization gradients following training with just a reinforced stimulus (Control) and following intradimensional discrimination training between a reinforced (S+) and a nonreinforced (S−) stimulus (PDG). The postdiscrimination gradient (PDG) exhibits a peak shift.

This gradient-interaction account of the peak shift predicts, and empirical findings have confirmed, that the size of the shift, or the likelihood of obtaining it, is inversely proportional to the S+/S− separation during training. In other words, the closer the two discriminative stimuli are, the larger the shift or the greater the likelihood of obtaining it. Unfortunately, a full evaluation of this account is difficult when predictions are derived from *hypothetical* excitatory and inhibitory gradients because the predicted PDG crucially depends on the form and steepness of each gradient. For instance, no peak shift is anticipated if the hypothesized inhibitory gradient is especially steep or especially flat. To avoid this difficulty, researchers have sometimes used actual excitatory and inhibitory gradients obtained after interdimensional discrimination training (see Figure 1) to predict the PDG following intradimensional discrimination training. The predicted PDGs sometimes resemble the empirically obtained PDGs, but sometimes do not.

Despite these theoretical difficulties, the increased potency of stimuli beyond the S+ is a well-established, reproducible finding. Researchers have also shown that the PDG will show a peak shift even when the 'negative' stimulus is not an S−. Specifically, a peak-shifted gradient also occurs when the stimulus alternating with the S+ is one that signals a lowered rate of reinforcement than that experienced during the S+. Apparently, such a stimulus is relatively 'negative' or aversive in comparison to the S+, and so controls a response tendency opposite to that controlled by the S+. Indeed, after interdimensional training, varying a reinforced stimulus that also signals a drop in the rate of reinforcement yields an inhibitory or incremental gradient.

CONCLUSION

Generalization tests are used to assess stimulus control, the degree to which particular stimulus features control responding. Gradients around a previously reinforced stimulus are typically

decremental, with the greatest amount or highest probability of responding at the former S+ and increasingly less responding to values further and further removed from it. Gradients around a previously nonreinforced stimulus (S−) are often incremental if responding is separately reinforced to another stimulus that does not contain the S− feature. Such interdimensional discrimination training also sharpens the generalization gradient around the feature when it serves as an S+. The sharpening occurs because discrimination training increases the relative control exerted by the predictive or relevant aspects of the training stimuli and reduces control by the irrelevant or incidental aspects. Intradimensional training involves discrimination between two stimulus values on a continuum and can often cause other stimuli to have a greater effect on generalized responding than the reinforced stimulus (S+) itself. This effect, called the peak shift, has been traditionally interpreted in terms of the combination of two opposing tendencies: a generalized tendency to respond to S+ and a generalized tendency not to respond to S− or to a stimulus with a lower reinforcing value than S+.

Gesture

Intermediate article

Susan Goldin-Meadow, University of Chicago, Chicago, Illinois, USA

CONTENTS

The hand movements that people of all ages and all cultures produce while talking are called gestures. These gestures can reflect thoughts that are not expressed in the speech they accompany and, as a result, can play a role in problem-solving and language acquisition.

INTRODUCTION

Gesture is frequently equated with nonverbal communication and it is indeed nonverbal – performed with the hands, arms, head, legs, and body but not with the apparatus specialized for speech. However, the study of nonverbal communication is concerned with how the behavior of others is regulated and how inner states are expressed (Mueller, 1998) and takes as its focus all parts of the body. In contrast, the current study of gesture focuses on how thought is represented and focuses primarily on the hands.

Gesture is comprised of a continuum of communicative actions which differ on a number of dimensions (Kendon, 1980) – whether they must accompany speech; whether their form is governed by convention; whether they are characterized by linguistic properties (e.g. are segmented and analytic). At one end of the continuum, sign languages invented by deaf communities are produced without speech, are conventionalized, and have the same repertoire of linguistic properties as spoken languages. At the other end, the spontaneous hand movements that are generated when people talk are always produced with speech, are idiosyncratic without recognized standards of form, and are characterized by global and synthetic rather than analytic and segmented forms of representation. In the middle, occupying less extreme positions on each of the dimensions, are gestures such as emblems (e.g. thumbs-up for OK) and pantomime (pretending to play a violin).

Because they are not bounded by convention, the spontaneous hand movements that accompany speech can offer a unique window into thought. As a result, they are the focus here.

THE RELATION BETWEEN GESTURE AND SPEECH

When people move their hands as they talk – they gesture. Gesture is a widespread phenomenon, occurring across cultures, ages, and tasks. Even individuals who are blind from birth gesture as they speak, despite the fact that they have never seen gesture (Iverson and Goldin-Meadow, 1998). Gesture thus appears to be an integral part of the speaking process.

Gesture and speech are tightly intertwined in time and meaning (McNeill and Duncan, 2000). For example, a speaker raises her hand just as she says, 'and he climbs up the pipe', with the upward gesture overlapping in time with the phrase 'up the pipe'. Typically, gesture slightly precedes its co-expressive speech, and it does so systematically – the more unfamiliar the word, the longer the interval between the onset of gesture and the onset of speech, and the longer the duration of the gesture itself (Morrel-Samuels and Krauss, 1992). Moreover, the processing unit that gesture and speech form resists division. Artificially delaying the feedback speakers receive from their own voices grossly disrupts the timing of speech, but gesture–speech synchrony remains intact (McNeill, 1992). Clinical stuttering also disrupts speech but has no effect on gesture–speech synchrony (Mayberry *et al*., 1998).

Producing gesture and speech together brings the imagery conveyed in gesture into the system of categories provided by the spoken language; perhaps not surprisingly, gesture is influenced by those categories. For example, English-speakers typically mention the manner by which a motion is carried out in the verb itself (e.g. *flies* out), while Spanish-speakers mention manner, if at all, in a separate construction, often a gerund (sale *volando* = exits *flying*). The way in which English- and

Spanish-speakers produce gestures for manner differs accordingly (McNeill and Duncan, 2000). English-speakers produce manner gestures in synchrony with their verbs; they use their manner gestures when they want to draw attention to manner (e.g. a flapping gesture to indicate how the flying was done), but use path gestures when they are forced by convention to mention manner in their verbs but do not want to focus on it (e.g. a forward-moving gesture to focus attention on the path of the flight rather than the flapping). In contrast, Spanish-speakers often omit manner from their speech but produce it in gesture nonetheless; their manner gestures do not synchronize with a single grammatical category but extend through multiple clauses. Thus, although gesture has a systematic relation to speech in all languages, the nature of that relation varies as a function of the particular language.

THE ROLE OF GESTURE IN PROBLEM-SOLVING

When produced within a single utterance, gesture and speech express the same underlying idea unit. However, the two modalities often highlight different aspects of that idea. For example, a speaker says 'I climbed the stairs' while spiraling his index finger upward. The speaker's gestures provide the *only* clue that the staircase is a spiral. By looking at gesture and speech as a unit, we gain access to thoughts that speakers have but do not express in their speech.

When in a problem-solving situation, a speaker's gestures often express thoughts that pertain to the same topic as speech but are not always easy to integrate with the aspects of that topic highlighted in speech. For example, consider a child explaining her judgment that the amount of water in a tall, thin glass changed when it was poured into a short, wide dish. The child says, 'they're different because that one's wider than that one', while at the same time indicating with her hands the height of the dish and then the glass. The child focused on the containers' widths in speech but their heights in gesture. Such *gesture–speech mismatches* (Church and Goldin-Meadow, 1986) are found in a variety of tasks and over a large age range: toddlers going through a vocabulary spurt; preschoolers explaining a game; elementary school children explaining mathematical equations and seasonal change; children and adults discussing moral dilemmas; adolescents explaining mechanical tasks; and adults explaining how gears work and problems involving constant change.

The gestures that speakers produce when describing a problem reflect their representations of that problem. Importantly, those representations play a role in predicting how speakers will then go about solving the problem (Alibali *et al*., 1999). For example, speakers often incorporate information about manner of change into their gestures when asked to describe algebra word problems involving continuous change (e.g. change in the amount of air pressed per minute into a hot air balloon over a 30-minute period) or discrete change (e.g. change in the number of books on each shelf of a six-shelf bookcase). The representation reflected in gesture is not always the same as the representation reflected in speech – a speaker may talk about the problem as one of continuous change while producing discrete, steplike gestures. When gesture reinforces the representation displayed in speech (e.g. both reflect a continuous representation), adults are very likely to solve the problem using a strategy compatible with that representation (a continuous strategy); this is much more likely than when gesture does *not* reinforce the representation reflected in speech (i.e. when gesture reflects a discrete representation, but speech reflects a continuous representation). Thus, gesture and speech together provide a better index of mental representation than speech alone.

Taken together, gesture and speech also provide an excellent index of a speaker's readiness to learn. Children who produce many gesture–speech mismatches when explaining their incorrect answers to math problems, or to reasoning problems about quantity, are particularly likely to benefit from instruction on those problems – much more so than children who produce few gesture–speech mismatches in their explanations of the same problems (Church and Goldin-Meadow, 1986; Perry *et al*., 1988). Gesture considered in relation to speech thus reflects mental processes. Does gesture also affect those processes? There are two different, though not mutually exclusive, ways in which gesture can bring about cognitive change (Goldin-Meadow, 2000).

The first is an outgrowth of the fact that gesture is 'out there', occurring routinely in naturalistic talk and reflecting aspects of a speaker's cognitive state. If communication partners are able to read the signals contained in a speaker's gestures, they may alter their interactions with that speaker as a function of the information they glean from gesture. Gesture, by influencing the input speakers receive from others, would then be part of the process of change itself. In fact, adults, and even children, are able to interpret the spontaneous gestures that

speakers produce in problem-solving situations (Goldin-Meadow and Sandhofer, 1999). Whether communication partners then act on the information they glean from a speaker's gestures, however, remains an open question.

The second asks whether gesture has effects on speakers themselves and thus brings about cognitive change more directly. Gesture externalizes ideas differently and draws on different resources than speech uses. Using gesture along with speech may therefore divide the cognitive burden across several systems. For example, if speakers are asked to remember a list of words while explaining how they solved a mathematics problem, they remember significantly more words when they gesture during their explanations than when they do not (Goldin-Meadow *et al*., 2001). The components of the verbal explanation that can be encoded in gesture are presumably shifted out of a verbal store and into a visuospatial store. Gesturing during the mathematics explanations thus reduces the load on verbal working memory, freeing capacity to be used on another verbal task (the word–memory task). In this sense, gesturing not only reflects a speaker's cognitive state but may assist in the allocation of mental resources and, in this way, plays a role in shaping that state.

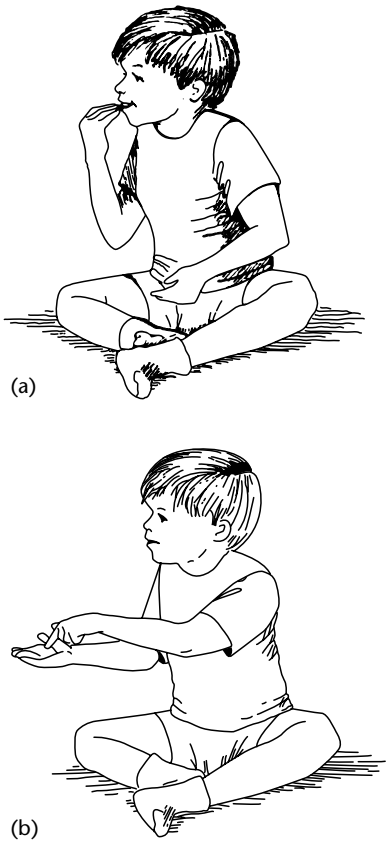

Figure 1. Self-made signs in a deaf boy never exposed to sign language. A two-sign sequence: (a) the first sign means 'eat' or 'food' (in this case, given immediately before the boy had pointed to a grape); (b) the second sign means 'give'. The total sequence presumably means 'give me the food'. From Goldin-Meadow (1981); drawing courtesy Noel Yovovich.

THE ROLE OF GESTURE IN LANGUAGE ACQUISITION

Gesture is very often a young child's first way of communicating with others. At a time when children are limited in what they can say, gesture can extend the range of ideas they are able to express. The earliest gestures children use, typically beginning around 10 months, are deictics, gestures whose referential meaning is given entirely by the context and not by their form: e.g. holding up an object to draw an adult's attention to that object or, later in development, pointing at the object (Bates *et al*., 1979). In addition to deictic gestures, children also use iconics. Unlike deictics, the form of an iconic gesture captures aspects of its intended referent and thus its meaning is less dependent on context, e.g. opening and closing the mouth to represent a fish. These iconic gestures are rare in some children, frequent in others. If parents encourage their children to use iconic gestures, these gestures become more frequent, facilitating, at least temporarily, the child's production of words (Goodwyn *et al*., 2000). The remaining types of gestures that adults produce – metaphorics (gestures whose pictorial content presents an abstract idea rather than a concrete object or event) and beats (small baton-like movements that move along with the rhythmical pulsation of speech) – are not produced routinely until relatively late in development.

Combining gesture and speech within a single utterance can also increase the communicative range available to the child. Most of the young child's gesture–speech combinations contain gestures that convey information redundant with the information conveyed in speech, e.g. pointing at a cookie plus 'cookie'. However, young children also produce combinations in which gesture conveys information that is different from the information conveyed in speech, e.g. pointing at a cookie plus 'mine'. This second type of combination allows a child to express two elements of a sentence (one in gesture and one in speech) at a time when the child may not be able to express those elements within a single spoken utterance. Interestingly, the onset of

this type of gesture–speech combination reliably predicts the onset of two-word speech. Children who produce combinations such as pointing at cookie plus 'mine' early in development are the first to produce combinations such as 'cookie mine' (Butcher and Goldin-Meadow, 2000). Note that it is the relation between gesture and speech that predicts change in the child's language, providing further evidence that gesture and speech form an integrated system.

All children who are learning a spoken language use gesture. But some children – deaf children with profound hearing losses, for example – are unable to learn the spoken language that surrounds them. If exposed to a conventional sign language, these deaf children would acquire that language. If, however, they are not exposed to sign, deaf children rely on gesture (Figure 1). Interestingly, their gestures do not have the global and synthetic form of their hearing parents' gestures but take on characteristics of systems at the other end of the continuum – self-created standards of form and the analytic and segmented properties of a linguistic system (Goldin-Meadow and Mylander, 1998); these systems are called 'home sign'. Thus, gesture is an adaptable modality, able to form with speech a single communication system or, as the need arises, assume on its own the properties of a linguistic system.

Group Behavior

Introductory article

Bibb Latané, Latané Center for Human Science, Highland Beach, Florida, USA

CONTENTS

By influencing one another in proportion to their strength, immediacy, and number, individuals create spatially clustered groups of people similar in their beliefs, values, and behavior.

The behavior of individuals interacting in social networks leads to the emergence of groups of like-minded individuals, and the interaction of these groups, in turn, leads to the temporal evolution and regional differentiation of the patterns of beliefs, values, and habits that characterize human culture. This broad generalization, based on the detailed modeling of such interactions, can provide a basis for understanding the reality of social life. The underlying models of the dynamics of social interaction may also help us organize ideas about the role of social groups and networks in shaping the contents of individual cognition.

SOCIAL INFLUENCE AND GROUP BEHAVIOR

We live in a physical and cognitive world constructed and modified by people following natural law operating through biological evolution. Assisted by large and small ideas and by harnessing animal and other sources of energy, humans working alone and together have transformed the surface of our planet. For better or worse, the world we have made is far different from that experienced by our earliest ancestors. Little of this could have happened without the human capacity and propensity for social influence.

Social influence is a pervasive component of human experience, permeating every aspect of our lives. Individuals affect one another in many different ways. We may be aroused by the presence of other people, frightened by their attention, touched by their plight, guided by their example, persuaded by their arguments, coerced by their power. Such forms of social influence can operate singly or simultaneously (the failure of bystanders in groups to intervene in an emergency, for example, can result from performance apprehension, social influence from seeing others not respond, and/or diffusion of responsibility). We learn by example and by instruction from our parents, from our peers, and from many generations of predecessors.

These types of individual influence come about from different mechanisms and can have different consequences. Sometimes the effect of the presence or actions of others is to reduce pressures on an individual to work hard in a group or to intervene in an emergency; sometimes the effect is to increase pressures to act or to change attitudes. Yet, each type of influence seems to follow certain general laws – the laws of social impact. Because individuals differ in their power, intelligence, and expressiveness, a major factor governing social influence is the strength of an influence source – just as a brighter bulb casts more light, some people are more influential than others. Because most influence takes place through direct contact, immediacy facilitates impact: strangers have less influence than neighbors. Because influence can be a gradual, cumulative process, it grows in proportion to the number of people who are the source of influence: a larger group can be more influential than a single individual. Research has shown that these effects tend to be multiplicative, so that the amount of impact or pressure to change experienced by an individual will tend to be proportional to the strength, immediacy, and number of people who are the source of pressures to change relative to the strength, immediacy, and number of people who provide support.

DYNAMIC SOCIAL IMPACT – THE EMERGENCE OF GROUPS FROM INTERACTING INDIVIDUALS

These laws may be useful in predicting and explaining the reactions of individual humans to their social environments, but they also raise a fascinating question: what should we expect from a network of people each responding to and being influenced by the others? For example, if persons *n* and *o* both affect *p*, the resulting changes in *p* will in turn affect the social pressures experienced by *n* and *o*.

In fact, analytic theory, computer simulation, and experimentation identify four group phenomena that should result from the interaction of individuals influencing one another:

1. Because members of minorities are exposed to more adverse influence than people in the majority, they are more likely to be converted, resulting in a *consolidation* of positions on any group topic.
2. Because people are more influenced by their neighbors than by more distant people, they are likely to become more similar to them, resulting in a *clustering* of positions on any given topic.
3. Because neighbors can influence one another on several different topics, a *correlation* of positions will emerge over time.
4. Because clustering produces neighborhoods of like-minded people, minority neighbors will shield one another from influence by the global majority, resulting in a *continuing diversity* of beliefs.

CONTAGIOUS THOUGHTS – AN EXAMPLE OF DYNAMIC SOCIAL IMPACT

To understand these phenomena, consider the results of some recent experiments in which 456 participants were organized into 24-person networks, each consisting of six four-person subgroups or 'families'. During five computer sessions spread over a three-week period, participants exchanged electronic messages with the other three members of their family as well as with one member of a neighboring family. People were randomly assigned to positions in the communication network and had no prior or concurrent contact with one another aside from the electronic message exchange. Message exchange was asynchronous, as when people correspond by e-mail. Messages sent one session were read the next.

Norm Detection

Participants were asked to guess the majority preference in their 24-person group on a series of bipolar choices such as 'Which will be the preferred colour, red or green?' or '…the preferred artist, Klee or Kandinski?' At the first session, each person guessed the positions thought to be held by the majority of the full group on each of six issues. At each succeeding session, these guesses were read and reacted to by the three other family members as well as by the outside contact. In order to motivate them, each person earned $1 each time their final answer corresponded to that of the majority of the 24 participants. Obviously, the best strategy for predicting the group norm would be to combine one's own best guess with the information from others, and indeed individuals seemed to do this, changing their own answers 75 percent of the time when three to four people disagreed with them, but only 5 percent when fewer did so. Under these conditions, beliefs about norms can be considered 'contagious' with people 'catching' whichever view is most common in their neighborhood. The four C's of social impact are exemplified in the emergent pattern of beliefs in the group.

Consolidation is shown by the fact that the number of people in the minority was reduced for each of the six issues by an average of 20 percent per item. For example, before discussion, 11 people thought Elgar would be more popular than Handel, while 8 thought so afterwards.

Clustering is represented by the fact that there is less disagreement within subgroups after message exchange than before. In this case, the chance of two people within the same family disagreeing about the group norm was only 6 percent, compared to the 50 percent to be expected by chance and found before discussion and for any two people not in the same group after discussion. The remarkable degree of within-group similarity is not a result of self-segregation, because people could not move from one group to another; in other situations in which they can move then clustering would be expected to be even greater.

Correlation is shown by the increased number of significant correlations across the 24 people between all possible pairs of issues: from 5 percent before message exchange to 35 percent after. Initially unrelated beliefs became related through a reduction in independence from social influence, not because of any inherent association. In real-world groups, such correlation can be expected to provide a basis for a perceived group ideology.

Continuing diversity is maintained because further messages should lead to little further change in individual norm estimates, since every person is now in a local majority. Even if the task were to continue indefinitely, there is no reason to expect further convergence.

EVOLUTION, DISSEMINATION, AND PRESERVATION OF IDEAS

These four phenomena are not restricted to beliefs about norms, or to situations where people are bribed to agree. Further research has shown that the same 'four C's' emerge when people are discussing political and social issues, giving reasons for their beliefs. In fact, across a wide range of tasks, 'the four C's' of social impact emerge in proportion to the degree to which people are influenced by one another.

Participants in this experiment had no knowledge of who was exchanging messages with whom, and thus could not see the 'family' resemblances that came about through communication. If we imagine that people did have a chance to see the similarities within their own neighborhood and how their group differed from others, we could expect them to form social identities, to make invidious comparisons, to develop group solidarity, and to engage in in-group favoritism. By such processes, groups can create an identity for themselves, and this identity can remain distinct over long periods of time and change. The 'four C's' of group dynamics can be understood as the nonlinear dynamics of spatially distributed individuals influencing each other in proportion to their strength, immediacy, and number. Like other self-organizing systems, groups of all sizes respond in complex, nonintuitive ways to external and structural change but often produce emergent factions or subcultures with an apparent life of their own. Such entities can even become institutionalized as they recruit and indoctrinate new members and codify their beliefs.

These subcultures can be seen as temporally evolving, regionally clustered, partially correlated sets of socially influenced beliefs, values, and behaviors held by individuals in a spatial network. They can be seen as social representations as characterized by the French social psychologist Serge Moscovici – shared beliefs that evolve from and form the basis for ordinary conversation. As evidence that such processes may have helped shape human history, consider the changing maps of language and dialect, of religious belief and political ideology, and how, on a global scale, they mirror the local neighborhoods described in the experiment above.

This article provides a basis for understanding how social interaction, even in the absence of social mobility, can lead populations to divide into groups of people who share distinctive patterns of beliefs and norms. Focusing on intra-group processes, the 'four C's' provide a foundation for understanding inter-group processes that are beyond the scope of the present article – social identity and inter-group conflict. Although they result from the interactions of individuals, these phenomena characterize groups as a whole, and can only be detected by knowing how individuals are located in a social group or network. They show that group norms can be created from the bottom up as well as imposed from above.

Human Altruism

Advanced article

CONTENTS

Altruism is a motivational state with the ultimate goal of increasing another's welfare. It is contrasted with egoism, which is a motivational state with the ultimate goal of increasing one's own welfare.

INTRODUCTION

Altruism refers to the motivation of one organism, usually human, for benefiting another. Although some biologists and psychologists speak of altruistic behavior, meaning behavior that benefits another, this use of the term altruism is not recommended. It fails to consider motivation for the behavior, and motivation is of primary concern in discussions of altruism. If the ultimate goal in benefiting another is to increase the other's welfare, then the motivation is altruistic. If the ultimate goal is to increase the organism's own welfare, then the motivation is egoistic. Motivation for benefiting another might be altruistic, egoistic, both, or neither.

THE BASIC QUESTION: IS ALTRUISM PART OF HUMAN NATURE?

The question of whether humans have the capacity to be altruistically motivated has been debated for centuries. The majority view among Renaissance and post-Renaissance philosophers, and more recently among biologists, psychologists, and social scientists, is that we humans are, at heart, purely egoistic, that we care for others only to the extent that their welfare affects ours (Mansbridge, 1990). A persistent minority has, however, insisted that altruism exists, that in some circumstances and to some degree, we can act to benefit others for their sakes, and not simply for our own.

In recent years, questions about the existence of altruism have been addressed at two distinct levels, at the level of evolutionary biology and at the level of human psychology. The questions addressed at these two levels differ because what is meant by altruism differs. Evolutionary altruism refers to behavior by one organism that diminishes its reproductive fitness relative to the reproductive fitness of one or more other organisms. Psychological altruism refers to a motivational state with the ultimate goal of increasing another's welfare. Evolutionary altruism is neither necessary nor sufficient to produce psychological altruism. The question of whether altruism is part of human nature concerns psychological altruism, not evolutionary altruism. Yet it is evolutionary altruism that has received the most attention in recent years.

EVOLUTIONARY ALTRUISM

Any behavior that diminishes the probability of an organism producing offspring may, at first glance, seem to decrease the likelihood of the genes carried by that organism appearing in the next generation. If such behavior is associated with a particular genetic alternative, or allele, then over successive generations this allele should decrease in the population and so should the behavior. This logic suggests that a genetically based inclination toward evolutionary altruism is contrary to the theory of natural selection, leading many biologists to conclude that evolutionary altruism cannot exist. Yet people do at times help in ways that reduce their reproductive potential.

In the 1960s and 1970s some evolutionary biologists (often called sociobiologists because of their interest in the genetic basis of social behavior) sought to explain how helping that diminishes the reproductive fitness of the helper, and thus seems to violate the theory of natural selection, really does not. Edward Wilson (1975), Richard Dawkins

(1976), and others pointed out that although biological reproduction occurs at the level of the individual organism, the unit of natural selection is not the individual but the gene. Under certain circumstances genes can enhance their own survival by leading the individual carrying them to risk personal survival to benefit another.

One such circumstance is *kin selection*. Kin selection occurs when the benefactor and the benefited share the same genes, and as a result of the benefactor's help, the benefited has a greater chance of passing these genes to the next generation. In such cases, it may be to the advantage of the shared genes for the benefactor to promote survival of the benefited even at expense to survival of self. Specifically, it will be advantageous when the degree of genetic overlap (relatedness) multiplied by the increased probability of the other placing his or her genes in the next generation outweighs the decreased probability of the benefactor placing his or her genes in the next generation. William Hamilton (1964) used this logic of *inclusive fitness* to explain the self-sacrificial behavior of sterile worker castes among social insects, including bees and wasps. This logic may also explain help given to siblings and other close kin.

A second circumstance is *reciprocal benefit*. Robert Trivers (1971) suggested that acts benefiting nonkin can be genetically based and consistent with the theory of natural selection if they are cases of what he called 'reciprocal altruism'. (We prefer the term 'reciprocal benefit' because, as noted, altruism refers to motivation not simply behavior, and behavior is all Trivers meant.) Helping another survive can be in the best interest of the benefactor's genes if the other is likely to return the benefit, either to the benefactor or to another organism carrying the same genes as the benefactor. As Trivers (1971) explained, 'Reciprocal altruism can also be viewed as a symbiosis, each partner helping the other while he helps himself. The symbiosis has a time lag, however; one partner helps the other and must then wait a period of time before he is helped in turn' (p. 39). For reciprocal benefit to be advantageous to the genes promoting it, three conditions must be met: (1) need situations must arise frequently (providing opportunities to give and receive benefits), (2) the proximity of potential helpers must be high, and (3) cheating (receiving help without reciprocating) must not be viable. One way to discourage cheating is for potential helpers to refuse future benefit to any individual who does not reciprocate. Another way is to inflict harm on cheaters. Consistent with this reasoning, Axelrod and Hamilton (1981) found that a form of reciprocal benefit and retribution, a tit-for-tat strategy, proved stable and effective in competitive encounters (iterated prisoner's dilemma games).

Group selection is the view that an allele promoting individually disadvantageous behavior such as helping can be selected for if this behavior enhances the survival of the group or species. Sociobiologists often took pains to distinguish their emphasis on the gene as the unit of natural selection from group selection. They noted that selection among individuals within the group would allow a self-benefit allele to drive out a group-benefit allele, even if the latter allele gave the group a selective advantage relative to other groups.

Sober and Wilson (1998) recently pointed out, however, that to juxtapose gene selection and group selection inappropriately contrasts the unit of selection (the gene) with a level of selection (the group). They suggested that gene selection can actually occur at a range of levels – at the level of the gene, the individual, and the group – leading them to propose a *multilevel* selection theory. Selection often occurs among individuals within groups, but there are cases of strong intra-group cohesion, coordination, and cooperation (e.g. social insect colonies) in which selection also occurs among groups. At times, the reproductive benefit of acting to benefit the group can outweigh the reproductive cost relative to other group members of this action. Viewed from the perspective of multilevel selection theory, kin selection and reciprocal benefit can be considered special cases of group selection. Whether human groups ever have the degree of cohesion necessary for genetically based group selection to evolve is, at present, unclear. Selection among human groups may be a product of cultural, rather than genetic, evolution (Campbell, 1975).

PSYCHOLOGICAL ALTRUISM

Over the centuries, the most frequently proposed source of altruistic motivation has been an other-oriented emotional response congruent with the perceived welfare of another person – what is today often called 'empathy'. If another person is in need, then empathic emotions include sympathy, compassion, tenderness, and the like. The empathy–altruism hypothesis claims that empathic emotion produces motivation with an ultimate goal of increasing the welfare of the person for whom the empathy is felt – that is, altruistic motivation.

Experimental research has provided evidence that feeling increased empathy for a person in

need can cause increased helping of that person (see Eisenberg and Miller, 1987, for a review). To observe an empathy-helping relationship, however, does not reveal the nature of the motivation that underlies this relationship. Benefiting the other person could be (a) an ultimate goal, producing self-benefits as unintended consequences, (b) an instrumental goal on the way to the ultimate goal of gaining one or more self-benefits, (c) both, or (d) neither. In other words, the motivation could be altruistic, egoistic, both, or neither. To know whether empathy produces altruistic motivation, it is necessary to determine whether benefiting the person for whom empathy is felt is an ultimate goal.

Three general classes of self-benefits have been proposed to result from helping a person for whom empathy is felt: (1) helping reduces one's empathic arousal, which may be experienced as aversive; (2) helping permits one to avoid possible social and self-punishments for failing to help (e.g. blame, guilt); and (3) helping offers one social and self-rewards for doing what is good and right (e.g. praise, pride). Advocates of the empathy–altruism hypothesis do not deny that these self-benefits of empathy-induced helping exist. They claim, however, that these self-benefits are unintended consequences of reaching the ultimate goal of reducing the other's suffering. Advocates of the egoistic alternatives to the empathy–altruism hypothesis disagree. They claim that one or more of these self-benefits is the ultimate goal of empathy-induced helping.

EVIDENCE FOR THE EXISTENCE OF ALTRUISM

To test these claims, it is necessary to employ experiments, not self-reports. People may not know, or report, their true motives. In the past 25 years, more than 30 experiments have tested the three egoistic alternatives against the empathy–altruism hypothesis (see Batson and Shaw, 1991, for a partial review). The basic research strategy has been to provide individuals induced to feel either low or high empathy for a given person in need with an opportunity to help that person. A cross-cutting variable is also included, making it possible for some of these individuals to obtain one or more of the self-benefits proposed as the source of empathy-induced helping without having to help. If this modification eliminates the increase in helping produced by empathy, then one has evidence that the ultimate goal of the empathy-induced helping was to obtain the self-benefit. If the modification does not eliminate the increase, then one has evidence that this self-benefit was not the ultimate goal. Only after all plausible self-benefits – and other motives – have been ruled out in this way does one have grounds for concluding that the ultimate goal is to benefit the person in need, that the motivation is altruistic.

Results of these experiments have effectively ruled out all plausible self-benefits and other motives proposed to date and have provided remarkably consistent support for the empathy–altruism hypothesis. Because these results contradict the dominant assumption in Western thought that all human motivation is egoistic, they have proved controversial. Attempts to find a plausible egoistic explanation for them continue. At this point, however, it seems likely that empathy-induced altruism is part of human nature. Whether there are sources of altruism other than empathy, such as a personal disposition to be altruistic (an 'altruistic personality'), is not yet clear.

One important contribution of the recent psychological research has been to provide experimental methods for differentiating altruistic motivation from various egoistic alternatives. These methods make it possible to address the question of the existence of human altruism directly by empirical observation of the behavior of humans in controlled laboratory conditions – rather than indirectly through deduction, extrapolation, anecdotes, and self-reports.

CONCLUSION

Evolutionary altruism refers to behavior by one organism that diminishes its reproductive fitness relative to that of one or more other organisms. Evolutionary altruism can exist in cases of kin selection and reciprocal benefit, both of which can be considered special cases of group selection in a multilevel selection theory. Psychological altruism refers to a motivational state with the ultimate goal of increasing another's welfare. The basic philosophical question about whether altruism is part of human nature concerns psychological altruism, not evolutionary altruism. Recent experimental evidence suggests that empathy-induced psychological altruism is indeed part of human nature.

Human Cognition

Intermediate article

H Plotkin, University College London, London, UK

CONTENTS

Human cognition is the set of processes and mechanisms by which we come to know the world, whether it be through learning, perception, or thinking and problem solving. Studies of cognition as an evolved set of traits which must be understood within a developmental framework are beginning to resolve some of the oldest philosophical problems of how we come to have knowledge.

INTRODUCTION

Epistemology is concerned with how knowledge is possible, and the certainty that we can attribute to that knowledge. How do we come to know anything; and what confidence can we have that what we know relates with any accuracy to the state of the world? Within classical philosophy, there is no more fundamental distinction and dispute than that between rationalist and empiricist approaches to epistemology. Philosophically, it is the oldest and most important difference of view that we have about how humans come to have knowledge. It is not surprising, therefore, that an almost exact distinction and dispute has been evident in psychological approaches to the understanding of human knowledge. It is equally unsurprising that cognitive science, the science of knowing, now offers the possibility of both theoretical and empirical resolution of this oldest of philosophical issues.

THE RATIONALIST–EMPIRICIST DISTINCTION

In its strongest form, rationalism argues that reason is the only, the unique, path to knowledge. In less strong form, the claim is that reason has precedence over other ways of acquiring knowledge. The oldest, and certainly most famous, of rationalists was Plato. The world to be known was for him that which existed as abstract objects that he called 'forms' or 'ideas', which are independent of thought. The forms are changeless and incorporeal, and the only way that we can come to have true knowledge of them is through thought. Knowledge that comes to us through our senses is only ever partial and always uncertain. True knowledge is an imminent property of every human child at birth – knowledge is innate – and it becomes accessible through long and patient study of subjects such as logic and mathematics. More recent philosophical exponents of rationalism have been Descartes, Spinoza, and Leibnitz.

An almost exactly opposite position is that of the British empiricists such as Locke, Berkeley, and Hume. Empiricists rejected the notion of innate knowledge. For them knowledge begins at our sensory surfaces and is based on what we experience of the world. In Hume's words, there is 'no idea without an antecedent impression'. It was John Locke in particular who attacked the notion of innate ideas and knowledge. The mind at birth, he argued, is a *tabula rasa*, a blank slate upon which experience writes, and experience begins with sensation. The empiricists were much influenced by the science of their day, especially that of Newton, and, of course, science begins with observation. Hence the empiricists developed Newtonian conceptions of the knowing mind, a mechanics of mind, in which knowledge is particulate and ruled by temporal and spatial proximity. The empiricists were, in effect, associationists seeking for laws of knowledge through an understanding of the lawful interaction of ideas whose origins are in sensory impressions.

RATIONALISM AND EMPIRICISM IN TWENTIETH-CENTURY PSYCHOLOGY

The founders of psychology as a natural science in the mid-nineteenth century were strongly

influenced by empiricist philosophy. The earliest science of knowledge, therefore, was inclined towards an empiricist skepticism as to the existence of innate knowledge. While Darwin's theory of evolution was published and widely discussed at about the same time that a scientific psychology was being established, evolution had remarkably little direct impact upon the new science of mind. It did, though, give rise to two movements that appeared at the start of the twentieth century, both originating in the proposed evolutionary continuity between species. The first led to the seeking of instincts in humans, instincts whose origins were assumed to lie in the history of natural selection pressures acting upon the minds of the ancestors of modern humans; and the second resulted in attempts to establish the existence of, previously largely unrecognized, rational powers of learning and thought in nonhuman animals.

In pursuit of the first of these movements, literally thousands of instincts were claimed to shape almost every aspect of human psychological functioning, such instincts comprising a form of innate knowledge that causes the human mind to function in specific ways. Much of this work was feeble speculative description without emprirical support which collapsed in the face of two developments. One of these, the outcome of the movement seeking rationality of some form in nonhumans, was the laboratory studies of animals by Thorndike and Pavlov, both presented within the framework of empiricist associationism, and convincingly supported by solid experimental evidence. If animal behavior is driven by general learning processes based on laws of association, why, it was asked, should this not apply also to humans? The other, related, development was the onslaught of a fierce environmentalism in all the social sciences that in psychology took the calamitous form of behaviorism. The legacy is what Tooby and Cosmides (1992) called the 'standard social science model' (SSSM) that came to dominate psychology for well over half a century, and which in Fodor's (1998) words 'takes a form of empiricism for granted: human nature is abritrarily plastic'.

Initially, the onset of the cognitive revolution in the late 1950s and early 1960s did not change the SSSM. It provided psychology with the powerful conceptual tool of invoking directly unobservable psychological constructs as causes of human behavior, constructs such as attention and different forms of memory. But under the influence of Piaget's powerful form of cognitivism, which had never conformed to the absurd strictures of behaviorism, cognitive theory remained focused upon general processes that wrote upon the blank slates of the human mind. It was only in the 1960s and onwards, and especially in the last two decades of the twentieth century, that the tide began to turn, with rationalism, and its basic tenet of innate knowledge, making a slow return to center stage in theories of human cognition. Three principal developments have been responsible for this. One is the ethological account of animal learning. The second concerns human language. Finally, recent studies of cognitive development in children have been profoundly important in changing the weight of opinion.

THE CHANGE IN VIEW

One group of scientists studying behavior had never relinquished the notion of instinct or innate behavioral tendencies. These were the ethologists, biologists who studied mainly animal behavior in natural settings and whose principal conceptual tool in explaining behavior, unlike psychologists, was evolutionary theory. Through the 1950s and in to the 1960s, ethologists, with their emphasis upon evolved behavioral dispositions, debated fiercely with psychologists, whose concepts inclined to center on flexible, learned, behaviors. This was but one more phase in the 'nature–nurture' argument which had been debated for almost a hundred years.

Attempting to resolve the issue, one of the founders of ethology, Konrad Lorenz, wrote a seminal monograph (Lorenz, 1965) in which he argued that, unnoticed by psychologists, one of the characteristics of learning is that it is almost always adaptive in outcome. This, he argued, can be explained only by learning itself being an adaptation, a product of evolution vested in evolved and innate neurological mechanisms, which he called 'innate teaching mechanisms'. This collapsed the dichotomy of nature and nurture into a singularity, an instinct (or instincts) for learning about specific features of the world.

At the time Lorenz had no hard evidence that learning in any species is tuned to acquiring specific forms of knowledge. Within a few years, however, laboratory-based evidence supporting this view began to accumulate. For example, from studies through the 1970s and beyond, it became clear that learning of song in songbirds is tightly constrained, resulting in powerful biasing towards species-specific song acquisition; hummingbirds were found to acquire a win-shift strategy more easily than a win-stay strategy that fits well with their natural foraging behavior; and sex differences

in spatial learning ability in different species of vole matched their reproductive strategies. Such findings gave rise to the general notion of learning by instinct (Gould and Marler, 1987), learning as evolved, adaptive, cognitive specializations constrained to operate within specific domains of information.

To echo the question about general learning processes of a half-centry earlier, but with an inverted meaning, if domain-specific learning, bearing all the hallmarks of evolved adaptive mechanisms for cognition, occurs in nonhumans, might this not apply to human cognition? Part of the answer came from studies of language learning in humans.

Language is a rule-based system of communication in humans that is defined by the quality of generativity: namely, the capacity to generate a virtually infinite number of messages from a finite, usually quite limited, number of component symbols. Despite claims that following intensive training a few chimpanzees show glimmerings of a language facility, it is widely accepted that such behavior has never been observed in nonhuman apes under natural settings, and that language is a human-specific cognitive characteristic. Earlier accounts of language learning, based either on associative learning principles or more general developmental processes, were eclipsed from the late 1950s onwards by the linguistic theory of Noam Chomsky. Though Chomsky's views have altered somewhat over the decades (Chomsky, 2000, represents his most recent position), his broad view as it affects theories of human cognition in general has remained constant: language is an innate organ of mind, the acquisition of which is driven by language-specific cognitive mechanisms. The evidence for this is that language acquisition, whichever of the world's five thousand plus languages is being learned, is remarkably constant across children both in terms of content (vocabulary) and structure (grammar and syntax); that this applies equally to profoundly deaf children who are raised within a signing environment and who communicate through a language based on hands and eyes rather than tongues and ears; and that rich linguistic structures invariably develop, even within linguistically impoverished environments. Recent brain imaging studies have shown that the same areas of the brain are activated by seeing sign language in deaf individuals expert in sign language as are activated when hearing people are listening to spoken language.

Nobody doubts, of course, that language is *learned* in the sense that children raised in an environment which has German as its native language do not end up speaking Japanese. But the strong claim from the evidence is that all children come into this world with innate knowledge of a single, universal, language which then unfolds within specific linguistic environments into particular versions of that language. The similarity to Lorenz's innate teaching mechanisms is striking. Two points, though, should be noted. One is that the Chomskian account is not universally accepted. Deacon (1997), for example, offers an alternative, more general-process view, which nonetheless is compatible with evolutionary approaches to language. The second point is that Chomsky himself, while always taking an unbending nativist (rationalist) stance, does not associate himself with an evolutionary account of language. Others (for example Pinker, 1994) have taken the view that an innate organ of mind like language must be a product of evolutionary processes.

What then of more general studies of cognitive development in infants and children? What follows is necessarily the briefest of sketches. Detailed reviews can be found in Hirschfeld and Gelman (1994) and Sperber *et al*. (1995). The methodological advance that resulted in much of this work came with the refinement of the dishabituation paradigm in the early 1980s. Habituation is a reduction in response to a familiar event, while dishabituation is an arousal of attention to an unexpected event.

Take the paradigmatic case of an infant placed on the lap of one of its caretakers and facing a screen. At the center of the screen is a ball, and after a few seconds a second ball appears at the edge of the screen, moves towards the stationary ball at the center, strikes it, and comes to a stop while the previously still ball is propelled off the screen. Such a launching display elicits little interest from the infant. But if the second ball comes to a stop some distance from the centrally placed ball, and the stationary ball then moves off the screen – an example of action at a distance which is never observed in inanimate objects – the infant stares long and hard at the screen. These so-called looking-time experiments have yielded a wealth of data taken at ages previously inaccessible to cognitive developmentalists. Other examples involving infants entail blocks being placed on other blocks which support them (the unsurprising experience), contrasted with blocks placed next to other blocks, unsupportd by the latter but remaining suspended in mid-air (the surprising experience), or occluding bodies with holes in them that do or do not reveal the objects over which they pass. The general finding has been that infants as young as 10 or 12 weeks, who have

spent much of their postnatal life sleeping, have a knowledge of 'intuitive' physics. That is, they are suprised by physical events when those events are contrary to the macrobehavioural events of the inanimate world perceived directly by our senses.

There are two opposed interpretations of such findings. One is that infants have had insufficient experience to have learned about the behavior of inanimate objects in so short a period, and that these experiments demonstrate the existence of innate knowledge of intuitive physics. The other interpretation is that two to three months, even with limited sensory capacities and periods of wakefulness, is a sufficient period for infants to learn, using general learning mechanisms, about the properties of the physical world. The former is of course, a form of rationalism; the latter is the empiricist stance.

Before evaluating these alternatives, consider some other findings of the last 20 years of the twentieth century, the most important of which concerns 'theory of mind' (ToM). ToM is generally held to underly knowledge of social causation, as opposed to the physical causation of intuitive physics. ToM is the means by which each of us, pathology apart, come to understand that others have minds made up of intentional mental states such as knowing, feeling, and wanting. The sequence by which this occurs appears to be invariant, though the contents of ToM are clearly culture-specific. During the first eight months after birth the infant appears to inhabit an egocentric sensory-motor world. From about 9 months, the previously dyadic interactions of self–other or self–object gives way to the triadic interaction of self–other–object. The infant begins to share attention with others, follows the gaze of others, and checks their gaze to ensure they are looking at the same thing. By about 15 months, declarative pointing appears; between the ages of 18 and 24 months pretend play becomes evident, and vocabulary begins to embrace mental state terms such as 'want' and 'know'. The defining point in the completion of ToM occurs at between 40 and 50 months when children come to understand that others can have false beliefs, which among other things means that others may have intentional mental states that are different from their own. Impairment to the normal development of ToM is thought to result in serious pathology, including the spectrum of autistic disorders.

The comparative literature indicates that while chimpanzees are able to act on the basis of what other chimpanzees know, this cannot be taken to mean that these animals are able to attribute mental states to others. Until there is evidence to the contrary, the assumption is made that ToM is a uniquely human adaptation essential for the human capacity for culture. Both functional imaging and brain lesion studies point to specific regions in the frontal and temporal lobes as being a part of the neurological substrates of ToM.

Other domain-specific human cognitive capacities that have been postulated to exist include various aspects of vision, including face recognition, hearing, the detection of cheaters, responses to sexual stimuli, comprehension of living forms (intuitive biology), and perhaps even the understanding of supernatural beings. Duchaine *et al*. (2001) provide a recent review.

ADDITIONAL CONSIDERATIONS

It is a truism of comparative neuroanatomy that the brains of vertebrates share a common ground plan. It is equally widely held that the organization of the forebrain, specifically the neocortex, in terms of major processing areas for sensory inputs and motor outputs, is both conserved across all mammals yet shows a degree of specialization for particular taxonomic groups (de Winter and Oxnard, 2001). This is strongly supported by recent genetic studies on phylogenetically widespread genes coding for the structure of brains, including those of invertebrate species. The general conclusion is that the brains of vertebrates, and especially the neocortex of mammals, are organized for some degree of specialized, localized function, such specialization being genetically part caused and partly emerging through normal developmental sequences, including activation of neural pathways. The human brain is expected to display at least a similar degree of structural and functional specialization. As indicated above with regard to ToM, though the general finding goes much wider than mental state attribution, localization of function across individuals is becoming a common finding across a range of cognitive functions. The brain is not equipotent under conditions of normal development, though this does not deny the extraordinary capacity of the brain for flexibly adjusting to abnormal conditions, whether these be the result of pathology or developmental circumstances.

INTERPRETATIONS OF MODULARITY

The modularity thesis asserts that the brain comprises a set of computationally specialized, informationally relatively encapsulated, automatic and rapid processors of specific domains of

information. When the thesis was first developed by the philosopher of mind Jerry Fodor in 1983, the emphasis was placed on modules as restricted processors of input: for example the conversion of a two-dimensional retinal array into three-dimensional visual images. In the years since then, the modularity conception has been widened, often to include whole psychological functional domains (such as reproductive strategies or reciprocity of social interactions in the sharing of resources), as well as more restricted sensory problems (like face recognition). This is sometimes referred to as 'the massive modularity thesis', and it has found special favor with evolutionary psychologists who subscribe to the view that the human mind, including cognition, is a set of specialized, evolved adaptations. Another variant of the modularity concept is that modularity is a product of development.

Whether it is the original, limited, Fodorian thesis of modularity, the more recent massive modularity espoused especially by evolutionists, or the developmental variation of the modularity conception, almost all cognitive psychologists now subscribe to one or other version of the modularity thesis. Where the deep divisions remain is in the interpretation of modularity and its causes. As indicated, there are three schools of thought, with the distinctions drawn usually being a matter of emphasis and degree, rather than absolute difference and theoretical exclusion. For example, no one denies that what humans are now is a result of the evolutionary history of our species. But just what those evolutionary processes were, and how specific have been their effects on human cognition, are the issues of contention. In general, these, often greatly exaggerated, differences revolve around the meaning attached to the concept of innateness, to a commitment to more rigid or more flexible developmental approaches, and adherence to specific evolutionary theory.

The first two schools of thought are both strongly nativist, and hence rationalist. The one, the strong evolutionary psychology school, maintains that human cognition comprises a set of specialized information-processing modules each with specific, innate computational features whose origins lie in past selection for specific cognitive functions which evolved through neo-Darwinian evolutionary processes. Pinker (1994) exemplifies this view. The second, characterized as the new rationalism (Fodor, 1998), espouses a strong form of innatism for some cognitive processes and mechanisms with tacit acceptance of genetic part causes of these; but is neutral, if not hostile, towards neo-Darwinist processes as the evolutionary origins of cognitive traits, that is of the manner such processes and mechanisms become manifest as specific forms of cognition.

The third position challenges innatist arguments, especially with regard to representational nativism, adopts a strong developmental (ontogenetic) stance, and offers connectionist neural network models as potential general processes underlying cognition. It is best described as a form of developmental empiricism. The mechanisms may be innate, and hence evolved, but the cognitive functions that they mediate are not based on specific contents, such as linguistic structure or facial configuration. Modularity emerges through a complex cascade of developmental events acting upon connectionist networks. Such networks, initially relatively untuned, act as holistic, parallel processors of information responding to specific informational inputs and correction procedures to the outputs of the networks, resulting eventually in networks trained to process specific forms of information.

SUMMARY: WAITING FOR EMPIRICAL RESOLUTION

The comparative, genetic, and neurological evidence all points to humans not being blank slates at birth. The brain, including the neocortex, does show a degree of specialized structure and function at birth, if only in terms of gross connectivity. The impasse in the argument as to whether such young infants come to have so much knowledge so early in their lives, and pass through relatively invariant developmental stages, because of relatively fixed innate causes or because of more flexible ontogenetic processes, will not be broken by cognitive developmental studies alone, unless there is a further methodological breakthrough in cognitive developmental procedures. Exactly how specialized in function the brain is at birth, just what extent of neural structure can be traced to specific genetic causes, how much flexibility there is in developmental pathways, and how much postnatal cognitive specialization can be attributed to more general developmental processes, are questions that all await empirical resolution. But it will be outside of the strictly cognitive experimental realm. There are, though, already signs that a resolution will be reached. For example, there is recent evidence that visual experience during the first few months of life is necessary for establishing the neural architecture that specializes in the expert processing of faces over the next ten or more years.

The answers will come in the next decades with increasing knowledge of neurogenetics, of developmental neuroscience of real neural networks, and the inevitable unfolding of understanding of the connections between brain structure and function and psychological mechanisms. What is becoming clear is that cognitive science is telling us that neither rationalists nor empiricists are entirely correct. We do come into the world with the slates of our knowing minds written upon; but how much is written and where that writing is coming from remains to be determined.

Human Factors and Ergonomics

Intermediate article

Peter A Hancock, University of Central Florida, Orlando, Florida, USA
Raja Parasuraman, Catholic University of America, Washington, DC, USA

CONTENTS

Human factors and ergonomics is the study and practice of designing technology around the capabilities, both physical and mental of the user. Included in the chapter are brief descriptions of neuroergonomics, the combining of neuroscience and ergonomics, and human factors and ergonomics in the twenty-first century.

INTRODUCTION

Most individuals reading an *Encyclopedia of Cognitive Science* will have more than a passing familiarity with the research areas and issues that they encounter in the text. Yet this may not be true for *human factors* and *ergonomics* (*HF/E*), since these terms appear to lie outside the mainstream of cognitive science. However, we hope to persuade the reader that HF/E represents a central concern of any cognitive science that aspires to be relevant to the real world. We support this claim by beginning with a reference to the origins of cognitive psychology and its historical antecedents.

Cognitive Psychology and Human Factors and Ergonomics

Most modern cognitive scientists are unconcerned with, or not fully cognizant of, the goals, issues and findings of HF/E. This relative neglect is understandable, but paradoxical, since the post-Second World War origin of modern cognitive psychology owes much to HF/E. The 'cognitive revolution' of the late 1950s supplanted the behaviorist tradition that dominated American (and, to a lesser extent, European) psychology. This paradigm shift is rightly seen as the beginnings of the cognitive science movement, accompanied by developments in artificial intelligence (Newell and Simon, 1956) and linguistics (Chomsky, 1957). Two of the leading figures of this cognitive revolution were George Miller in the USA and Donald Broadbent in the UK. The latter can be seen in action at the prime of his career in Figure 1.

Broadbent's classic information-processing model of the human cognitive system (Broadbent, 1958) inspired many hundreds of cognitive psychologists, and still remains influential today. Both Broadbent and Miller were especially interested in applications of cognitive psychology to real-world problems, and Broadbent in particular was a leader in the early development of HF/E. Many younger cognitive scientists who may be aware of Broadbent's contribution to cognitive psychology may nevertheless be surprised to learn that he also made fundamental contributions to such areas of HF/E as evaluation of the effects of noise, vigilance, stress, and industrial health and productivity. His classic book *Decision and Stress* (Broadbent, 1971) summarized this work and made an eloquent case for continued interaction between basic cognitive psychology and HF/E, a collaboration that we support and seek to sustain for the continued vitality and well-being of each area.

What Are Human Factors and Ergonomics?

Although human factors and ergonomics have different historical antecedents (see Jastrzebowski, 1857), they can now be regarded as essentially synonymous (see Dempsey *et al*., 2000). HF/E concerns the way in which people work with technology, where the latter is a broadly encompassing term that embraces artifacts ranging from something as simple as a paper clip to those as complex as a nuclear power station, as well as environments at work, at home and while in motion. HF/E is both a science and an engineering discipline. The science of HF/E consists of developing theories, empirical

Figure 1. Donald Broadbent the motorcyclist at the height of his powers. Many cognitive scientists remain unaware of Broadbent's fundamental contributions to human factors and ergonomics.

databases and quantitative models of human physical and cognitive capabilities and limitations in relation to the use of technology. The goal of HF/E as an engineering discipline is to design technologies and environments for effective and safe human use. Unfortunately, many products and processes are designed with little if any attention to such human capabilities and limitations. Any cognitive scientist who has struggled to learn to use a new software interface, or any individual who has been fooled by the complexity of action modes of a TV remote control, or any older person who is puzzled by the mystery of 'butterfly' voting ballots will recognize this problem immediately. More often than not we find ourselves unable to use technologies effectively because of poor HF/E design. Consequently, one definition of HF/E is 'the branch of science which seeks to turn human–machine antagonism to human–machine synergy' (Hancock, 1997).

One of the notable qualities of HF/E is the range of activities that it embraces. At one level, HF/E is represented by a real-world practice concerned only with engineering and design decisions regarding a manufactured product. Foundation-level information about human performance is taken as the premise for new system design. Often this foundation may be lacking in substance and sophistication, so that many elements of design (e.g. those evident in interface development) may represent more of an art than a logical scientific process. Development is often contingent on 'user preferences', and usability analysis has to tread a fine line between the use of objective measures and subjective response to create new and effective systems. Thus, in the practical world, HF/E lies at the confluence of science and art, where the preponderance of the contribution of each is very much contingent upon the type and training of involved personnel. In this article, however, we shall focus on the *science* of HF/E.

Overview

In what follows, we shall first articulate the science of HF/E through an examination of the relationship between the psychology of action and the application of cognitive science in HF/E. Secondly, we shall examine the process of interaction with particular reference to the control of 'virtual' systems in which the laws of psychology rather than the laws of physics hold primary sway. Thirdly, we shall demonstrate how inherent human abilities and limitations are magnified in designed worlds, and finally we shall promulgate a new interdisciplinary endeavor – neuroergonomics, which seeks a marriage of ergonomics and neuroscience. We shall conclude with an affirmation of the centrality of HF/E to any cognitive science concerned with behavior in real-world settings and to an even greater extent in envisioned worlds.

COGNITIVE SCIENCE, HF/E AND THE PSYCHOLOGY OF ACTION

How can the study of cognition be linked to issues surrounding the human use of technology in the real world? One possibility is to develop modular theories of parts of cognition, and to apply these modules to the solution of real-world HF/E problems. However, since all action is situated, the context of the behavior exerts a crucial influence on the outcome (Flach *et al.*, 1995; Hancock *et al.*, 1995). Thus the strategy of trying to understand behavior in complex worlds through the concatenation of multiple theories of simple behaviors is crucially flawed, as the component interaction of each simple theory and the complexity of the circumstances in which behavior occurs both act to defeat this constructivist aspiration.

An alternative strategy is to begin not with individual components of behavioral capability, but with a more fundamental understanding of the actual environment in which behavior occurs. We are, of course, aware of the direct link of this notion to ecological psychology, from which this persuasion emanates (Gibson, 1966, 1979). Indeed, it is of

more than passing interest to note that some of Gibson's earliest work focused on the very practical HF/E issue of vehicle control, and that his work on driving (Gibson and Crooks, 1938), with its construct of the 'field of safe travel', represents one of the earliest but most crucial contributions to practical driving research even today (Figure 2).

Unlike some more radical ecological theorists, we see technology and the manufactured world as the contemporary ecology to be explained. Technology certainly adds a layer of complexity to understanding, since the world as we experience it is largely a palimpsest of previous design decisions by those who have preceded us. Furthermore, despite the fact that most living humans exist to a considerable extent in a designed environment, their resident capabilities are derived from many millennia of evolution and are not, in and of themselves, intrinsically amenable to sudden change or development. The fact that technology provides magnifications of these perception/action capacities, often incorporating their faults as well as their virtues, is a major design issue (Hancock and Chignell, 1995; Hancock, 1997). Thus anyone who wishes to understand cognitive capabilities cannot ignore the externalization of those abilities into the real world, first as a formative influence and secondly as a clear clue to functional significance. It is in this respect that HF/E is central to cognitive science and in crucial ways expresses the same essential goal. That this facet of science should also express opinions about what should be (i.e. *purpose*) as well as what is (i.e. *process*) is a polemical contention but one that we directly support. If the goal is to understand human behavior, individual and collective purpose cannot be omitted from the equation.

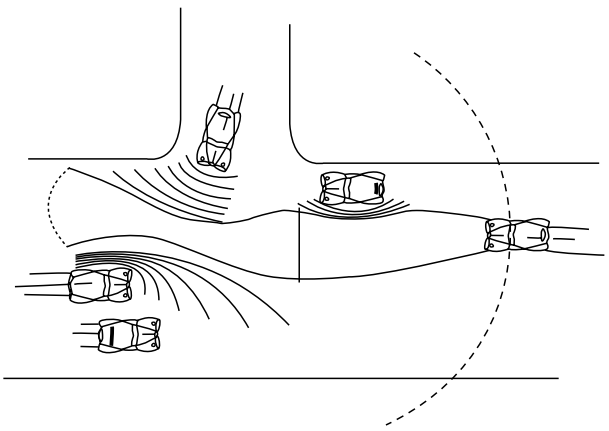

Figure 2. Illustration of the 'field of safe travel' and the 'minimum stopping zone' from the seminal paper by Gibson and Crooks (1938). Like other psychological theorists, Gibson's questions are firmly founded on concern to understand real-world experience.

Cognitive science seeks to understand mind and brain. It is our contention that one method by which such a complex activity can be understood is to observe its outcome. We suggest that tools (or more generally technology) represent collective extensions to cognitive capability, and that the fabricated world around us represents the summed action of collective human cognition. Thus, in much the same way as sophisticated, modern brain-imaging techniques allow us to window the structure and function of individual brains, so examination of the modern world allows a similar glimpse of brains' collective output. Furthermore, since technology represents the most powerful formative force in the modern world, contemporary interaction with technology acts to shape who we will be in the future. Since all behavior is situated in and crucially dependent upon context, and since that context is largely dictated by technology, the way in which humans design, develop, fabricate, interact, perform and occasionally recover from the effects of technology – that is, ergonomics – is central to a dynamic understanding of cognitive science.

The notion that cognition should be considered in relation to action in the world has many antecedents. Piaget's work on cognitive development in the infant and its dependence on exploration of the environment certainly anticipated the concept of situated or embodied cognition. A modern statement of this thesis can be found in the philosopher Andy Clark's engaging book, *Being There*: *Putting Brain, Body and World Together Again* (Clark, 1997). Clark goes beyond the old distinction between mind and matter to examine the characteristics of an embodied mind that is shaped by and helps to shape action in a physical world. If a true cognitive science therefore cannot study minds in isolation, but must examine them in interaction with the physical world, then it is a natural second step to ask how to design artefacts in the world which best facilitate that interaction. This is the domain of HF/E.

HUMAN PERFORMANCE CAPABILITIES AND LIMITATIONS

To illustrate the intimate link between HF/E and cognitive science, we only have to consider how the study of certain processes is common to each. Consider, for example, short-term or working memory. While those in cognitive science seek to explore this

facility and its limitations, those in HF/E take such knowledge and seek ways in which memory limits can be obviated in the real world. A specific example may help to explain this transfer process. During the take-off sequence, an aircraft attains two crucial velocities, labeled V1 and V2 in the aviation realm. Although these are critical speeds, they are not constant even for the same aircraft, since weather conditions, load and other variables act to dictate their exact value on a particular take-off on any given day. Thus V1 and V2 must be calculated during the preflight procedure and held in working memory by the pilot. Clearly, take-off is a critical time and it is best not to overload the pilot at this juncture, since during take-off emergencies things can happen quickly, and briefly memorized but crucial information can be forgotten. One design answer to support pilot memory was 'speed-bugs.' These small markers were attached to the airspeed indicator so that the pilot could position them during preflight and immediately 'see' the velocity values, rather than having to refer to short-term memory. Unfortunately, as with many good ideas, it was thought that if two were good, more would be better, and soon the proliferation of 'bugs' meant that the memory load was returned to the operator, who now had to remember which of the specific attached markers related to which crucial speed value. This is a design situation that is constantly encountered in HF/E, where good original conceptions are distorted by well-meaning but uninformed designers. This was highlighted by the ballot failure experienced in specific counties in Florida during the US Presidential election of 2001 (see Woods and Hancock,2001).

The moment of take-off is also an example of the problem of cognitive or mental workload (Hancock and Meshkati, 1988). An especially difficult construct to define unequivocally, nevertheless mental workload retains high face validity and indeed utility in the practical realm since, like fatigue, many individuals can identify and empathize with the experience. The fundamental question, and certainly one related to the theoretical notions of attentional capacity, concerns the maximum tolerable level of cognitive activity that an individual can sustain, and for how long they can do this. In addition to questions of acute and chronic mental overload and underload, fundamental developments in naturalistic decision-making (see Klein, 1999) have been stimulated by the problem of understanding the real-world choices of novices and experts in different application domains. Similarly, many cognitive scientists might well know Fitts' name because of its association with a fundamental law of movement relating speed to accuracy, without being aware of his central role in HF/E in relation to air-traffic control (Fitts, 1951) or pilot error (Fitts and Jones, 1947). Indeed, as well as the early referenced work on car driving, Gibson's fundamental theories originated from his experiences with practical aviation problems during the Second World War. More recent examples abound. The multiple resource theory of attention promulgated by Wickens has been used extensively as a design heuristic, especially in aviation psychology, a field to which Wickens himself has made a number of fundamental contributions. Finally, the present authors are each intimately concerned with both theoretical aspects of cognition and their application in diverse applied settings (Parasuraman and Mouloua, 1996; Hancock, 1997). In summary, there is no part of cognitive science which does not have its counterpart and leave its mark in the applied world, and we submit that this information flow is strongly bidirectional, and should be even more so.

The study of human performance capabilities and limitations must also be considered in relation to the ecological validity of the environment (e.g. the laboratory) in which performance is elicited. Cognitive science methods, such as laboratory experiments, computational modeling, etc., do not necessarily make intimate contact with human performance in real settings. We recognize the value of such basic research, but suggest that it must be supplemented by research which examines cognition in relation to the work setting and technology, not just individual cognition in isolation. Of course, there has been an ecological validity movement in cognitive science for some years now (Hutchins, 1995), and situated cognition theorists do consider the environment, but even then, if the environment is simulated in the laboratory at a very basic level, the theoretical principles that emerge may not apply to the real world. This necessarily means that some of the artificial laboratory tasks of basic cognitive science may not be generalizable to complex real-world systems.

An example will illustrate the value of a combined basic and applied research agenda. Broadbent's (1958) classic theory of short-term memory and attention was developed following observations of the fallibility of air-traffic controllers in handling multiple messages. He studied the real-world problem, abstracted it in a laboratory task and developed a theory. Irrespective of the current validity of Broadbent's theory, its heuristic power for cognitive psychology research is undeniable.

Thus real-world problems can advance empirical studies and theory in cognitive science. The theories in turn, if applied judiciously, can impact on real-world problems. This interactive relationship between basic cognitive science and HF/E was present in the early days of both disciplines, but has perhaps been lost over the years and needs to be revived.

HUMAN INTERACTION WITH TECHNOLOGY

One of the major issues in HF/E continues to be human interaction with complex systems. In this context, 'complex' usually refers to large-scale process control systems such as nuclear power or advanced computer-based systems (e.g. those found in aerospace and aviation operations). Spectacular failure in these areas has always provided an impetus for gaining a greater understanding of what are often conceived of as human failures. In recent decades, these systems have achieved such complexity that some of them simply cannot be operated without computer support, and their momentary control implies the presence of computer mediation. In HF/E, the question of function allocation has been a continual concern (Hancock and Scallen, 1998). In a human–machine or human–computer system, who does what when is a central design and operational issue. As more automation has been introduced, and as the human operator has become progressively more divorced from momentary, hands-on control, the question of interaction with such semi-automated systems has become of paramount importance (Parasuraman and Riley, 1997).

Automation can be defined as the execution by machine (usually a computer) of a function previously performed by a human (Parasuraman and Riley, 1997). Given their rapid growth in speed, capacity and 'intelligence', computers are increasingly being assigned functions that at one time could only be performed by humans, including complex cognitive activities such as decision-making and planning. Automation has also been extended to functions that humans cannot perform as accurately or reliably as machines. Consequently, automated systems are now common in many areas, including air, ground and maritime transportation, medical systems, manufacturing and process control (Parasuraman and Mouloua, 1996). Further reductions in the size and cost of computers will result in far-reaching applications of automation to virtually all aspects of life (Rawlins, 1996; Satchell, 1998).

The advent of these technologies has been accompanied by growing research on human interaction with automation. An important finding to have emerged from this research is that automation can fundamentally change the nature of the cognitive demands and responsibilities of the human operators of systems, often in ways that were unintended or unanticipated by the designers (Wiener and Curry, 1980; Bainbridge, 1983; Woods, 1996; Parasuraman and Riley, 1997). Much of this work has examined the factors that promote or limit effective use of automation by humans, and the consequences for system efficiency and safety. These findings have raised the issue of the degree to which automation should be implemented in a given system. Given the capabilities of current and projected automation technologies, which system functions should be automated and to what extent? For example, should a computer be responsible for virtually all aspects of decision-making, allowing the operator only a limited veto? Or should the computer only be allowed to generate potential decision options, leaving the choice to the human? Specific aspects of automation have definite consequences – both good and bad – for human performance. Understanding these consequences is critical to the design decision to automate. Several other factors, including risk, reliability, safety, ease of system integration, implementation cost and liability, are also important (Parasuraman *et al*., 2000).

The developing knowledge base of human performance research can be used to design more effective automation. All too often automation has been designed with purely technical considerations in mind. This might have been justified at one time, given the relative paucity of human performance data on the use of automation, but that is no longer the case. There is now an extensive body of empirical work on human performance in automated systems. Details of this growing knowledge base, which includes cognitive theory, laboratory experiments, simulator studies, field studies, incident analyses and accident investigations, can be found in original sources and more detailed expositions (Rasmussen, 1986; Parasuraman, 1987; Wiener, 1988; Sheridan, 1992; Billings, 1997; Parasuraman and Riley, 1997; Sarter *et al*., 1997; Wickens *et al*., 1998).

Research on automation also illustrates how commonalities between basic and applied research can be revealed to their mutual benefit, even though the researchers involved may be ignorant of each other's work. The problems with high-level automation are that human operators tend not to

monitor the automation (exhibiting so-called 'complacency'), they may lose their overall 'picture' (or 'situation awareness') of the system, and their manual cognitive skills may degrade over time (Parasuraman and Riley, 1997). One solution to this problem that has been advocated by applied researchers is adaptive function allocation, in which the automated task is returned to the operator for manual performance for a brief period of time, a procedure that has several benefits (Parasuraman *et al*., 1996). The explanation is that people are more aware of their environment and can respond better to anomalies when they are actively involved in the system than when they are simply passively monitoring the system. This phenomenon has a parallel in the basic cognitive science literature on memory, as pointed out by Farrell and Lewandowsky (2000), namely the so-called generation effect (Slamecka and Graf, 1978). This refers to the improvement in memory performance when subjects have to self-generate the second half of a word pair (e.g. 'Short-T----?') compared with when they read the word pair 'passively' (e.g. 'Short-Tall') and do not have to generate a word. The reading condition, which can be regarded as a form of 'automation' because the second word is 'produced' for the subject without him or her having to do anything, leads to poorer memory performance for the word pairs compared with the generation condition, just as automation does in comparison with manual performance. Farrell and Lewandowsky (2000) accordingly developed a connectionist model of complacency and adaptive automation that had as its basis the improvement in memory strength that self-generation (or manual performance) provides. We would venture that most basic memory researchers in cognitive science are unaware of HF/E research on human–automation interaction, and perhaps vice versa. However, as this example illustrates, the two groups might do well to be cognizant of each other's work.

COGNITION AND THE PHYSICAL ENVIRONMENT

If our central thesis concerning the primacy of context for understanding behavior is accepted, then one of the obvious sequelae is that, contingent upon the present state of knowledge, one can design and fabricate environments that foster optimal performance. Up to the present time, and largely in the area of ergonomics, this idea has only been expressed as a form of defense (i.e. how to protect the individual from harmful circumstances). One of the more entertaining ways to understand this protection was suggested by Haddon (1970), who referred to dangerous environments as 'ecological tigers'. Haddon went on to describe such tigers as the uncontrolled escape of ranges of energy. In particular, kinetic, thermal, radiative and chemical forms of energy were a major concern. In typical HF/E handbooks, these are dealt with as individual concerns, such as heat stress (Hancock and Vasmatzidis, 1999), with some general overviews of system safety (Karwowski and Marras, 1999). As the currency of work has evolved from the erg to the byte, concern about major forms of physiological stress in HF/E has declined somewhat, although modern problems of manual materials handling are unfortunately alive and well, and cost the modern world many billions of dollars each year (Karwowski and Marras, 1999). Although these physical issues have been partly superseded by concerns in *cognitive ergonomics*, in the developing world ergonomics is still fundamentally considered to be the science of physical work.

If, in the past, protection in the industrial world has been concerned with physical sources of threat, contemporary concerns are much more directed towards factors that interfere with optimal productivity in more sedentary, computer-mediated work. Thus most recent ergonomic concerns have been expressed in relation to office design, such as repetitive strain trauma, seating issues, glare, lighting and the many other environmental concerns that relate to the modern workstation environment (Leuder and Noro, 1994). Those still concerned with physiological rather than psychological conditions have focused on issues of performance in exotic and threatening conditions, such as productivity in outer space and in the deep ocean. Despite our advances and sophistication, many people still have to perform hard, dirty, unpleasant physical tasks round the clock, and scientists involved in the traditional aspects of ergonomics still do a tremendous service in seeking to improve the work environment of such individuals. If protection from physical harm is the history of ergonomics, direct interaction with specific brain function is the future, and it is to this that we shall now turn.

NEUROERGONOMICS

If the view that cognition occurs in specific environments and is therefore 'situated' should not be surprising, then the realization that cognition is *embodied* should also not ruffle any feathers, and of course the brain provides the controller for the

embodiment. Until the 1980s cognitive psychology did not pay much attention to the brain. In the 1950s and 1960s, many cognitive scientists pinned all their hopes on understanding human cognition on artificial-intelligence-inspired models. Their rallying cry was that the mind is software which must be understood, irrespective of the hardware that implements it. Accordingly, the rules of mind could be as easily studied in a computer as they could in a human. The actual hardware – the structures and mechanisms of the brain – was unimportant. Similarly, HF/E has been blissfully unconcerned with the brain, even as cognitive psychology has abandoned its previous hostility to brain research and embraced the new paradigm of cognitive neuroscience (Parasuraman, 1998b; Gazzaniga, 2000).

We believe that this neglect is shortsighted. One of us (Parasuraman, 1998a, 2002) has therefore coined the term 'neuroergonomics' to refer to the inclusion of neuroscience in HF/E. Neuroergonomics can be defined as the study of brain and behavior at work. Traditionally, ergonomics has not paid much attention to neuroscience or to the results of studies of the brain mechanisms underlying human perceptual, cognitive, affective and motor processes. To paraphrase the philosopher Mario Bunge (1980), until recently psychology (and HF/E) has been 'brainless', whereas neuroscience has been 'mindless'. At the same time, neuroscience and its more recent offshoot, cognitive neuroscience, have been only partially concerned with whether their findings bear any relation to human functioning in real (as opposed to laboratory) settings, with the exception of applications to clinical disorders. Neuroergonomics is a response to this twin disregard.

To the extent that cognitive neuroscience advances theoretical knowledge of human functioning, it can influence the application of that knowledge to the design of systems. At the same time, HF/E may provide an avenue for examining the practical utility of basic findings generated by cognitive neuroscientists. There are several examples of work that can be characterized as falling within the rubric of neuroergonomics. For example, knowledge of the brain mechanisms and neurochemical systems that control circadian rhythms could be used to devise optimal schedules for shift work, or to minimize circadian disruption due to travel across time zones. This is a pressing practical problem, given that we are moving towards a 24-hour society in which up to one-third of the labor force is involved in some form of shift work.

A second example is the use of functional brain-imaging measures of cerebral blood flow to index human operator mental workload. Event-related, functional magnetic resonance imaging (fMRI) studies of visual attention (Corbetta *et al*., 2000) and working memory (Jiang *et al*., 2000) have revealed the temporal dynamics (to a resolution of the order of a few seconds) of neural activity in localized cortical regions that mediate the component operations associated with these domains of cognition. Such techniques are highly suited to the problem of evaluating mental workload during complex, multitask performance. A recent study by Peres *et al*. (2000), in which fMRI was used to evaluate the cognitive strategies of expert pilots during a simulated aviation task, provides an example of this type of research. We anticipate that there will be many more such studies in the near future. Functional brain-imaging studies of workload can considerably aid the HF/E goal of optimizing the design of human–machine systems for safe and efficient use by human operators.

HF/E IN THE TWENTY-FIRST CENTURY

Neuroergonomics represents an emergent subdiscipline of HF/E that we envisage will be prominent in the new millennium, and will take advantage of the startling pace of new developments in cognitive neuroscience. More generally, we anticipate a growing realization that brain and behavior must be examined both in relation to technology and in context. Given that computer technologies are likely to continue to predominate in the future, work on human–computer interaction will remain at the forefront of research and practice. As computers continue to increase in power and decrease in size, their omnipresence – in the daily artifacts of everyday use, in our clothes, in our modes of transportation and at home – will necessitate new conceptualizations of computers as information appliances (Norman, 2000), and new ways of examining how best to design them for effective use by humans.

SUMMARY

Through the themes that we have developed and prosecuted here, we hope to have persuaded even the most theoretical of cognitive scientists that an excursion into the world of HF/E will repay itself. Cognition is an activity that occurs in context, and the contemporary context is technology. The fact that technology itself is an outflow of cognition

completes the circle, and surely shows why these two pursuits are synergistic in their fundamental aims and processes. Furthermore, we have advocated that HF/E must be concerned with what should be, as well as with what is. This being so, cognitive science must embrace a larger and societally more influential role, since the study of the brain, as the quintessential science, is the foundation of all human aspiration. It is this knowledge and power that must be used wisely, for the true marriage of HF/E and cognitive science will change the world.

Human–Computer Interaction

Introductory article

John M Carroll, Virginia Tech, Blacksburg, Virginia, USA

CONTENTS

Human–computer interaction is an area of applied cognitive science and engineering design. It is concerned both with understanding how people make use of devices and systems that incorporate computation, and with designing new devices and systems that enhance human performance and experience.

HUMAN–COMPUTER INTERACTION AND COGNITIVE SCIENCE

Three touchstone themes are frequently sounded in cognitive science: the importance of investigating and analyzing real domains of cognition; the possible synergies between cognitive science and cognitive engineering; and the need for broader and better-integrated models and theories of cognition. These themes were heard in many of the talks at the inaugural meeting of the Cognitive Science Society in 1979, and have guided the vision of cognitive science ever since. As a scientific endeavor, the discipline of human–computer interaction (HCI) was created – largely by cognitive scientists – to address these three themes.

Investigating Real Domains of Cognition

The first decade of cognitive science research investigated the nature and role of areas of domain knowledge such as algebra, mechanics, radiology, and HCI. During the 1970s, a set of challenging cognitive issues in HCI had been identified, under the banner of the 'software crisis': programming languages were difficult to learn, programming activity was poorly supported by tools and methods, and the software produced was unreliable and hard to correct and maintain. The rapid expansion of computing into business organizations made the problems more urgent: if professional programmers could not deal effectively with computers, then who could?

HCI research in the 1980s took these problems as a realistic test-bed for assessing and developing concepts, models, and techniques from cognitive science: software design was analyzed as a type of problem solving. Learning and performance with programming languages and command interfaces were analyzed as psycholinguistic tasks. Interactions with text editors and programming tools were analyzed as cognitive skills.

This strategy proved effective. Cognitive science provided HCI with a research framework from its inception. This guided HCI researchers in planning empirical projects and making sense of results. It raised the intellectual level of early HCI research from studies of assorted problematic phenomena to studies of general issues. Throughout the 1980s, HCI research on routine expertise, ill-structured problems, concept names, mental models of hypermedia information structures, and a host of instructional technologies, from 'discovery learning' to intelligent tutoring systems, was articulated and pursued as mainstream cognitive science. HCI, in turn, provided a very high-profile case study of how real domains of cognition could be investigated. By the mid-1980s, in the wake of the personal computer 'revolution', HCI was the most visible application of cognitive science.

Synergies Between Cognitive Science and Cognitive Engineering

HCI proved to be a particularly suitable domain in which to explore the synergies between cognitive science and cognitive engineering. Software systems are highly malleable, affording powerful experimental approaches that are not possible in traditional areas of cognitive science like natural language and naive physics. Thus, the hypothesis that a command language with given linguistic properties might evoke certain patterns of confusion could quickly be tested by specifying the command mappings in a real software system. Integrating specific cognitive science research with real HCI contexts narrows the gap between building knowledge and building products, and

increases the likelihood that research outcomes will have practical import. Indeed, HCI is a paradigmatic example of Simon's 'sciences of the artificial' (sciences that investigate artifacts and systems produced by humans).

Originally, it was hoped that cognitive engineering work would contribute creatively to cognitive science. This is a sophisticated and ambitious objective: even a reliable one-way relationship between basic and applied science is fairly rare. However, direct manipulation and user interface metaphors are two examples of scientifically significant engineering developments in HCI.

Direct manipulation is a style of computer interaction whereby a person manipulates data and functions through gestures with display objects – for example, pointing and clicking in windows with a mouse – rather than by referring to data and functions by name in typed command strings. Direct manipulation was developed because it seemed to simplify and streamline human–computer interaction. Subsequently, this innovation in cognitive engineering guided the emergence of new cognitive theories of human action.

During the 1970s, user interfaces became more elaborate, developing from single input lines on a teletype to graphical displays incorporating direct manipulation. As user interfaces became more elaborate, users and designers interpreted them using more elaborate analogies: the user interface as a typewriter, as a stack of papers, as a desktop, as a virtual world. There is a considerable body of research and theory on analogy in cognitive science, and this general theory guided early design work in HCI. However, cognitive science research tends to focus on the role of analogies in attaining concepts in natural science domains. Because HCI is a design domain, it allows a far greater variety of analogies. Today there are hundreds of analogies (called user interface metaphors) employed in user interface designs.

Broader and Better-Integrated Models and Theories

Cognitive science seeks to integrate the variety of perspectives on cognition from different disciplines. It seeks to balance the tendency of researchers to focus ever deeper on problems that are ever smaller by encouraging interdisciplinary approaches to problems of broader scope. HCI is a case in point. Even the earliest cognitive modeling efforts in HCI were unusually comprehensive by the standards of the time. They had to be: in order to generate predictions about user performance in realistic contexts, the models had to make assumptions about perception, attention, short-term memory operations, planning, and motor behavior. Interestingly, these models were sometimes criticized within HCI for being incomplete and too narrow. For example, even fairly successful models of error-free expert performance were criticized for not describing error diagnosis and recovery, skill acquisition, and user affect. Over time, HCI models have become increasingly complete and comprehensive, and have had a continuing influence on modeling research throughout cognitive science.

Because HCI is defined in part with respect to computer technology, it is in some respects broader and intellectually more eclectic than cognitive science itself. HCI incorporates all ideas and technologies that facilitate understanding and enhancing the use of devices and systems that incorporate computation. Some of the ideas appropriated by HCI have pushed back the boundaries of cognitive science. An example of this is the incorporation of ethnomethodology into HCI, which occurred during the late 1980s following the publication of Suchman's book *Plans and Situated Actions*. This work had a huge influence on HCI because it demonstrated very concretely how work activity depends on coordination among participants, and how it can go awry when interactions are not sufficiently intelligible to all participants – including machines. Ethnomethodology contributed to a significant broadening in HCI theory which eventually also incorporated (Russian) activity theory, (British) sociotechnical design, (Scandinavian) participatory design, and ethnography.

In this respect, HCI appears to be able to serve as a conduit for broader theory in cognitive science. Suchman dismissed the representational theory of mind, and characterized her work as an empirical refutation of the concept of planning as developed in cognitive science and artificial intelligence. Without HCI, her work might have been ignored by mainstream cognitive science (like much other work in ethnomethodology). But in 1993, a special issue of the journal *Cognitive Science* was devoted to reconsideration of her book.

CURRENT CHALLENGES

Even the most fundamental issues in HCI are constrained by computer technology and the computing industry. It is likely that the basic scenario of human–computer interaction (namely, a person working with a keyboard, mouse, and graphic display) will change in the early twenty-first century,

perhaps radically. This will raise new challenges for HCI and for cognitive science.

Ubiquitous Computing

Many of the technologies underlying HCI improved steadily in the last quarter of the twentieth century. Increased processor capacity and memory density, and low-power displays, allowed the development of portable and handheld computers. Wireless applications are being developed and deployed rapidly, raising the possibility of totally mobile networked computing in the future. Other technologies are more specific to the user interface: examples include high-quality synthetic speech and robust speech recognition, and devices like sensing gloves, which permit finely articulated gesture input with no input surface, and heads-up displays incorporated into glasses.

These technologies could make computing invisible and ubiquitous – seamlessly, pervasively, and intimately incorporated into every facet of daily activity and experience. Ubiquitous computing raises many questions in cognitive science. How will people perceive and perform in computer-augmented realities? How will they think about and manage personal information processing when they, in effect, wear it? How will people conceive of themselves, if most human activity becomes computer-mediated?

Computer-Supported Cooperative Work

In the 1980s, the focus of HCI was on individual users: word processing and spreadsheets were HCI paradigms. In the 1990s, the focus shifted to computer-supported cooperative work (CSCW): email, instant messaging, and the World Wide Web became paradigmatic. By the end of the 1990s, these technologies had transformed many everyday activities, including shopping, information seeking, interactions with family and friends, and workplace collaboration.

The emergence of CSCW was closely linked with cognitive research in HCI, drawing upon concepts like 'common ground' from psycholinguistics, input–process–output models of group functioning from social psychology, and ethnographic and ethnomethodological models from sociology. For example, the design and investigation of relatively large-scale infrastructures like scientific collaboratories and community networks has allowed real and long-term collaborative processes to be investigated as never before. Such mediated collaborations can be more effective than face-to-face interaction when the technology makes task-irrelevant factors (like culture, age, and sex) less salient, and facilitates sharing of resources.

CSCW is also a tool for investigating traditional cognitive science issues. For example, anonymity is an important factor in problem solving activities like brainstorming, but it is difficult to study. The adoption of CSCW technology has been so rapid that studies can now be carried out in real task contexts instead of in contrived laboratory simulations. Many studies have described how anonymity can attenuate the effects of various sorts of power imbalance and evaluation anxiety, but at the same time evoke social 'loafing' and certain antisocial behaviors.

In the near future, it is likely that comprehensive collaborative environments will become widely available; tools like email, messaging and the Web will be integrated and supplemented by video conferencing and joint authoring and editing. As these CSCW technologies are deployed throughout society, further cognitive science issues will need to be addressed. For example many social practices depend upon physical or ephemeral acts and artifacts: what will happen as all data and interaction becomes digital and permanent?

Integrated Models and Theories

HCI is a good illustration of what cognitive science is about and how it operates with respect to the themes of understanding real domains of cognition, capitalizing on possible synergies between science and engineering, and developing better-integrated theories of cognition. In HCI, as in cognitive science itself, every success raises new challenges. HCI is valued and well utilized by the computer industry, but there is often tension between research and product development. HCI is a far more diverse area of cognitive theory now than it was in 1980. And the people who work in HCI now are more diverse than those who founded the discipline: they include graphic designers, electrical engineers, computer scientists, and business administrators.

The challenge now is to create an integrated cognitive science of HCI, one that encompasses the considerable range of models and theories currently in use, that defines effective tools and methods in a manner accessible to all HCI practitioners, and that anticipates likely future challenges, such as ubiquitous computing and computer-supported cooperative work.

Hypnosis and Suggestion

Introductory article

Steven Jay Lynn, State University of New York, Binghamton, New York, USA

Judith W Rhue, Ohio University, Athens, Ohio, USA
Joseph P Green, Ohio State University, Lima, Ohio, USA

CONTENTS

Hypnosis has been defined as a procedure in which a person designated as a hypnotist gives suggestions to a person designated as a subject, client, or patient for changes in sensations, perceptions, thoughts, feelings, and behaviors.

INTRODUCTION

Shrouded for centuries in mystery and myth, hypnosis has inspired equal measures of suspicion and fascination. During hypnosis, many people appear to lose control over normally voluntary behavior; some exhibit temporary, selective amnesia; they report seeing and hearing things that are not present and not seeing or hearing things that are present; while still other people report dramatic changes in sensations such as pain. Although the term 'hypnosis' was coined by the nineteenth-century British physician James Braid (1843), the dramatic changes in hypnotized subjects' appearance, experiences, and behaviors that the term encompasses had been well known for at least a half-century earlier under the names 'animal magnetism' or 'mesmerism'.

By the later eighteenth century, the idea that effects of hypnosis were due to magnetism was refuted by scientific evidence, whereas other outrageous claims – such as that hypnosis enabled the subject to see without the use of the eyes and to detect disease by seeing through the skin – were debunked by the mid-nineteenth century. Fortunately, such hokum did not dissuade the most renowned scholars of human behavior, including Sigmund Freud, Alfred Binet, William James, Wilhelm Wundt, Clark Hull, and Ernest R. Hilgard, from turning their attention to hypnosis. At the present time hypnosis is a subject of intensive investigation in psychological laboratories around the world, and is widely used as a catalyst for psychological and medical treatments.

HYPNOTIC SUGGESTIBILITY AND INDIVIDUAL DIFFERENCES

A consensus has begun to emerge about how to define hypnosis, across theorists and practitioners with widely divergent views about hypnosis. The American Psychological Association, Division of Psychological Hypnosis, has adopted a definition of hypnosis as a procedure during which changes in sensations, perceptions, thoughts, feelings, or behavior are suggested.

There are considerable differences in the extent to which people respond to hypnotic suggestions. Approximately 15–20 percent of the population is minimally suggestible, 15–20 percent of the population is highly suggestible, and the remainder of the population scores in the medium range of hypnotic suggestibility. People who are likely to respond to hypnotic suggestions exhibit the ability to respond to waking imaginative suggestions, almost to the same degree that they do during hypnosis. In addition, responding to suggestion is correlated with positive beliefs, attitudes, expectancies, and motivation to respond to the hypnotist's suggestions. Some studies have shown that imaginative abilities, fantasy proneness, dissociative experiences, a tendency to become absorbed in experiences, and openness to experience also contribute to hypnotic suggestibility. However, questions have been raised about whether the correlations between hypnotic suggestibility and measures of these constructs are inflated simply because they are measured in the same test context. Studies have shown that when hypnotic suggestibility and these

measures are tested in independent contexts, the correlations are either not statistically significant or very small in magnitude. Nevertheless, research into individual differences in hypnotic suggestibility remains a fruitful and important area of inquiry.

FACTS ABOUT HYPNOSIS

Many misconceptions about hypnosis come from movies, television, books, and stage hypnosis. Individuals who hold the popular yet mistaken belief that only gullible people respond to hypnosis, or that hypnosis induces a sleep-like trance state marked by loss of control, are not likely to respond fully to hypnotic suggestions. Contrary to popular misconceptions, hypnosis is neither sleep nor relaxation; suggestions that emphasize alertness are as effective as suggestions that emphasize drowsiness and relaxation. Additionally, participants retain control during hypnosis and can refuse to respond to suggestions if they wish.

Research has also documented the following points:

- Most hypnotized people are neither faking nor merely complying with suggestions.
- Suggestions can be responded to with or without hypnosis. The function of a formal induction is primarily to increase suggestibility to a small degree.
- A wide variety of hypnotic inductions can be effective. Authoritative, traditionally worded hypnotic techniques are as effective as permissive, open-ended, suggestions.
- All of the behaviors and experiences occurring in hypnosis can also be produced by suggestions given without the prior induction of hypnosis.
- Hypnotic suggestibility is relatively stable, with test–retest correlations reported as high as 0.71 over a 25-year follow-up. This stability has been variously described as a reflection of the trait-like aspects of hypnotic suggestibility or a reflection of attitudes and beliefs about hypnosis, and interpretations of hypnotic suggestions that remain stable over time.
- Hypnotic suggestibility can be substantially modified by training programs that: (a) inculcate positive attitudes, beliefs, and expectancies about hypnosis; (b) instruct participants to imagine and get involved in test suggestions; and (c) train individuals in how to interpret correctly the implicit requirements of test suggestions (e.g. not passively wait for a response to occur to a suggestion for hand levitation).
- Hypnosis depends more on the efforts and abilities of the subject than on the skill of the hypnotist.
- Subjects typically remain aware of their surroundings and recall what transpired during hypnosis.
- Hypnosis is not a dangerous procedure when practised by qualified clinicians and researchers.
- Some studies suggest that hypnotic suggestibility is related to dissociative disorders, posttraumatic stress disorder, and phobias.
- Reliable physiological indicators of hypnosis, independent of the effects of administered suggestions, have not been identified in well controlled, consistently replicated studies.
- Hypnosis does not permit subjects to literally re-experience the events of childhood or to function in a truly child-like fashion.
- Hypnosis increases inaccurate as well as accurate memories and tends to inflate confidence in what is remembered, regardless of accuracy.

HYPNOSIS IN THE LEGAL ARENA

Concerns about the reliability of hypnotically enhanced recall have led many psychotherapists to eschew the use of hypnosis to recover memories of purportedly repressed traumatic events. Relatedly, many courts in the USA have expressed serious concerns about the admissibility of hypnotically elicited testimony and have banned the entire testimony of a witness subjected to hypnosis for memory retrieval. Some courts have stipulated that hypnotically augmented testimony can be admitted only when certain procedural guidelines and safeguards are implemented in the way hypnosis is conducted, while a number of states and federal courts allow exceptions to the 'admissibility with safeguards' rule and, instead, apply a 'totality of circumstances' test. When the latter test is applied, the case is judged not so much in terms of whether specific guidelines were followed or not, but in terms of the 'totality of circumstances' that attended the hypnosis session. However, the majority of states (25 of 30 state supreme courts that have ruled on admissibility of hypnotically elicited testimony) have rejected the idea of admitting hypnotic testimony on a case-by-case basis and considering the totality of circumstances; they have, instead, opted for excluding hypnotically elicited testimony.

THEORETICAL ACCOUNTS

Different explanations of hypnosis have been as vigorously debated as the use of hypnosis in the courtroom. Hypnosis was traditionally regarded as an altered state of consciousness (or trance), and the effects of hypnotic suggestion were hypothesized to be due to the induction of that hypothesized state. However, beginning in the 1950s, the socio-cognitive theorists Theodore Sarbin and T. X. Barber rejected the idea that hypnotic responses were due to an altered state, and maintained that

all the phenomena of hypnosis, including behavioral responses to suggestion, and even the subjective experience of a trance state, can be accounted for without postulating any special state or condition. From this perspective, and the vantage point of other socio-cognitive theorists such as Spanos and Chares, Kirsch, Lynn and Rhue, and Wagstaff, hypnotic behaviors are like other complex social behaviors; they are a product of such factors as ability, attitude, belief, expectancy, attribution, and interpretation of the situation.

Neodissociation theories have emerged as strong competitors of sociocognitive models. Hilgard's neodissociation theory is based on the idea that there exist multiple cognitive systems or cognitive structures in hierarchical arrangement under some measure of control by an 'executive ego'. The executive ego or 'central control' structure is responsible for planning and monitoring functions of the personality. During hypnosis the hypnotist's suggestions take much of the normal control away from the subject. An amnesic barrier prevents conscious awareness of particular ideas, imaginings, and fantasies, thereby producing the subjective impression of nonvolition that typically accompanies hypnotic responses.

Whereas neodissociation theorists contend that an altered state is a characteristic of the person at a descriptive level, they do not claim that a particular altered state of consciousness explains or causes hypnotic phenomena. In fact, when the term 'hypnotic state' is used by researchers today, it is usually used merely in a descriptive sense to denote the subjective changes that hypnotized subjects report experiencing. It is not used to explain those changes. Instead, most hypnosis researchers agree that the impressive effects of hypnosis stem from social influence and personal abilities, not from a trance-like state of altered consciousness.

A number of other theories of hypnosis have been proposed. These include psychoanalytic theories, psychobiological models, interactive-phenomenological models of hypnosis, the theory of dissociated control, and derivatives of traditional trance theory. Despite considerable agreement on the basic empirical findings, there is no consensus on how those findings are to be explained.

CLINICAL HYPNOSIS

There is considerable consensus regarding the fact that hypnosis can have great clinical value. Hypnosis is not a type of therapy, like psychoanalysis or behavior therapy. Instead, it is a procedure that can be used to facilitate therapy. As it is practised today, clinical hypnosis can be defined as the addition of hypnosis to accepted psychological or medical treatment.

Hypnosis can have clinical utility for a number of reasons. Hypnosis can foster a positive collaborative working alliance with the client, provide a structure for therapeutic suggestions and activities, and facilitate a focus on selected thoughts, feelings, images, and experiences that could never occur in reality. Hypnosis also provides a context in which clinicians can do the following: (a) talk with clients in metaphoric, rather than strictly literal terms; (b) use suggestions and imagery to desensitize fears and rehearse coping responses to stressful tasks and situations; (c) interrupt negative patterns of thoughts, feelings, and behaviors; and (d) enhance positive affect and feelings of self-control. Hypnotic procedures can be defined as 'self-hypnosis' to enhance perceptions of treatment success and the likelihood that what is learned during the therapy hour will be implemented in everyday life. Additionally, posthypnotic suggestions (e.g. relaxation, calmness) can be used to generalize treatment gains to everyday life. Because many clients have positive attitudes about hypnosis, the hypnotic context may enhance their confidence in the effectiveness of therapy and thereby produce a placebo effect without the deception that is generally associated with placebos.

Meta-analyses have demonstrated that the addition of hypnosis to cognitive–behavioral and psychodynamic treatments substantially enhances their efficacy. Positive effects of hypnosis were associated with the treatment of hypertension, anxiety, phobias, and duodenal ulcers. But the most impressive effect was found for weight reduction treatments, and this was particularly impressive at long-term follow-up.

Recent reviews that have examined the empirical support for hypnosis as an adjunctive intervention revealed that: (a) suggestion can be a very effective means of alleviating severe and persistent pain and that this effect is not restricted to highly suggestible clients; (b) hypnotic procedures generally yield higher rates of smoking abstinence relative to deferred treatment (i.e. wait list) and no treatment conditions; (c) hypnosis can successfully treat a variety of medical conditions such as irritable bowel syndrome, dermatological disorders, and postchemotherapy nausea and emesis, and can assist in the preoperative preparation of surgical patients; and (d) there are indications that hypnosis can be useful in the treatment of trauma and the treatment of children with a variety of conditions

including nocturnal enuresis and pain associated with medical operations.

CONCLUSION

Hypnosis has fired the imagination of scholars, researchers, and clinicians for more than 200 years. However, it is only in the past half-century or so that hypnosis has received the empirical attention and status in the scientific community that it deserves. The study of hypnosis has the potential to shed light on the way that interpersonal communications can be transformed into deeply felt subjective experiences, with vital power to relieve human suffering. Hypnosis researchers have contributed to our knowledge of the determinants of profound alterations in consciousness, the role of imagination and fantasy in everyday life, the link between responses to suggestion and physiological processes, the genesis of false memories, and the way that expectancies shape myriad subjective and behavioral responses. The study of hypnosis will contribute as much to our understanding of basic cognitive and interpersonal processes as insights from social, cognitive, and biological psychology will contribute to our understanding of hypnosis.

Idioms, Comprehension of

Intermediate article

Patrizia Tabossi, Università degli Studi di Trieste, Trieste, Italy

CONTENTS

Idioms are fixed expressions whose meaning is not a direct function of the meanings of their parts. Their comprehension involves both recognition and parsing processes, and hinges upon people's pragmatic as well as syntactic and semantic competence.

IDIOMS: A CHALLENGE TO CURRENT MODELS OF LANGUAGE COMPREHENSION

Idioms are usually characterized as strings of words whose meaning is not a direct function of the meanings of their parts. For example, the meanings of the words *kick*, *the*, and *bucket*, composed according to the syntactic relations among them, do not produce the meaning 'die suddenly'. This is conventionally associated to the string and a person must know the convention in order to correctly understand it.

Thus, idiomatic expressions defy the standard view of language comprehension according to which understanding a sentence requires at least recognizing the words in the sentence, retrieving from the mental lexicon the different types of information associated with them, and combining their meanings according to their grammatical relations. (*See* **Language Comprehension**; **Parsing: Overview**; **Sentence Processing**; **Sentence Processing: Mechanisms**)

Idioms are multifaceted objects with properties along several distinct dimensions, including the following:

Informality
Idioms are used more frequently in spoken than written language, typically in colloquial and informal situations. They, along with other tropes such as metaphor, irony, or metonymy, convey meaning in a vivid fashion, and usually possess an affective connotation.

Figurativeness
We often perceive that some degree of figurativeness is involved in the meanings of many idioms When we are able to recover the relation between their literal and figurative meanings, the idioms are said to be transparent (e.g. *sweep under the carpet*); otherwise they are opaque (e.g. *kick the bucket*).

Frozeness
Frozeness refers to the fact that typically idioms occur only in limited syntactic constructions. Idioms are very different with respect to the syntactic operations that they can undergo. While some are almost completely unconstrained (e.g. *spill the beans*, *let the cat out of the bag*), others allow very few operations, if any (e.g. *by and large*, *trip the light fantastic*).

These characteristics are not necessary features of idioms. *Pay attention to* or *care for*, for example, can easily be used in formal occasions, and figuration is hardly involved in idioms like *by and large* or *try for*. However, they tend to be related to one another and to other characteristics in interesting ways. Frozeness, for example, often co-varies with opacity and ill-formedness, i.e. an idiom's lack of a literal interpretation. In fact, ill-formed idioms tend to be less syntactically flexible than well-formed ones, and typically involve little or no figuration.

In general, idioms constitute a very heterogeneous class of expressions. Although these expressions do not appear to serve a logical function in language, they are very common and reflect our tendency to say things in conventionalized ways. How are these elusive expressions understood?

THE 'CLASSIC' VIEW

Traditionally, idioms have been considered as one of the many forms of figurative language, and have been conceived as 'dead metaphors', i.e. expressions which were once innovative but are now conventionalized. Within this framework, idiomatic understanding occurs only after the literal analysis of the string has failed or its outcome does not fit in the context. At this point, the comprehension system goes into a special mode to retrieve the

string's conventional interpretation from an idiom list (Bobrow and Bell, 1973). (*See* **Metaphor**)

The idiom list hypothesis predicts that comprehending an idiomatic expression should take longer in its figurative than in its literal meaning. Empirical evidence, however, fails to support this claim. Understanding the figurative meaning of an idiomatic expression is a fast process; even faster than understanding the expression's literal meaning. To cope with these findings, Swinney and Cutler (1979) proposed the lexical representation hypothesis. According to this influential view, idioms are stored in the mental lexicon as long, morphologically complex words, and are recognized like any other lexical item. The process of idiom identification starts at the beginning of a string, and runs in parallel with the computation of its literal meaning. However, computing is a longer process than retrieving; hence, the idiomatic meaning of the string becomes available before its literal one. (*See* **Lexicon**; **Lexical Semantics**; **Morphology**; **Lexical Access**; **Word Recognition**)

This view correctly accounts for the basic fact that idioms are easy to understand. Several lines of investigation, however, have recently challenged its claims.

NOT JUST COMPLEX WORDS

Compositionality

Some years ago, Nunberg *et al*. (1994) argued that although idioms have conventional meanings, at least some of them are combining expressions. There are many idioms, in fact, whose constituents 'carry identifiable parts of their idiomatic meanings'. In *spill the beans*, for example, there is a clear, albeit motivationally opaque, correspondence between *spill* and *beans* and the relevant parts of its figurative meaning 'divulge information'. This analysis fits well with the intuitions of people who are relatively consistent in their ratings of idioms' compositionality and seem to be faster at understanding decomposable than nondecomposable idioms (Gibbs *et al*., 1989).

Syntactic Parsing

Peterson *et al*. (2001) investigated the relationship between syntactic processing and availability of figurative meaning during the comprehension of well-formed idioms. They found that the syntactic parsing of an idiomatic expression continues even after its figurative meaning has been retrieved and the computation of its compositional semantics terminated. These findings suggest that a full syntactic analysis of the idioms is always computed, regardless of the status of their literal interpretation. (*See* **Sentence Processing**; **Sentence Processing: Mechanisms**)

Flexibility and Productivity

Idioms may be not only syntactically but also lexically flexible: a word in an idiom can be substituted by a synonym, leaving the meaning and the acceptability of the string virtually unchanged (e.g. *hit the hay* and *hit the sack*) (Gibbs *et al*., 1989). Furthermore, idioms can be altered productively to create new variants. *Shatter the ice*, for example, modifies the meaning of *break the ice*, adding a striking alternative to the original meaning of breaking down an uncomfortable social situation. McGlone *et al*. (1994) compared the reading times of sentences containing idiomatic strings in their canonical form (e.g. *He had two left feet*), in their variant form (e.g. *He had three left feet*), or in their respective literal paraphrases (e.g. *He was extremely clumsy*, *He was incredibly clumsy*). The canonical form was read faster than either variants or paraphrases. However, the latter two did not differ from each other, suggesting that they are processed in much the same way, i.e. compositionally.

Recognition

Scrape the bottom immediately calls to mind *of the barrel*, whereas *hit the nail* does not makes one think of its idiomatic conclusion *on the head*. Tabossi and colleagues referred to the two types of idioms as predictable and nonpredictable, and named as key the word following which idioms come to mind. In a series of studies, they explored the time course of activation of the figurative meaning of early and late key idioms. Idiomatic meanings were found to activate sooner in early than in late key expressions, but never at the beginning of the strings.

This suggests that the recognition of idioms and words may differ in important ways. It is generally agreed that spoken word recognition is a continuous process involving the initial activation of multiple lexical candidates. However, the activation of idiomatic meanings is rather slow. Moreover, it is influenced by factors different from those relevant in word identification. In particular, an idiom key,

unlike a word's uniqueness point, indicates a point at which a string can still have multiple completions, and, unlike the recognition point, does not depend on the context of the occurrence of an idiomatic string (Cacciari and Tabossi, 1988; Tabossi and Zardon, 1993). (*See* **Word Recognition**)

A NEW PERSPECTIVE

In light of these findings, Cacciari and Tabossi (1988) proposed that idioms are mentally represented as configurations of words whose meanings become activated whenever sufficient input has rendered the configuration recognizable. A configuration is made up of the same lexical items that need to be activated during the comprehension of literal discourse; at what point in the string the idiomatic meaning is activated depends on the position of the key in that string.

This hypothesis explains how idioms are recognized in their canonical form and is compatible with the fact that they are fully parsed. It also complements current views on idiom comprehension (Glucksberg, 2001).

But at present, there is no full-blown theory that can account for the various limitations that apply to the different idioms, and explain, for example, why people are reluctant to interpret the *bucket was kicked* idiomatically, even though they cope perfectly well with *the beans were spilled*. However, a promising working hypothesis is that the variations an idiom can undergo without losing its figurative interpretation are constrained by (at least) the following factors:

The syntactic and semantic properties of its parts. *Kick*, for example, denotes a discrete action and its progressive form can only refer to the repetition of the action. However, one cannot repeatedly die, and hence *kicking the bucket* is not usually acceptable in its idiomatic meaning.

The idiomatic meaning of the string. Dying can occur tragically, but not sharply. Accordingly, *He tragically kicked the bucket* is acceptable, but *He sharply kicked the bucket* is not.

The pragmatic function of the variation. It is true in general that variations are introduced for communicative reasons, without which they sound odd. *The bucket was kicked by John* sounds odd because no entity in the discourse corresponds to the bucket, and the expression is therefore contextually inappropriate.

Depending on whether all, some, or none of these constraints are satisfied, a variation will result in an expression which will be perceived as ranging from perfectly appropriate to totally unacceptable.

IMPLICATIONS FOR THEORIES OF LANGUAGE COMPREHENSION

In current psycholinguistics, idioms are relegated to the sidelines. Research on language comprehension tends to focus on the lexicon: how individual words are mentally represented and recognized. It also concentrates on the parsing processes which lead people to compositionally reconstruct the semantic interpretation of ever-new sentences. No doubt, this approach captures the crucial fact that people use language creatively. However, in its rigid distinction between what is creative – the syntax – and what is not – the lexicon – it may incur the risk of underestimating the relevance of people's use of conventional language. (*See* **Lexical Access**; **Lexical Ambiguity Resolution**; **Means–Ends Analysis**; **Sentence Processing**; **Representations Using Formal Logics**)

Idioms constitute an important part of the vast family of fixed expressions which includes compounds (e.g. *frequent flyer program*), names (e.g. *Boston Pops Orchestra*), clichés (e.g. *gimme a break*), titles of songs, books, movies (e.g. *All You Need is Love*), quotations (e.g. *May the force be with you*), foreign phrases (e.g. *C'est la vie*). The number of fixed expressions that we have available for use is comparable with the number of individual words. It is a reasonable assumption that these expressions, which can hardly be considered marginal, are represented in the lexicon (Jackendoff, 1995). Hence, no theory of the lexicon may aspire to be psychologically adequate unless it provides an acceptable account of how fixed expressions are mentally represented and processed.

The complex nature of idioms with respect to compositionality and syntax makes them a rather special type of fixed expression, and lexical processes are unlikely to account for how people understand the variants that each idiom can take. The study of idiom comprehension suggests that much of their syntactic behavior may be explained outside the syntactic realm. This factor highlights the need for a greater integration of the syntactic, semantic, and pragmatic aspects of people's competence to appropriately understand their actual use of language. (*See* **Modularity**)

Illusions

Introductory article

Richard L Gregory, University of Bristol, Bristol, UK

CONTENTS

The senses we rely on for knowing the world about us, such as sight and hearing, can suffer dramatic errors known as illusions. Illusions of sight are the best-known and have been used to elucidate the nature of visual perception.

INTRODUCTION

We rely on our sense of seeing – and hearing, touching, tasting, smelling and so on – for surviving, and knowing the world of objects. However, our senses are not completely reliable. They can suffer dramatic errors known as 'illusions'. These may occur when the sense organs (the eyes, ears, and so on) are physiologically disturbed; or, very differently, illusions can occur when we perceive special kinds of objects, even though the physiological function is normal. Some distortion illusions occur for pictures, though not for normal objects. Illusions of sight have been most studied, and will be mainly considered here. Theories are controversial: the following text presents one view of illusions.

There are many kinds of illusions, and there are many causes. Some are dangerous; some are useful, especially for artists. Understanding the phenomena of illusions is useful in science – for finding ways of avoiding them, and for discovering how perception works. They have interested people for centuries, including the ancient Greek philosophers, although the latter's knowledge of perception was limited. They did not even know that eyes have optical images. Illusions can be dangerous for flying or driving: but are useful for special effects in the cinema.

It is surprisingly hard to define the concept of illusion. Illusions are departures from truths of object reality; but how should we define, or indeed recognize, truths of what objects really are? This is not a 'merely academic' question, for there are very different accounts of reality in science, in art and religions, and the many flavors of metaphysics. Science's accepted realities grow ever further from how things appear to common sense. Objects do not look at all like the descriptions of physicists, and (as John Locke realized in the seventeenth century) much that appears inherent in objects is created by the mind or brain, including colors.

Science's accepted reality changed from the 'mechanistic' physics of the nineteenth century, to the quantum physics and relativity of the twentieth. As science departs ever further from commonsense appearances, we may be tempted to say that all experience is illusion; but this is no more helpful than saying that reality is a dream. If we say this, 'dream' simply loses any meaning. The problem is to decide which, of various candidates, we should accept as the reference reality for recognizing departures of illusion.

The familiar visual illusions figures, in children's books and texts of psychology, are departures from simple measurements of lengths, curvatures of lines or edges, and so on. There are also simply measured illusions of speed, temperature, and nonvisual illusions of weight and time. The reference we accept for judging illusions seems to be the world of 'kitchen physics' – simple measurements with rulers, scales, clocks, and thermometers. It is indeed because perceptions of length, weight, time and so on are subject to illusion, that these instruments have been so important for crafts and science.

There are also 'qualitative' illusions – especially mistaking one object, or kind of object, for another. There can be spontaneous alternations – the brain never making up its mind. Such ambiguities are important for showing that perceptions are guesses – perceptual hypotheses – of what might be out there in the world of objects. Some illusions cannot be matched against 'reality'; for there are perceptual fictions, and also paradoxes, which do not exist in the physical world, yet are seen.

KINDS OF ILLUSIONS

There are four principal phenomena of visual illusion: ambiguities, distortions, paradoxes, and

fictions. It may be no accident that these correspond to errors of language, for language may have developed from ancient, prehuman, perceptual classification of the world of objects and of actions. This could explain how language developed so fast in humans.

Ambiguities

A retinal image – like any picture – is infinitely ambiguous. It could correspond to, or represent, an infinity of shapes and sizes and distances. Thus, an ellipse in a drawing could represent a tilted circle, which might be small and near, or distant and large. The possibilities are endless; yet amazingly, we generally see just one of the infinite possibilities. How the visual brain usually selects a single possibility is not fully understood.

The term 'ambiguity' is itself ambiguous. It can mean several possibilities though but one or a few are seen or chosen. Alternatively, it can mean spontaneous changes of perception, as occurs with the images in Figures 1 and 2. The first is passive confusion of different stimuli or patterns; the second is active generation of alternative perceptions from the same stimulus or pattern.

Figures that flip between a few possibilities (ambiguous figures) show the dynamics of perception, as guesses of what might be out there; for perception creates hypotheses of object reality. Ambiguities are spontaneous changes between visual hypotheses, though there is no change in the object. The primary ambiguity is between something and nothing: objects, and spaces between objects (Figure 1). Objects can also 'flip' in orientation; a well-known example is the Necker cube (Figure 2). A well-known example of change of object is the old woman/young woman image in Figure 3.

Dynamic ambiguities are useful for research into how perception works, as perceptions change though the objects remains unchanged. This shows

Figure 1. Ambiguity: Spontaneous changes of perception occur in which the figure is either present or absent.

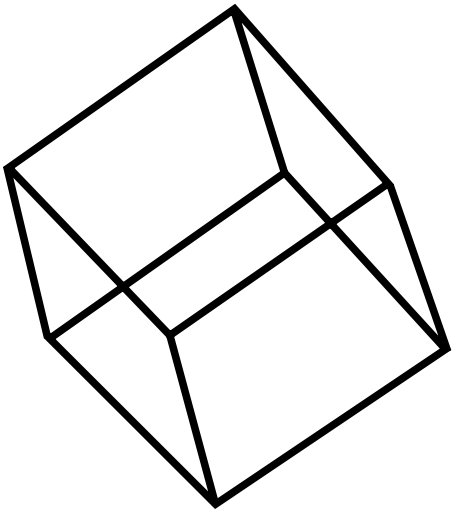

Figure 2. The Necker cube, which 'flips' in orientation. This was discovered by the Swiss crystallographer L. A. Necker in 1832 while drawing rhomboid crystals seen through a microscope.

Figure 3. Old woman or young woman?

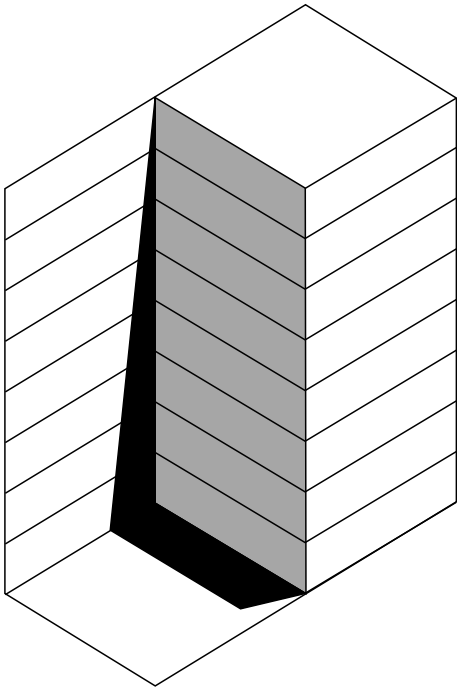

Figure 4. Mach corner (or card). A shadow (or painted shadow) on a card bent to this shape changes brightness each time the corner 'flips' in depth. When 'in' it is darker than when seen as 'out': this is because when 'in' it is accepted as a shadow, and shadows are minimized as they are not behaviorally significant objects.

Figure 5. The hollow side of the mask appears as a normal face because the hollow form is too unlikely to be seen.

that perceptions are not directly linked to objects. More technically, they allow us to separate 'bottom up' signals from the eyes, from 'top down' knowledge of objects, stored in the brain. Much of what is seen is psychologically projected into the world, especially colors, which are created in the brain although they appear to lie on the surface of external objects. A revealing demonstration by the

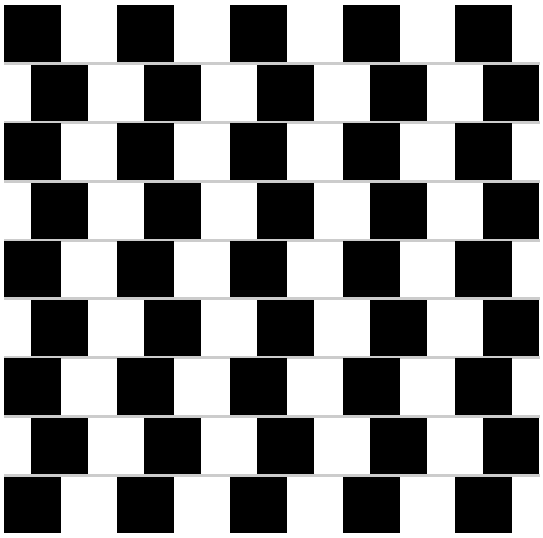

Figure 6. The 'café wall' distortion illusion. The alternating light and dark 'tiles' are rectangles, and the horizontal 'mortar' lines are parallel, although they appear as wedges.

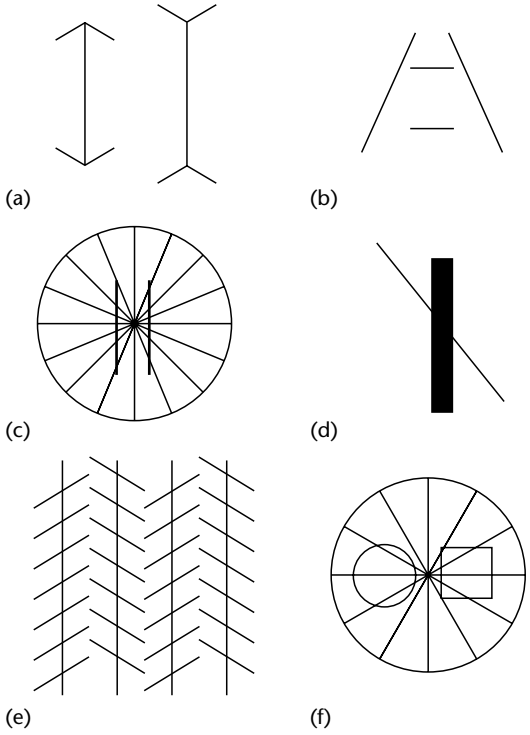

Figure 7. Cognitive distortions. The illusions of (a) Müller-Lyer, (b) Ponzo, (c) Hering, (d) Ponzo, (e) Zollner and (f) Orbison (two combined).

Austrian physicist Ernst Mach (1838–1916) shows how simple sensations such as brightness are affected by how a figure or an object is seen in different ambiguous states (Figure 4). This illusion

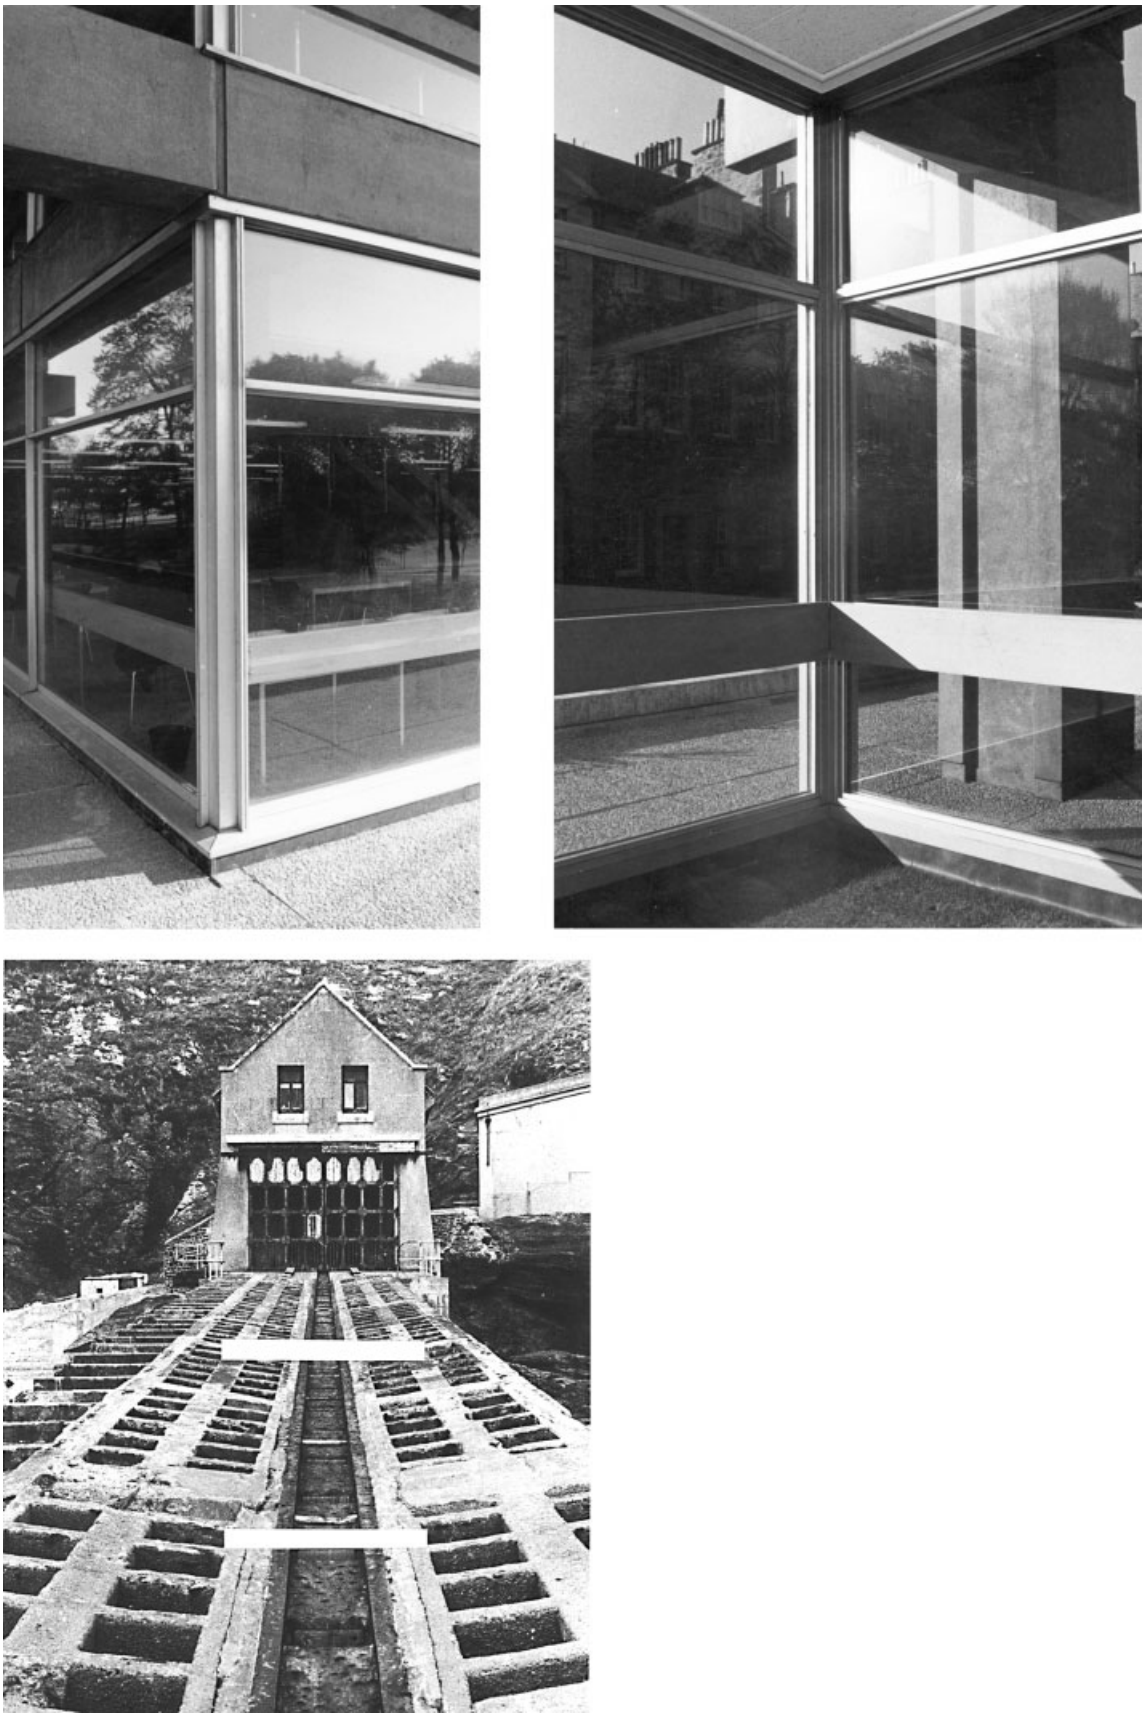

Figure 8. Distortion figures correspond to typical perspective depth.

shows something of the power of 'top down' knowledge in visual perception. Anatomically there are more descending nerve fibers from the cortex than ascending nerve fibers from the eyes. Vision therefore seems to be more 'top down' than 'bottom up': it depends more on knowledge from the past than on signals from the present. So, although not all of perception is in the mind, most of it is! This is surprising, and not all authorities would agree.

The most dramatic demonstration that knowledge is important for perception is the 'hollow face' (Figure 5). Although hollow, it appears to be a normal face with the nose sticking out – simply because a hollow face is too unlikely to be seen. This is strong evidence of the power of 'top down' knowledge to challenge and beat 'bottom up' signals from the eyes, including considerable stereopsis. It works for any object that is very unlikely to be hollow, but is most effective for a typical human face; like Jekyll and Hyde, it morphs from outside to inside face and back again, without becoming (as it truly is) hollow.

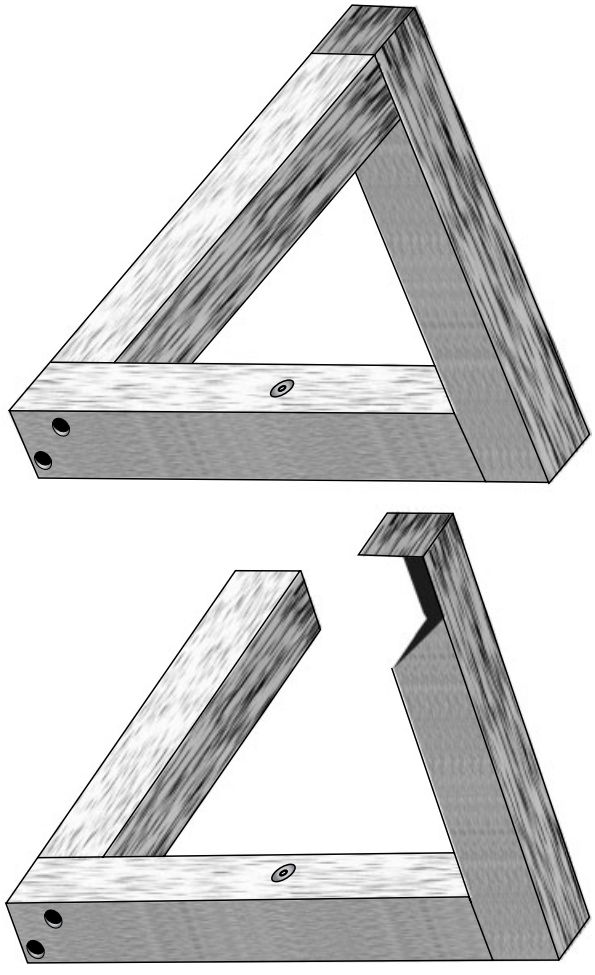

Figure 9. Paradoxical illusion: the 'impossible triangle'. It appears to be impossible when viewed from one position (top), but when seen from a different viewpoint (bottom) it becomes a realistic object.

Distortions

It is well known that size and shape may be distorted in simple illusion figures. Many of these were discovered by physicists and astronomers in the nineteenth century, when designing hairlines for eyepieces of optical instruments – to make their measurements more accurate! There is a longstanding controversy as to whether these are due to distortions of signals from the eyes, or whether they are cognitive in origin. It turns out that there are these two very different kinds of distortions, which may be hard to distinguish experimentally. The 'café wall' illusion (Figure 6) is almost certainly due to physiological signal distortion.

Figure 7 gives well-known examples of what are almost certainly cognitive distortion illusions. Among the best known, and easiest to measure, is the Müller-Lyer image (Figure 7(a)). The line between the outward-pointing arrows looks longer, even though both lines are the same length, as may be checked with a ruler – though the ruler may appear distorted! The illusions in Figure 7 are associated with perspective, signaling depth in flat pictures. The outgoing fins of the Müller-Lyer image may represent an inside corner of a room, the ingoing ones an outside corner of a building.

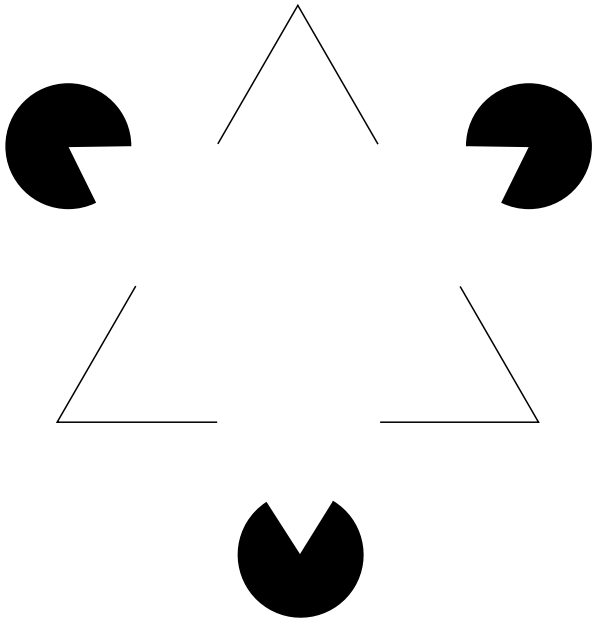

Figure 10. Fiction illusion: the 'ghostly triangle'.

The Ponzo illusion (Figure 7(b)) is a perspective of parallel lines, such as a road or railway. In all cases, features represented 'further' are seen as 'larger'. The idea is that size scaling is set by these perspective distance cues. Objects are normally seen as much the same size over a wide range of distance – although the retinal image shrinks with object distance. This shrinking with distance is normally compensated by active 'size scaling'. The idea, here, is that the perspective in flat pictures sets size scaling almost as for normal scenes (Figure 8), but as the pictures are flat, this normally useful compensation produces distortion – expanding features that are signaled as distant in the flat picture.

It is important to note that in pictures, depth cues such as perspective set constancy scaling even though the figure is seen as flat. When seen with appropriate depth (with a stereoscope) the distortions disappear. This shows they are cognitive phenomena. This is very different from the café wall illusion in Figure 6, in which the illusory wedge distortion occurs with no perspective or other depth cue. It is caused by the brightness contrast across the neutral 'mortar' lines pulling the edges together for half of each 'tile', forming small wedges, which integrate to give the long wedges across the figure. These 'physiological' processes are very different from the 'cognitive' distortions, given by depth cues mis-setting size scaling.

Paradoxes

Many perceptions are unlikely – some are impossible. Because probable alternatives of ambiguous figures are favored this is surprising, demanding explanation. It fits the view that perceptions are hypotheses generated by rules. Similarly, hypotheses of science can be paradoxical when generated by rules from incorrect assumptions. The best-known perceptual paradox is the 'impossible triangle', devised by the English geneticist Lionel Penrose and his son the cosmologist Roger Penrose (Figure 9). It can be an object, made of wood, but is paradoxical when seen from a certain position. This paradox arises from the visual rule that touching features are most likely to be at the same distance. Here this assumption is false, as the ends do not touch in the third dimension, though they do at the retina. This false visual assumption generates the paradox.

Table 1. Classification of illusions

Kinds	*Physical*		*Cognitive*	
	Optical	*Physiological*	*Rules*	*Knowledge*
Ambiguous	Cataract Mist and fog Some shadows	Retinal rivalry	Figure–ground Ames window 'Twin peaks' (Patric Hughes)	Vase–face Duck–rabbit Necker cube Hollow face Johansson dots
Distortion	Astigmatism (shape)	Café wall	Müller-Lyer	Size–weight (smaller object feels heavier)
	Mirage (of place)	Tilt after-effect	Ponzo	Mystery spots (tilted room)
		Color contrast	Poggendorff	Induced movement?
	Mirror reversal (physics: not optical)	Pulfrich pendulum	Zollner Sander's parallelogram Horizontal–vertical?	
Paradox	Looking-glass (oneself doubled)	Rotating spiral (expands without getting larger)	Impossible triangle (figure and model) Devil's fork Shepard's elephant	Magritte painting of man in mirror – the face appearing instead of the back of the head
Fiction	Rainbow	After-images (brightness and color)	Ilusory edges and surfaces (Schumann, Kanizsa)	'Faces in the fire'
	Moiré patterns	Mach bands Autokinetic movement Phi movement Bidwell's ghost		Ink blots

Fictions

The most famous fiction illusion is the 'ghostly triangle' of the Italian artist–psychologist Gaetano Kanizsa (Figure 10). Gaps may be actually gaps, or may be due to some nearer eclipsing or occluding surface, hiding part of the object. When vision postulates a nonexistent nearer object to 'explain' the gap, an illusory surface is seen. This process is generally useful: small blind regions of the eye (including the blind spots, where the optic nerves leave the retinas) are usefully filled in, to be invisible and so not distracting.

CLASSIFYING ILLUSIONS

Classifying phenomena is important in science. Illusions may be classified by appearances and causes. Some are caused by physical (optical) effects, between objects and the eyes; others by physiological disturbance of neural signals; others by cognitive misreading of neural signals. A classification in these terms is given in Table 1.

WHAT CAN ILLUSIONS TELL US?

- Perceptions are indirectly related to the object world.
- Perceptions are guesses – predictive hypotheses – which may be wrong (illusory) in characteristic ways.
- The main kinds of illusions are: ambiguities, distortions, paradoxes, and fictions.
- Phenomena of illusions can be used to discover principles of perception: adaptations (especially distortions) can tease out physiological channels; ambiguities can separate 'bottom up' signals from 'top down' knowledge; paradoxes can reveal cognitive rules and assumptions; and fictions can show rules of creativity.
- Some illusions are useful, especially for artists; some can be dangerous.
- Realizing that we are all subject to illusions might make us generally more tolerant and less dogmatic.

Imagery

Introductory article

Maryjane Wraga, Smith College, Northampton, Massachusetts, USA
Stephen M Kosslyn, Harvard University, Cambridge, Massachusetts, USA

CONTENTS

A mental image is an internal representation that produces the experience of perception in the absence of the appropriate sensory input.

INTRODUCTION

The term 'mental imagery' historically has been used in two ways. The first refers to the subjective experience of 'seeing with the mind's eye', 'hearing with the mind's ear', and so on. The second refers to the current usage in cognitive science, that defines mental imagery as an internal representation that gives rise to the experience of perception in the absence of the appropriate sensory input. This scientific sense of the term construes imagery as a perceptual representation, stored in short-term memory and corresponding to a particular brain state. The conscious experience of imagery is thought to be a byproduct of the brain state.

Imagery traditionally has been studied via several methodologies, ranging from observations of behavior (e.g. recording response times and accuracy levels of imagery task performance) to neuropsychological techniques (e.g. observing imagery deficits following brain damage; recording brain areas activated during imagery tasks). Because research on mental imagery has focused primarily on visual imagery, we will focus on this type of imagery in this article.

USES OF IMAGERY

Mental imagery is a versatile cognitive ability. In this section we examine its functions, as well as situations in which it appears to be used spontaneously.

Predicting the Outcomes of Actions

One of the main functions of imagery is to help people reason and solve problems by allowing them to predict the outcome of a given action. Such actions can involve the imagined movement of objects or the observer. For example, when packing up a moving van, individuals can visualize the most efficient arrangement of their belongings before actually placing any of the items. In attempting to cross a rock-strewn stream, the safest route can be plotted by imagining jumping along the path of rocks that best affords a dry, sturdy crossing. In each case, the observer creates an imagined scenario and 'watches' what happens in order to solve the problem.

Creating Mental Models

Imagery can also be used to reason on a more abstract level. For example, consider the following problem: Rich is older than Pete, and Paul is younger than Pete. Who is the oldest? One way to solve the problem is to imagine each person as a dot appearing sequentially on a vertical line. If the dots are ordered from bottom to top according to chronological age, then solving the problem becomes the simple matter of observing which dot is at the top. Such strategies may aid in language comprehension by allowing one to create a mental model of what is said.

Visualizing and Retrieving Memories

Another purpose of mental imagery is to help one remember information that may not have been noticed in detail at the time a memory was encoded. For example, when asked a question such as 'What geometric shape most closely resembles a cat's ear?' most observers report using imagery to arrive at the answer of 'triangle'. Such information is not likely to have been considered explicitly before. Thus, the answer is not readily accessible: it has

not been stored verbally or in any other explicit manner. Instead, the information is available implicitly in a mental image of a cat, and it is retrieved from memory via imagery. One forms the image and then 'inspects' it to find the answer.

Learning

As discovered by the ancient Greeks, mental imagery can help one memorize a list of objects. For example, to remember what items to purchase at the grocery store, one can employ the 'method of loci', in which the individual items are imagined as if they were placed along a familiar route. In this case, let's say that the route is the path from your home to the grocery store. Using items from the grocery list, you might imagine a loaf of bread at a letter box, a carton of eggs near a lamppost two blocks farther down, and so on. In order later to recall the entire list, you would need simply to visualize the route, imagine walking along it, and 'see' what is stored at each landmark. In general, items visualized in an interactive fashion are remembered best (e.g. imaging the loaf of bread stuck in the slot of the letter box rather than sitting beside it). Creating interactive images allows one to utilize the associations among objects in addition to their individual names and images. Such associations have been shown to aid in later memory retrieval.

Imagery can also help one to improve skills. In trying to improve a tennis serve, for example, you can watch a professional player and then mentally replay his or her actions, 'observing' them in order to improve your own performance. Or you can replay and 'observe' your own tennis serve, tuning the stored information that guides the physical performance of that action.

Insights from Daydreaming

Kosslyn and colleagues asked people to keep track of their imagery on an hourly basis, and found that most reported imagery occurred in daydreams. However, for some subjects, even such seemingly aimless images proved useful. The subjects occasionally noted that their daydreaming suddenly gave them a new idea or revealed an important oversight in a previous situation. Such insights may occur because mental images contain information that is stored implicitly in memory. Once objects and events are visualized, one may observe features and relationships that previously went unnoticed.

FUNCTIONAL PROPERTIES OF IMAGES

Most uses of imagery rely on the ability to transform or manipulate images. In this section we discuss three ways of manipulating images that cognitive scientists have studied.

Scanning

Just as one can scan a physical scene with one's eyes, it appears that images can be scanned with the 'mind's eye'. For example, Kosslyn and colleagues showed subjects a drawing of a map and had them memorize the locations of landmarks such as a hut, palm trees, and a well. Subjects then formed an image of the island and mentally focused on a specific landmark. The subjects then heard the name of a second, target landmark, which may or may not have appeared on the actual map. The task was to locate the target on the image. The farther away targets were from the initial landmarks, the longer it took subjects to locate them. This finding makes sense if images are depictive, (i.e. they preserve spatial extent), and thus requiring more time to shift attention over larger distances. Not all researchers agree with such an interpretation, however. In fact, the findings of scanning experiments have been a focus of contention in a long-standing debate on the nature of image representation. In the section on rotation, we discuss an alternative theory to the depictive-imagery view.

Zooming

In order to 'see' an imaged object in finer detail observers can 'zoom in' on it. For example, suppose you visualize a bird perched high up in a distant tree. If you are asked to indicate whether the bird has a crest on its head, you can 'zoom in' closer to the image to see this feature more clearly. Experiments have shown that the amount of time it takes to answer such questions is dependent on the initial 'viewing distance' of the observer from the visualized object. The farther away the object appears in the image, the longer it takes to report the correct answer. Further evidence comes from Malstrom and colleagues, who demonstrated that when participants imagine objects at different distances, their eyes actually change shape in accordance with distance, much as they do when observers look at physical objects.

Rotation

Just as observers require time to scan or zoom in on an imaged object, they also require time to transform imaged objects. For example, Roger Shepard and colleagues presented subjects with depictions of pairs of three-dimensional multiarmed objects, one of which was at a different orientation with respect to the other. The task was to decide whether the objects were the same or different. The time to make a response increased linearly with the angle of displacement between the two objects. Shepard and colleagues interpreted this finding as evidence that subjects had mentally rotated one object into alignment with the other. (*See* **Mental Rotation**)

Perhaps the most intriguing aspect of the findings on image transformations is that the internal processes are analogous to the corresponding physical process. In the real world, physical properties such as distance and the fact that objects cannot change position instantaneously constrain what we can do – but such physical properties are not actually present in mental images. For example, mental images are not rigid objects that must pass through a trajectory when rotated. So why do images mimic actual objects? Although evolutionary and information-processing theories have been posited to explain this correspondence, no one theory has compelling support.

An alternative account is that mental images do not mimic actual objects at all. According to this view, proposed by Pylyshyn and others, the image transformation findings that show a linear relationship between imaged and physical object movement are an artifact of observers' reliance on tacit knowledge of physical laws and object properties. For example, observers know through experience that it takes less time to rotate an object a short distance than a longer distance. Pylyshyn proposed that such knowledge is stored in the mind in an abstract, languagelike form (in representations termed 'propositions') rather than as picturelike images. Access to propositional information allows observers to treat the corresponding imagery task as a kind of pretend version of real rotation. In this case, they simply wait longer before responding when they think it would have taken longer to perform the corresponding actual operation (such as rotating a figure a greater amount). Pylyshyn's theory was important in that it inspired imagery researchers to construct experiments aimed at defining the precise structure of mental images. However, most researchers in the field today tend to hold the view that images involve both depictive and propositional forms of representation. (*See* **Representations, Abstract and Concrete**; **Representation Formats in Psychology**)

DISSOCIATIONS BETWEEN IMAGERY AND LANGUAGE

Although nonhuman animals may rely on imagery as the major vehicle of thinking, we humans have another means: language. How are imagery and language related? Each type of representation characterizes different types of information. For example, visualize a dog sitting under a tree. Depending on your degree of imagery skill, you will be able to 'see' concrete characteristics of the object, such as the shape of the dog, the shape of the tree, and the location and size of the dog with respect to the tree. Notice that the latter relationship is inherent in the image; nothing about the spatial characteristics of the dog relative to the tree must be inferred. Now consider the sentence, 'The dog is sitting under the tree.' Nothing about the manner in which the words 'dog' and 'tree' look or sound resembles their physical counterparts. In addition, the spatial relationship of the dog to the tree does not exist without the explicit specification provided by the preposition 'under'. The relationships between the words and their meanings are completely arbitrary.

What is the functional significance of having two types of representation? You may rely upon one or the other form, depending on what information is needed. For example, in answering the question, 'Are dogs animals?' one would resort to the linguistic representation of information associated with dogs; a mental image of a dog would not be helpful. On the other hand, the question 'Which are bigger, the dog's front or hind legs?' might be best answered by relying on an image of the dog. Such distinctions have led Paivio and colleagues to hypothesize that information is encoded in two forms, as images and as words. Empirical support for this idea is found in studies where verbal tasks are shown to interfere with verbal encoding, whereas pictorial tasks interfere with visual imagery encoding.

Despite the differences between imagery and language, the two may interact with each other. For example, Barbara Tversky and colleagues, as well as Michel Denis and his colleagues, have shown that representations of scenes constructed from verbal descriptions tend to preserve the spatial relationships occurring in the scene. The time it took subjects to indicate the relative

locations of objects described in a text was directly related to their imagined position in the scene. Imagery is also used to answer certain types of questions, particularly about subtle visual properties that cannot be inferred from other information – such as the shape of a cat's ears, the number of windows in your living room, or the precise color of a cantaloupe.

SIMILARITIES/DIFFERENCES BETWEEN IMAGERY AND PERCEPTION

Whereas imagery and language are largely distinct, there is ample empirical evidence that visual imagery shares many of the same mechanisms as visual perception. For example, visual images interfere with visual perception more than with auditory perception; the opposite is true for auditory images. Indeed, visual images can sometimes be mistaken for physical stimuli. Moreover, visual illusions sometimes occur in imagery. For example, we tend to have difficulty seeing oblique lines, compared to vertical or horizontal ones – and the same thing occurs in imagery.

However, the correspondence between imagery and perception is not perfect. Experiments using reversible figures, which perceptually can be construed as more than one object (such as the classic duck/rabbit; see Figure 1), have demonstrated limitations to the imagery–perception analogy. Subjects were briefly shown a reversible figure and were asked to arrive at an alternative interpretation from that initially perceived. Most subjects had difficulty with this task. It was only after they were allowed to draw the figures from memory that they were able to arrive at the alternative interpretation. Later studies showed that specific hints provided by the experimenter, such as directing the subjects to think of the object's facial profile as the back of the new object's head, helped them to discover the alternative interpretation. However, this ability did not reach the degree of spontaneous reinterpretation that occurs with an actual visual image. Images fade quickly and have an inherent organization; if the organization must be changed substantially, it can be difficult to retain the image long enough to complete this process.

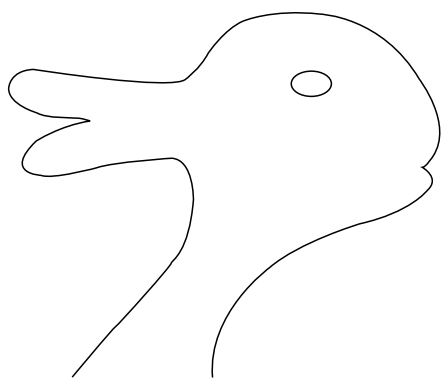

Figure 1. A classic reversible figure, which can be seen either as a duck or a rabbit.

THE NEUROPHYSIOLOGICAL BASIS OF IMAGERY

Both studies of brain-damaged patients and neuroimaging experiments have shown that imagery shares most of the same neural machinery with perception. Thus, it is not surprising that brain damage often has corresponding effects in imagery and perception. For example, patients with damage to the right parietal lobe of the brain often ignore objects in the left half of the visual field. Thus, a patient standing in front of a building will not notice its left side. These patients will have the same difficulty if asked to close their eyes and visualize the building. However, if the patient is asked to turn so that the previously unattended side of the building is now in the perceivable half of space, he or she will now be able to 'see' it, both in actual perception and in forming a mental image.

In the past two decades, the advent of neuroimaging technology has led to much progress in our understanding of the neural underpinnings of mental images. One finding indicates that about two-thirds of the brain areas that are activated by either perception or imagery are activated in common by the two functions. Of particular interest is the finding that the primary visual cortex, which is the first part of the cortex to receive input from the eyes, can also be activated during mental imagery – even when the eyes are closed. This finding is important in part because it suggests that imagery can modulate perceptual processing in the brain from the start, thus determining not only what we see but what we remember seeing. Thus, it is not surprising that imaged objects are often mistakenly remembered as actual objects. We can 'see' objects in visual images precisely because they are generated as patterns of activation within the areas of the brain used by visual perception.

CONCLUSIONS

Images are important for two major reasons. First, they make use of the brain machinery used in

perception. Thus, we can re-present objects and events, and notice characteristics that previously escaped notice. Second, because images can stand in for objects, we can mentally transform them and observe the likely consequences of performing the corresponding actual transformation. Mental imagery is a world within, and can be used to help us navigate, learn about, and master our interactions with the world itself.

Implicit Learning

Introductory article

AS Reber, Brooklyn College of the City University of New York, New York, USA

CONTENTS

Implicit learning is essentially learning without awareness. Knowledge that has been acquired implicitly is knowledge that has been acquired and held largely without conscious effort.

INTRODUCTION

Implicit learning is the capacity to pick up information about complex stimulus displays largely without awareness of either the process or the products of learning. People generally display implicitly acquired knowledge by improved performance of various tasks independently of whether they can report knowing the material that has enabled them to perform effectively. In many ways, it is akin to the layperson's notion of intuition. When people make what they regard as 'intuitive' judgments or guesses they are, in fact, using considerable knowledge about the particular situation within which the judgments or guesses are made, and typically find themselves unable to articulate the nature of that knowledge.

In the normal course of events, implicit acquisition mechanisms can be seen operating in virtually every interesting thing that human beings do. Natural languages are acquired with substantial contributions from implicit acquisitional mechanisms. Children do not learn to speak the languages of their social community by testing hypotheses or carrying out 'top-down' analytical procedures. Rather, they gradually induce the underlying structure of the various structured components of the rich and diverse communicative network – specifically the semantic, syntactic, pragmatic, gestural, and metalinguistic elements of communication. Similar arguments can be made for other complex acquisitional frameworks such as socialization and acculturation.

In principle, the mechanism that underlies implicit learning is the detection of patterns of covariation expressed in the stimulus displays. Relatively simple patterns of covariation detection are seen virtually everywhere. The most commonly studied example of implicit learning is classical conditioning, where an organism acquires an associative link between a once-neutral conditioned stimulus (the CS) and another unconditioned stimulus that reliably elicits a response (the US). Importantly, even in this relatively simple 'bottom-up' system, the acquisition is easily shown to be the detection of genuine covariation and not mere co-occurrence. As has been often and famously noted, Pavlov's dogs only learned to respond to the CS, not to Pavlov. In the original study the bell became a reliable predictor of the arrival of food because it covaried with food. Pavlov, because of his presence whether or not food was forthcoming, merely co-occurred with food. Even at this simple level the fundamental associative process can be seen operating.

As this example suggests, it is important that implicit learning be seen in an evolutionary perspective. Mechanisms that operate largely independently of consciousness, as implicit learning appears to, are probably supported by neurological systems that are old evolutionarily and antedate those 'top-down' systems that are dependent on complex encoding and conscious control, the hallmarks of explicit systems. This evolutionary argument has a number of important implications that provide insight into how implicit and explicit acquisition and representational systems can be dissociated from each other; these will be explored in more detail below.

WHAT INFORMATION CAN BE LEARNED IMPLICITLY?

As the above discussion suggests, implicit mechanisms operate in a wide variety of domains, from the distinctly primitive (classical conditioning) to the compellingly complex (some aspects of natural language acquisition). Exactly what kinds of information can be acquired using implicit mechanisms is

unknown – although the current literature gives some hints.

Basically, implicit learning mechanisms are 'bottom-up' systems. They function by picking up patterns of covariation in environmental displays. Such mechanisms are rather easily simulated by connectionist architectures that capture and represent these covariations. These acquisitional mechanisms are not particularly effective in settings that involve problem solving, hypothesis testing, or creative extrapolation. In short, they are mechanisms typically not associated with processes normally thought of as 'smart'. Yet, there are good reasons for suspecting that implicit mechanisms are not 'stupid'. Considerable evidence suggests that they are powerful and capable of carrying out sophisticated inductions, resulting in representations that seem to have at least some abstract and symbolic features. This issue is the focus of rather intense debate and will be discussed in more detail below.

TESTS OF IMPLICIT LEARNING

Various tasks have been used in the study of implicit learning. Perhaps the simplest are those based on the 'hidden covariation' procedure of Lewicki and his colleagues. In these studies simple elements of a complex display covary, and implicit learning is assessed by participants acquiring a sensitivity to these covariants. Most other procedures use more complex settings. A good bit of early work was done by Broadbent and his colleagues, using a 'production control' task. Here, subjects had to adjust complex relationships between such factors as worker satisfaction, pay, and productivity in order to maximize the efficiency of a mythical production plant. Other procedures have used processes as diverse as the detection of phonetic patterns in auditory displays, the development of preferences for structured visual and melodic sequences, responding rapidly to repeating sequences of stimuli, and artificial grammar learning where the stimuli consist of strings of symbols whose order is determined by complex probabilistic rule systems.

While diverse in their superficial forms, all of these procedures share common features. Stimulus displays always contain some degree of regularity or lawfulness. Subjects approach the tasks in a relatively neutral mode in the sense that they are not informed about the structured nature of the displays, usually treating them as memorization tests or motor learning tasks. Participants learn or become sensitive to the environmental regularities largely without conscious knowledge of either the process or the products of acquisition. Of the many procedures in use, two have dominated the attention of workers in the field, the sequence learning procedure and the artificial grammar learning experiment. The following sections take a closer look at these and outline the general findings.

Sequence Learning

The most commonly used procedure here is the sequential (or serial) reaction time (SRT) task introduced by Nissen and her colleagues. The task, at least on the surface, is simplicity itself. Participants sit in front of a monitor on which a number of locations are marked (usually four but occasionally five or six). A series of target stimuli (typically an asterisk or other symbol) appears at the locations. The participant's task is to press the key that corresponds spatially with the location of each target as quickly and accurately as possible.

In the canonical procedure the sequence of target locations displays some degree of regularity. In Nissen and Bullemer's original study and in most of those run since, a repeating sequence with particular statistical properties is used, although several investigators have used a nonrepeating sequence where a complex set of rules dictates successive locations. The classic finding is straightforward and remarkably robust. Reaction times (RTs) decrease as subjects learn to exploit the structure in the target sequence. To show that this is more than just the learning of a motor task, the introduction of a block of trials where the sequence is modified in some fashion produces an increase in RTs.

A common variation uses a secondary task. In this 'dual-task' experiment, somewhere during the interval between the key press and the next target, either a high- or low-pitched tone sounds. Participants must also keep an accurate running count of how many, say, high-pitched tones occurred in each block of trials. The extent to which this tone-counting task does (or does not) compromise learning is evaluated. The dual-task protocol has given the SRT experiment a special cachet as a forum for evaluating models of such diverse phenomena as implicit learning, divided attention, working memory, and the form of memory representations.

The reasons for this attention are easy to specify. First, the basic procedure is a model environment for the study of implicit learning. In these studies participants generally proceed unaware of the structured nature of the sequence. In cases where explicit knowledge can be shown to exist, it is

typically insufficient to account for the full range of behavior observed. Second, by manipulating aspects of the tone-counting task the role of attention in learning can be readily explored. Third, by manipulating the statistical characteristics of the sequence, the procedure becomes a forum for examining the impact of complexity and the contributions of working memory on learning. Fourth, the reliability of the basic findings makes it a useful vehicle for exploring the neuroanatomic underpinnings of implicit learning. Finally, because of the large and reliable data base, it is an excellent platform for testing theoretical models of learning and representation.

While there are dissenting voices, the general consensus is that the learning manifested in these tasks is classic implicit learning. Subjects are generally unaware of the nature of the sequence, particularly in experiments where the sequences are generated by complex rules. The acquisition of knowledge is accompanied by other markers of implicit functioning such as the development of preferences for structured displays over those that violate the rule. And intact functioning is observed in a variety of patient populations who show severe deficits in more controlled, top-down cognitive tasks.

Artificial Grammar Learning

The typical artificial grammar (AG) task involves the use of a complex set of rules that dictates the order of a string of arbitrary symbols. The most commonly used AGs are based on conditionalized rules such as 'strings may begin with either a T or a V', 'if a T occurs in the first position, it can only be followed by another T or a Q', and so forth. Although these AGs can, like natural languages, produce strings of unlimited length, most experiments have subjects work with items that are between three and eight symbols long.

In the standard AG learning experiment, subjects are presented with a series of exemplary strings from the grammar and asked to memorize them. Following this learning phase they are informed (for the first time) that the letter sequences were, in fact, rule-governed and are asked to carry out a grammaticality task. Here, they are presented with a series of novel letter strings, some of which follow the rules of the AG and some of which contain a violation, and asked to judge how well formed these items are. Evidence of learning is successful classification of novel strings at rates above chance and above what control subjects who never experienced the learning phase accomplish.

The data from literally hundreds of studies using AGs look remarkably like that from the SRT studies. Participants learn a considerable amount of knowledge about the underlying structure of the symbol strings. The learning appears to be taking place largely independent of awareness, and subjects find it particularly difficult to communicate to others the knowledge they are applying. Developmental level appears to be no barrier since young children, adults, and aged populations all perform at roughly the same levels. And, as with the SRT task, participants develop a marked preference for items that follow the rules over those that do not – including items that are completely novel.

Perhaps not surprisingly, the same fundamental arguments can be found. Despite the converging lines of evidence here, dissenting views exist. These alternative perspectives tend to argue either that the tests of subjects' awareness of the underlying rules have not been carried out with sufficient care, or that the learning is trivial and does not reflect any particularly sophisticated cognitive processing. The next sections will examine these issues and attempt to put them into a framework based on basic principles of evolutionary biology.

CONTINUUM OF IMPLICIT–EXPLICIT REPRESENTATION

There has been an unfortunate tendency to view the implicit–explicit issue in an either/or framework: a particular experiment taps either implicit mechanisms or explicit ones; a memory representation is either available to consciousness or it is not. This polarization tendency is almost certainly a mistake and has clouded issues in unhappy ways. Virtually everything cognitively interesting that people do is a complex blend of consciously controlled processing that is declarative in nature and implicit, automatic functioning that lies largely outside of awareness. Task purity is going to be hard to find.

Moreover, these systems and the underlying neuroanatomical mechanisms that subsume them have a distinct evolutionary history, and any theory of implicit and explicit functioning must cohere with basic principles of evolutionary biology. As has been argued in several places, explicit systems, linked as they are with conscious control, are relatively recent arrivals on the evolutionary scene. Implicit systems, which function procedurally and largely independent of top-down control, are much older. In fact, they are almost certainly as old as the original neural nets since organisms as primitive as *Aplysia californica*, a sea slug of

most modest intellectual achievements, can, nevertheless, detect patterns of covariation in its environment and exhibit differential Pavlovian conditioning.

It is virtually certain that as neural systems grew in complexity and natural advantages accrued to systems that exhibited modulatory control, what we like to call 'consciousness' emerged. But this self-reflective, top-down system with all of its cognitive richness does not neutralize or diminish the importance of the older, bottom-up mechanisms. They are still very much present and, by virtue of the hierarchical nature of evolutionary processes, form the foundation upon which the more recently emerged systems function. In short, we expect to see a blending of the implicit and the explicit in virtually all complex human behaviors.

However, this line of argument still leaves unanswered the question of representation. There is no doubt (except, perhaps, in the minds of radical behaviorists) that human consciousness forms representations that are abstract and symbolic. However, no such consensus exists when it comes to the cognitive unconscious. Perruchet and Pacteau, in a recent critique of the representation issue in implicit learning, put the matter quite starkly: 'We do not question human abstraction ability, no more than we question the existence of unconscious processes. What we do question is the joint possibility of unconscious abstraction'. There are, to be sure, difficulties with this point of view.

The term 'abstract' comes from the Latin for drawn away and usage turns on the notion that for qualities of objects, events, or phenomena to be abstract is to regard them as separate from the specific objects, events, or phenomena themselves. 'Symbolic' has a more checkered etymology, but the essential notion is similar. An action, an idea, an utterance, a mental state can be regarded as symbolic if it signifies actions, ideas, utterances, or mental states beyond or distinct from the original instance.

But neither of these notions has firm definitional boundaries. Being abstract is not an either/or situation. Many implicit learning experiments find subjects forming representations with a measure of abstractness or symbolic content. This is commonly seen in the experiments on transfer where subjects learn an AG instantiated with one set of letters and then make judgments on the grammar of strings composed of a different set of letters. In fact, as Manza and Reber showed, abstract representations can be encouraged simply by presenting the learning stimuli in two different instantiations. When subjects memorize strings like XXRTRXV and QQWMWQP where individual letters have shared privileges of occurrence, they tend to set up representations that are not tied to the physical form of the inputs.

In short, there is no 'default' form of mental representation. Implicit representations, like the explicit ones, can be either abstract and contain symbolic content, or they can be rigid, inflexible, and tied to the form of the stimulus inputs. It is likely that the implicit tend more toward the inflexible simply because they are dependent on older and more primitive neuroanatomical systems. But it would be a mistake to conclude that because of this evolutionary antiquity that the systems must be ineluctably tied to the stimulus inputs. The patterns of covariation among the elements of the environments that we live in are under constant flux. Any representational system, even the most basic and cognitively unadorned, must be sensitive to these variations. And since implicit learning is essentially the detection of patterns of covariation among elements in stimulus displays, to be viable the representational mechanism must be able to capture random adjustments in form and structure.

ARE IMPLICIT AND EXPLICIT MEMORY SYSTEMS SEPARATE?

This question contains two different elements. First (echoing the preceding), are there reasons for suspecting that implicitly formed representations are different in kind from explicitly formed? Second, are there distinct anatomical systems for the implicit and the explicit?

Differences between Implicit and Explicit Memories

There is a tendency to think that implicit representations are inflexible and tied to the form of the stimulus input, while explicit representations are abstract and flexible. And, as noted, while on occasions they may take these forms, it is unlikely that they must. The literature on implicit memory strongly suggests that unconsciously held representations are rigid and tied to the form of the stimulus environment. The literature on implicit learning suggests that such representations are often rather flexible and abstract. These seemingly conflicting findings are unhappily confounded with methodological difficulties.

In the typical implicit learning experiment something new is learned. Subjects acquire knowledge about a structured sequence of events, a set of rules

for symbol ordering, an obscure or hidden pattern of covariations and, for the most part, this knowledge is held without awareness of its content. As noted above, the form of this knowledge may be flexible or inflexible, abstract or concrete, symbolic or tied to the form of the input. Because material is learned and knowledge is acquired, task demands, encoding constraints, context effects, and the like will play a large role in determining the nature of the representation.

On the other hand, in the canonical implicit memory experiment *nothing new is learned*. The typical study consists of the presentation of knowledge subjects already possess – a list of words, a set of pictures – all of which were part of the subjects' knowledge base when they entered the experiment. Under these conditions, subjects tend to form episodic memories based on mnemonics or other encoding tags that emphasize each item's uniqueness. The results of such a process are memory representations that are concrete in nature and close to the physical form of the input stimulus. Hence, it is not surprising that degrading or modifying superficial features of probe stimuli reduces evidence of implicit memory. Findings such as these have led to the conclusion that implicit memory representations are relatively inflexible.

In short, the question of whether implicit and explicit memories can be regarded as fundamentally distinct based on the nature of the encoding and the resulting representations is, to date, unanswerable.

Differences in Anatomical Structures for Implicit and Explicit Systems

The other line of attack on this issue, however, has proven more fruitful. One of the corollaries of the standard model of evolutionary biology is that older systems, because they form the foundation for later developments, should be more robust in the face of disorders and dysfunctions than more recently evolved systems. The natural implication of this argument is that we can expect to see a pattern in the lost and preserved functions that accompany particular disorders. There is an enormous literature here virtually all of which points to exactly this picture. Specific neural correlates of explicit processing are known, and damage to them typically produces little or no impairment of related implicit functioning. Implicit learning and implicit memory processes remain intact in a large number of psychiatric and neurological disorders where explicit cognitive functions are severely impaired.

Patients with anterograde amnesia who show an inability to acquire new explicit memories typically have damage to one or more areas in the medial temporal lobes. Nevertheless, these patients exhibit the same artificial grammar learning ability as control participants, even when the test is given using a novel letter set applied to the same underlying grammar. These patients are also unaware of the underlying rule structure of the AGs and are impaired at recognizing the training strings compared with control participants. Amnesic patients also show normal learning on an SRT task and, not surprisingly, are impaired in recognizing or reporting the sequence.

In a similar fashion, amnesic patients show virtually normal implicit memory. Indeed, the first, critical insight into the neural basis of consciousness in learning and memory came from the assessment of the famous patient H.M. This patient became profoundly amnesic following surgery (to control otherwise intractable epilepsy) that removed, bilaterally, most of the medial-temporal lobe including the hippocampus, amygdala, and surrounding cortical regions. The striking result of this surgery was a profound anterograde amnesia that essentially eliminated H.M.'s ability to acquire new explicit knowledge of everyday facts and events while leaving his general cognitive functions largely intact. For example, his memory impairment is such that one half-hour after eating lunch, he cannot remember a single item that he ate or, in fact, that he ate at all. But, his memory impairment is selective for encoding new explicit, long-term memories. His immediate memory (e.g., digit span) is normal, he is able to retrieve explicit memories for childhood, and his post-surgery IQ is above normal and his implicit learning and memory systems function well within normal limits.

Psychotic patients whose overall functioning is so poor that they can barely solve simple numerical problems perform at virtually normal levels on AG learning tasks. And, while not exactly in the category of neurologically impaired, infants show intact implicit learning of phonetic patterns and are virtually indistinguishable from adults in their ability. In aged populations, implicit processing is almost invariably intact even as consciously controlled cognitive functions begin to decline. Performance on the SRT task doesn't begin to diminish until extreme old age and, even then, the elderly display performance levels much closer to that of younger adults than then do on explicit tasks such as problem solving, reasoning, and long-term memory.

One hypothesis is that implicit learning and memory occur within the cortical areas involved in processing the stimuli for which the learning is occurring, and hence will be found virtually throughout the brain. If this model proves correct, only with diffuse lesions would one expect global impairments in implicit learning. Focal lesions would result in impairment only for those implicit learning tasks supported by the affected area, with other implicit learning functions still being operative. As suggested above, one of the hallmarks of implicit learning is that it is less vulnerable than explicit learning to neurological damage. If implicit processing is supported by widely divergent and diffuse neural structures, then this robustness is to be expected. In short, the neurocognitive literature strongly suggests that the explicit and implicit systems are distinct.

CONCLUSION

The evidence that has accumulated over the past several decades of research supports the notion of an evolutionarily old acquisition and representation system that operates largely independent of consciousness and of top-down control mechanisms. This implicit system operates primarily by picking up and encoding patterns of covariation in the stimulus environment. It is a relatively robust mechanism that shows considerable resilience to psychological and neurological disorders, displays little variation across developmental level, and enables the establishment of memorial representations that, under the proper circumstances, can capture rather sophisticated features.

Individual Differences

Introductory article

David Lubinski, Vanderbilt University, Nashville, Tennessee, USA
Rose Mary Webb, Vanderbilt University, Nashville, Tennessee, USA

CONTENTS

Variation among individuals is observed on various behavioral attributes, including global dimensions of human cognitive ability, interest, and personality, as well as more specific attributes. The scientific study of the nature and causes of human variation is known as the study of individual differences or differential psychology.

INTRODUCTION

Individual differences research focuses on the systematic assessment of relatively stable attributes measured for the purpose of allowing longitudinal forecasts (behavioral predictions over time) pertaining to broad behavioral patterns and proclivities. Dimensions of human abilities, interests, and personality play critical roles in structuring a variety of important behaviors and outcomes (e.g. educational and vocational choice, academic achievement, occupational performance, income, health-risk behavior, crime and delinquency). Since particular attention is devoted to socially relevant phenomena, individual difference dimensions are important variables to consider in various areas of social and medical research, especially those that examine people at risk for negative outcomes or those showing promise for positive outcomes.

The preferred method of assessing individual differences has been to build scales based on the aggregation of many multiple-choice items. This method is based upon the observation that, although an individual item on a scale possesses only a sliver of genuine information about an attribute, a series of lightly correlated items can combine to yield an informative measure of the attribute under analysis. This aggregation is analogous to the information one gleans from an individual's grade in a single college course, as compared with knowledge of that individual's college grade point average over a four-year period.

DISPOSITIONS

Organization of Cognitive Abilities

The dominant scientific conceptualization of intelligence views cognitive abilities as being organized hierarchically. This organizational scheme is clearly revealed by Carroll's factor-analytic examination of decades of ability research. In this framework, the attribute of general intelligence (g) represents what is common to cognitive tests. That is, g is what is common in the secondary level of more content-specific abilities, such as quantitative reasoning, spatial visualization, and verbal ability. These are in turn supported by more circumscribed abilities closely associated with specific tasks, such as numerical facility, reading speed, memory span, and reading comprehension. Such molecular skills are most closely associated with the manifest content of cognitive tests.

The attribute g represents approximately half of what is common among many different kinds of cognitive (aptitude and achievement) tests. It is a distillate of the elements common to each cognitive test. In terms of its external connections, g reflects the largest dimension of psychological diversity revealed by differential psychology. Since the early twentieth century, large-scale studies have documented the utility of g in forecasting educational outcomes, occupational training, and work performance. To a lesser degree, g is related to a number of diverse phenomena: for example, it is positively correlated with altruism, sense of humor, practical knowledge, response to psychotherapy, social skills, and supermarket shopping ability, and negatively

correlated with impulsiveness, accident-proneness, delinquency, smoking, racial prejudice, and obesity. (*See* **Academic Achievement**)

There are important abilities beyond the general factor. Mathematical, spatial–mechanical, and verbal reasoning abilities have all been shown to have psychological import beyond *g*. This is especially relevant in predicting individual differences in performance across educational and vocational domains, and also for predicting educational and career paths that people self-select (different learning niches). For example, a recent study compared three different types of profoundly gifted individuals identified as belonging to the top 0.01% on either mathematical or verbal reasoning ability. Initially, they were assessed at age 12 on the Scholastic Assessment Test (SAT), and scored either 700 or more on SAT-Mathematics or 630 or more on SAT-Verbal (several participants met both criteria). These participants were tracked over 10 years, and assigned to the following groups for analysis: those with highly advanced mathematical reasoning ability, relative to their verbal ability (high-math); those with highly advanced verbal reasoning ability, relative to their mathematical ability (high-verbal); and those whose mathematical and verbal reasoning abilities were more uniformly advanced (high-flat). Differential interests among these groups were apparent in their choice of favorite courses in high school and college (see Figure 1). High-math individuals tended to prefer mathematics and science courses, whereas high-verbal individuals tended to prefer humanities courses. Course preferences for high-flat individuals were intermediate. (*See* **Quantitative Reasoning**)

Awards and other special accomplishments of these groups, defined by differing ability profiles, demonstrated a similar pattern: high-math individuals tended to succeed in areas of science and technology, whereas high-verbal individuals tended to succeed in the humanities and arts (see Table 1). Again, high-flat individuals were intermediate. These findings further emphasize the importance of specific abilities beyond general intelligence. (*See* **Intelligence**)

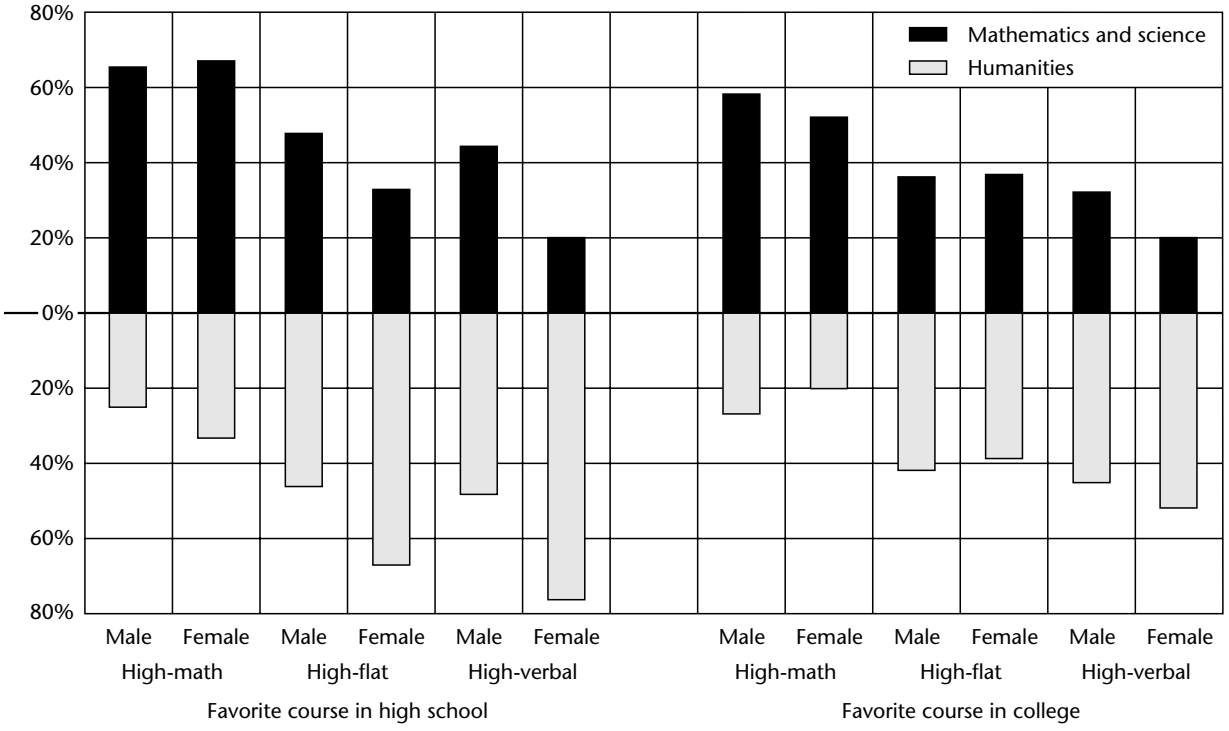

Figure 1. Favorite courses in high school and in college of participants in a study of individuals who at the age of 12 scored very highly in SAT-Mathematics ('high-math'), SAT-Verbal ('high-verbal'), or both ('high-flat'). Percentages in a column do not necessarily sum to 100% because only participants indicating either mathematics and sciences or humanities courses are displayed. Significance tests for differences among groups for favorite course are as follows: high school mathematics and science χ^2 (2, $N = 320$) = 20.7, $p < 0.0001$; college mathematics and science χ^2 (2, $N = 320$) = 18.2, $p < 0.0001$; high school humanities χ^2 (2, $N = 320$) = 36.6, $p < 0.0001$; college humanities χ^2 (2, $N = 320$) = 30.2, $p < 0.0001$.

Table 1. Special accomplishments as listed by the participants. Numbers in parentheses after an accomplishment represent the number of participants associated with the accomplishment. All other entries are for a single individual

Total high-verbal	7	13	

Interests

A general model of interest dimensions has emerged which is helpful for understanding how people approach and operate within learning and work environments. This model is a hexagonal structure known as RIASEC. It is defined by six general interest themes, with adjacent themes most correlated and opposite themes least correlated (see Figure 2). Briefly, the six themes are: 'realistic' (working with things and tools), 'investigative' (scientific pursuits), 'artistic' (aesthetic pursuits and self-expression), 'social' (contact with and helping people), 'enterprising' (buying, marketing, and selling), and 'conventional' (office practices and well-structured tasks).

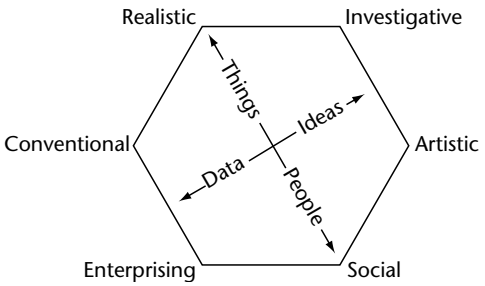

Figure 2. The RIASEC model of the structure of interest. Adapted from: Holland JL (1996) Exploring careers with a typology. *American Psychologist* **53**: 728–736.

While RIASEC has emerged repeatedly in large samples and across cultures, it is not embraced by everyone. It has been argued that the hexagonal model can be reduced to two relatively independent bipolar dimensions: people versus things, and data versus ideas. The former runs from 'social' (people) to 'realistic' (things) while the latter runs from the midpoint of 'enterprising' and 'conventional' (data) to the midpoint of 'artistic' and 'investigative' (ideas) (see Figure 2). Although there are certainly finer gradations of interest that carry psychological importance, RIASEC constitutes a useful framework for the study of interests. It also contains one of the largest sex differences discovered by psychological science on a continuous dimension, namely, people versus things. Females score much higher on the former, males on the latter. This difference has important implications for the kinds of work males and females prefer doing, other things being equal.

Research on educational and vocational interests comprises both temporal stability analyses (reliability) and forecasts of occupational group membership (validity). These investigations have established interest measures as among the most important in applied psychology. Research indicates that interests begin to crystallize during adolescence; they can forecast antecedents to occupational choice (e.g. college major) and, as such, serve as important tools in counseling and educational contexts. These are scientifically significant tools, which (like cognitive abilities) are predictive of a broad spectrum of criteria ranging from educational and vocational settings to activities in everyday life (hobbies and pastimes). Individual differences in interests are estimated to be approximately 50% heritable.

The most commonly used interest inventory is the 'Strong Vocational Interest Inventory' (SVII), which assesses an individual's interests in different occupational fields by asking them to indicate their preferences for various activities. Since people in a given occupation tend to share common interests that differentiate them from people in other occupations, the SVII compares an individual's unique combination of interests with average interest profiles of individuals in many different occupations. Occupational interests are classified according to the hexagonal structure of interest outlined above, and individuals are characterized by the relative strengths of these six occupational themes.

Personality

Although some consensus has emerged on the major personality dimensions, it is less clear-cut than for cognitive abilities and interests. Most studies of personality have followed the 'lexical' approach, which is based on the idea that important dimensions of human behavior are encoded in natural language for economy of thought. Hence, the dictionary, when systematically examined, proves an invaluable source for identifying personality characteristics. A working model of descriptors from the dictionary is available, commonly referred to as the 'big five'. Labels for each of the five factors have varied, but they include: 'extraversion' (joy, positive emotionality), 'agreeableness' (the opposite of antagonism), 'conscientiousness' (will to achieve), 'neuroticism' (anxiety, negative emotionality), and 'openness' (culture, or an intellectual orientation).

Other investigators argue that the big five need to be augmented by two additional dimensions: 'positive valence' and 'negative valence'. Positive valence is represented by terms such as 'outstanding', 'excellent', and 'remarkable', which form a continuum from ordinary to exceptional, or common to impressive. Negative valence is represented by terms such as 'cruel', 'evil', and 'sickening', which form a continuum from worthy to evil, or decent to awful.

Some of the best contemporary evidence for the scientific significance of broad dimensions of personality is found in predictions of vocational criteria. Several studies have shown that individual differences in personality dimensions, like those of vocational interests, are around 50% heritable.

Perhaps the most widely utilized personality inventory is the 'Minnesota Multiphasic Personality Inventory' (MMPI), which asks respondents to indicate which items are like or not like them. Although the MMPI has extensive clinical applications (in the identification of various forms of psychopathology), it also includes scales of several dimensions of personality, including social introversion, ego strength, and dominance. The 'California Psychological Inventory', which shares many of its items with the MMPI, eliminates those scales of the MMPI intended to identify psychopathology and concentrates on personality dimensions only. Another widely used personality scale is the NEO Personality Inventory, which yields assessments of each of the big five. Several other measures of individual differences in personality are available on a collaborative public website designed to help scientists to improve these inventories (see Further Reading).

CONSTELLATIONS OF ATTRIBUTES

Examining dispositional attributes individually can be challenging because the manner in which each operates depends on the full constellation of personal characteristics. Similar interest and ability patterns often produce markedly different behavioral patterns as a result of differences on dimensions from other classes. The paths traveled by two mathematically gifted students, for example, are likely to be very different if the two students occupy very different positions on the 'people versus things' interest dimension (other things being equal). Assuming that more comprehensive assessments will enhance psychological theory and practice, an approach that combines abilities, interests, and personality dimensions is generally considered to be the ideal.

One model of adult intellectual development, embraced by P. L. Ackerman, uses cognitive

abilities, personality, and interest dimensions simultaneously to describe developmental changes in cognitive content and processes throughout the lifespan. This is the 'process, personality, interests, and knowledge' theory of intellectual development. Interest and personality attributes channel the development of intelligence-as-knowledge down different paths, while intelligence-as-process determines the complexity and density of the knowledge assimilated. In other words, intelligence-as-process, through interactions with interests and personality, fosters adult intellect (intelligence-as-knowledge). Over time, personality and interests direct the application of intelligence-as-process towards the development of particular knowledge structures. This model provides a useful way of revealing why individuals with similar cognitive profiles can, and frequently do, differ widely in their knowledge base.

Analysis of the relationships among ability, interest, and personality attributes has revealed that these dispositions are not entirely independent. Four across-attribute (ability, interest, personality) trait complexes have emerged: social, clerical–conventional, scientific–mathematical, and intellectual–cultural. The social trait complex includes social and enterprising interests, and the personality traits of extraversion, social potency, and well-being, but does not include any ability traits. The clerical–conventional trait complex includes perceptual speed (an ability trait), conventional interest, and the personality traits of control, conscientiousness, and traditionalism. The scientific–mathematical trait complex includes two cognitive abilities, mathematical reasoning and visual perception, and realistic and investigative interests, but does not include any personality traits. The intellectual–cultural trait complex includes crystallized intelligence and ideation fluency (ability traits), artistic and investigative interests, and the personality traits of typical intellectual engagement and openness to experience. Note that these trait complexes are not mutually exclusive.

The constellations formed by the salient features of these personal attributes differentially tune people to opportunities in education and the world of work, thereby serving as critical components in determining lifestyle and influencing important life outcomes. A large part of what goes into understanding oneself, from a psychological point of view, involves coming to terms with one's abilities, interests, and personality, and using this information to make life choices and structure opportunities for personally relevant psychological growth throughout the lifespan.

STYLES

Psychological 'styles' refer to the temporal dynamics of behavior, rather than its content or structure. 'Capacity to work', 'industriousness', 'will', and 'zeal' are descriptors frequently found in the scientific literature on psychological 'tempo' or style. One of the most systematic accounts of style is found in Dawis and Lofquist's four dimensions of personality style: celerity, pace, rhythm, and endurance. Celerity refers to the speed at which one reacts to the environment. Pace is defined by the individual's level of activity. Rhythm refers to the stability of that activity level. Endurance represents the duration of an individual's interaction with the environment.

Although measures of these important psychological attributes are not readily available, there is little doubt that large individual differences exist in the temporal dynamics of behavioral patterns. These attributes are certainly important to consider when large differences are observed in performances and outcomes between two individuals with comparable ability, interest, and personality structures.

GENETIC AND ENVIRONMENTAL CONTRIBUTIONS TO INTELLIGENCE

There has been a great deal of discussion regarding the relative contributions of genetics and environment to intelligence. Historically, this debate has been referred to as the question of 'nature versus nurture', but more recent discussions have recognized the importance of both nature (genetics) and nurture (environment). Clearly, both contribute to the individual differences observed in intelligence. However, the question of their relative contributions remains a debated issue in psychology.

The genetic contribution to individual differences in intelligence refers to the effects of one's genes, which are inherited from one's parents. Half of an individual's genetic make-up is inherited from the individual's mother, and half is inherited from the individual's father. The specific combination of genes inherited from one's parents are unique to an individual, that is, no other person will have exactly the same combination of genes (except in the case of identical twins, which will be examined in further detail below). The degree to which individual differences in a trait are genetically influenced is represented by an estimate of heritability, the proportion of the observed individual differences on a given trait that are attributable to genetic differences among the individuals.

The environmental contribution to individual differences in intelligence is less clearly defined than the genetic contribution. Environmental contributions are broadly defined as all non-genetic influences. These influences include obvious components such as the individual's educational opportunities and family circumstances (e.g. parental education, family income, social standing), but they also include less obvious components of the environment such as pre- and post-natal nutrition, hormonal influences, and illness. Environmental contributions are further parsed into shared and non-shared components, which are, respectively, those elements of the environment that are common to compared individuals and those elements of the environment that are unique to compared individuals.

Genetic and environmental contributions to intelligence are certainly intertwined and may even interact, but there are research methods that allow the disentanglement of genetic and environmental sources of variation in intelligence, as well as other personological traits. The heritability of intelligence, which provides an estimate of the proportion of the observed individual differences in intelligence that are attributable to genetic differences among the individuals, may be gleaned by studying the degree of similarity on that trait among family members. These studies often include examinations of parent–offspring, sibling, identical and fraternal twin, and adoptive relationships. The premise underpinning these behavioral genetic research methodologies is that more closely (genetically) related family members should be more alike in intelligence than less closely (genetically) related family members, if indeed the trait is at least partially determined by genetic factors. For example, to the extent that individual differences in intelligence are genetically determined, monozygotic (identical) twins (who are genetically identical) should be more similar to each other than dizygotic (fraternal) twins (who share only half of their genes).

Quantitative estimates of heritability vary somewhat across studies, but typically the heritability of intelligence is estimated at between 0.4 and 0.8 (on a scale from 0 to 1). Monozygotic twins who have been reared apart (in different environments) provide a unique opportunity to directly measure the contribution of genetics to individual differences in intelligence; these studies indicate that the heritability of intelligence is about 0.70, meaning that genes account for approximately 70% of the individual differences observed in intelligence. Other familial relationships suggest similar, or slightly lower, estimates.

Adoptive relationships are also informative because one set of parents provides the genetic make-up of the child and a different set of parents provides the environment in which the child is raised, thereby allowing an examination of the unique contribution of the environment to the individual differences in intelligence. Studies of various adoptive relationships suggest that rearing environments account for no more than 30% of the individual differences in intelligence observed in children, and account for practically none of the variance in adults.

Recent behavioral genetic research has moved beyond the simplistic 'nature versus nurture' question towards an understanding of how nature and nurture interact in the development of intelligence. For example, it has been observed that estimates of heritability of intelligence tend to increase across the lifespan, from less than 40% in childhood to more than 60% in adulthood. This pattern is thought to be a reflection of the tendency for individuals to self-select environments congruent to their own proclivities as they grow older and become less constrained by familial demands and expectations. Conversely, the influence of rearing environments diminishes to practically zero in adulthood, as individuals rely increasingly upon themselves for their selection of environments.

However, the fact that intelligence is highly heritable does not mean that individual intelligence is not malleable through environmental intervention. The environmental (or non-genetic) contribution to the individual differences observed in intelligence is certainly important, but it is still unknown which aspects of the environment may be manipulated, and which interventions, if any, might increase an individual's intelligence.

Modern scientific advances are taking genetic research to the next step: molecular genetics. Scientists are now searching the genetic make-up of humans for genetic markers of intelligence. For example, a study of the genetic make-up of a group of precocious adolescents (the same group who were examined phenotypically in Figure 1 and Table 1) and their biological parents is currently under way. The DNA from these children, some of whom have differential intellectual strengths (e.g. exceptional verbal abilities relative to mathematical abilities), is being examined for genes relevant to general and specific intellectual abilities. Indeed, this work appears to suggest the identification of a number of genes related to general intellectual functioning. (*See* **Behavior, Genetic Influences on**)

EMOTIONAL INTELLIGENCE AND MULTIPLE INTELLIGENCES

Innovative measures and theories periodically surface in psychology which purport to explain psychological phenomena or to at least to put them in a clearer light. Emotional intelligence and multiple intelligences are two examples of such constructs.

Briefly, the theory of emotional intelligence involves many aspects of social intelligence. These aspects began to be discussed shortly after the first tests of general intelligence began to appear. Emotional intelligence is seen as an amalgam of interpersonal skills and social judgment. However, valid measures of this complex construct have yet to be developed.

The theory of multiple intelligences (MI) postulates seven distinct intelligences: musical, bodily–kinesthetic, logical–mathematical, spatial, linguistic, interpersonal, and intrapersonal. It asserts that these seven intelligences are mutually independent. Moreover, it assumes that every individual has the potential to excel in one of the seven areas, and proposes that society should recognize and value each in equal measure.

MI has attracted much attention, particularly within educational circles. Given its 'something for everyone' basis, it is certainly attractive. However, there is little scientific evidence to support the structure of intelligence it suggests, beyond the meager evidence that led to its initial formulation.

Both emotional intelligence and MI are intuitively appealing, especially given that virtually everyone agrees that there is much more to effective functioning than the dimensions outlined above. Nevertheless, as S. Messick has pointed out, very similar concepts have been proposed before, but when measures have actually been developed to assess them they have been found to be unable to improve scientific forecasts beyond the existing measures, and the existing measures are almost always superior predictors. The situation is similar with 'moral reasoning' measures, which were used for decades in hundreds of studies. When they were finally compared with verbal ability measures, it was found that they had little more to offer. The problem of attaching different names to scales that measure essentially the same attribute is so common in psychology that Truman Kelley has named it the 'jangle fallacy'.

This is not to say that we should not try to improve the measurement of individual differences in psychological science: there is still much room for improvement in the prediction process. However, innovative measures need to be evaluated against existing measures of ability, interest, and personality before it can be claimed that they capture something new, and, especially, before they can serve as a foundation for more comprehensive models of human functioning.

Inductive Reasoning, Psychology of

Introductory article

Steven Sloman, Brown University, Providence, Rhode Island, USA

CONTENTS

Inductive reasoning is the capacity to draw uncertain conclusions from known facts. Despite lacking a sound justification, people make inductions in systematic ways.

THE PROBLEM OF INDUCTION

You have just encountered your first Rhode Island native, and have discovered that this person knows a lot about shellfish. Should you infer that most Rhode Islanders are likely to know a lot about shellfish? This is a question of inductive reasoning, and it has no definitive answer. Your new knowledge about one particular Rhode Islander does not allow any certain conclusions about all Rhode Islanders, although it may provide more or less evidence about the general statement; it may increase your degree of belief in the conclusion even though it does not make the conclusion logically necessary.

We can express the question as a request for a judgment about the strength of an argument:

One Rhode Islander knows a lot about shellfish.
Therefore, most Rhode Islanders know a lot about shellfish.

where the first statement is a premise and the second a conclusion. Each statement can be broken down into a predicate (knows a lot about shellfish) and a category (Rhode Islanders). In this case, the premise category is particular, it has only one member. The problem of induction has traditionally concerned categorical arguments, like this one, in which a predicate is projected from a category to a more general superordinate one (in the extreme case, from a particular to a universal).

Most work in cognitive science has focused on a more general class of arguments, those that project a predicate from one category to another that may or may not be superordinate. This includes the specific to general case (e.g. dogs to mammals), as well as arguments in which premise and conclusion categories share a superordinate (e.g. dogs and horses to cats). The class of inductive arguments excludes those in which the conclusion or its negation is logically derived from the premise (e.g. dogs and cats have fleas, therefore dogs have fleas), causal arguments (e.g. the man ate greasy food, therefore the man had a heart attack), and abductive arguments in which inferences are made to the best explanation of a known fact (e.g. the DNA test shows her blood at the scene of the crime, therefore she's guilty of murder). Nevertheless, the class of inductive arguments is large enough that logic, causal reasoning, and explanation each enter into the determination of the strength of many inductive arguments.

The philosopher Nelson Goodman stated the problem of induction in terms of how to determine the projectibility of a predicate. Presumably you found the argument above about shellfish to be less than completely convincing. Nevertheless, it is stronger than:

One Rhode Islander is related to the Governor.
Therefore, most Rhode Islanders are related to the Governor.

In Goodman's terminology, the predicate 'knows a lot about shellfish' is more projectible than the predicate 'is related to the Governor'. The problem of induction is to develop an objective means of assessing the projectibility of a predicate, and thus the strength of an inductive argument. David Hume argued long ago that no such objective method is possible because no number of observations can justify a law and, in fact, no proposed inductive system has achieved a consensus.

This is not to say that there are no generally accepted constraints on how people judge argument strength. For example, an argument with a more specific conclusion cannot be weaker than an argument with a more general one. The premise 'All A are P' provides more support for the conclusion 'All B are P' than for the conclusion 'All B and

C are P', because if Bs and Cs are P, then Bs are P. Such constraints are captured by probability theory; in this case, by the conjunction rule, that – given A – the probability of B is not less than the probability of B and C. Probability theory has emerged as the most frequent formal model of inductive strength, but it is not an inductive logic because it does not provide a general means of determining the believability of a conclusion from knowledge of premises. Nevertheless, probability theory is a normative theory of induction in that argument strength judgments that violate the constraints of probability theory are usually considered fallacious. For example, the probabilities that X occurred and that X did not occur cannot both be high, so two arguments with identical premises but contradictory conclusions cannot both be strong.

Partial solutions to the problem of induction have been offered. For example, when sample spaces are clear and well-defined, statistical models can provide great leverage in determining the probability of a conclusion conditional on some premises. Knowing that 999 new, randomly chosen light bulbs work and one doesn't provides good reason to believe that the probability is 999/1000 that the next light bulb chosen will work.

INDUCTION PHENOMENA

The general problem of induction has not been solved and may never be. But whether or not the procedures that people use for making inductive inferences are always justified, people make them in very reasonable ways. We quickly learn such things as which mushrooms to make soup with. In fact, the evidence shows that even infants of less than a year of age make inferences. The following systematicities in inductive reasoning have been experimentally demonstrated. They reflect general tendencies in how people judge argument strength, tendencies that are sometimes overriden by extreme cases or by other factors.

Similarity

Arguments are strong to the extent that categories in the premises are similar to the conclusion category. For example,

Robins have sesamoid bones.
Therefore, sparrows have sesamoid bones.

is judged stronger than

Robins have sesamoid bones.
Therefore, ostriches have sesamoid bones.

because robins are more similar to sparrows than to ostriches.

Inclusion Similarity

Similarity relations can even override transparent class inclusion relations. If you believe that all lakes are bodies of water, then you should judge

Every individual body of water has a high number of seiches.
Every individual lake has a high number of seiches.

to be a perfectly strong argument because all members of the conclusion category must have the property if every individual member of its superordinate does. But people do not always judge this argument perfectly strong even when they agree that a lake is a body of water. In fact, people often judge

Every individual body of water has a high number of seiches.
Every individual reservoir has a high number of seiches.

to be an even weaker argument, presumably because reservoirs are less typical bodies of water than lakes.

Typicality

The more typical premise categories are of the conclusion category, the stronger is the argument. For example, people are more willing to project a predicate from robins to birds than from penguins to birds because robins are more typical birds than penguins.

Asymmetry

Switching premise and conclusion categories can lead to arguments of different strength:

Tigers have 38 *chromosomes.*
Therefore, buffaloes have 38 chromosomes.

is judged stronger than

Buffaloes have 38 *chromosomes.*
Buffaloes have 38 chromosomes.

either because tigers are more typical mammals than buffaloes or because tigers are more familiar than buffaloes.

Diversity

The less similar premises are to each other, the stronger the argument tends to be. People are

more willing to draw the conclusion that all mammals love onions after being told that hippos and hamsters love onions, than after being told that hippos and rhinos do, because hippos and rhinos are more similar to each other than hippos and hamsters.

Monotonicity

When premise categories are sufficiently similar, adding a premise will increase the strength of an argument. Telling people that elephants also love onions increases their willingness to believe that mammals do.

Nonmonotonicity

A counterexample to monotonicity occurs when a premise with a category dissimilar to all other categories is introduced:

Crows have strong sternums.
Peacocks have strong sternums.
Rabbits have strong sternums.
Therefore, birds have strong sternums.

is weaker than

Crows have strong sternums.
Peacocks have strong sternums.
Therefore, birds have strong sternums.

Variability/Centrality

All the phenomena mentioned thus far reflect how people treat the relations amongst the categories of an argument. But the nature of the predicate matters too. People are more willing to project predicates that tend to be invariant across category instances than variable predicates. For example, people who are told that one Pacific island native is overweight tend to think it is unlikely that all natives of the island are overweight because weight tends to vary between people. In contrast, if told the native has dark skin, they are more likely to generalize to all natives because skin color tends to be more uniform within a race. Having dark skin may be seen as less variable by virtue of being more central, having more apparent causal links to other features of people.

Relevance

People's willingness to project a predicate from one category to another depends on what else the two categories have in common. For example, people are more likely to project 'has a liver with two chambers' from chickens to hawks than from tigers to hawks, but more likely to project 'prefers to feed at night' from tigers to hawks than from chickens to hawks. More generally, argument strength depends on how people explain why the category has the predicate. If the premise and conclusion of an argument are explained in the same way, the argument will be judged stronger than if they are explained differently.

Preferred Level of Induction

Both adults and children find arguments stronger the more specific the categories involved. If told that dalmations have an ulnar artery, people are more willing to generalize ulnar arteries to dogs than to animals. The judged strength of arguments drops off sharply when the premise and conclusion categories are not members of a common basic-level or more specific category.

Human Bias

Small children prefer to project a property from people than from other animals. Four-year-olds are more likely to agree that a bug has a spleen if told that a person does than if told that a bee does. Adults show the opposite preference.

Naming Effect

Children prefer to project predicates between objects that look similar than between objects that look dissimilar. However, this preference is overriden when the dissimilar objects are given similar labels.

Gap Effect

Inductions are stronger from categories that one would not expect to support the predicate than from categories whose support is less surprising. Learning that baby giraffes can survive for several days without water makes it seem likely that adult giraffes can. But learning the fact about adult giraffes doesn't support the inference about baby giraffes as strongly.

MODELS OF INDUCTION

Many of these phenomena are clearly sensible. For example, in favor of the diversity phenomenon, philosophers of science have argued that diverse evidence supporting a hypothesis should be more convincing than similar evidence which is

more redundant. To the degree that people's inductions have a rational justification, they can be described using probability theory, constrained as it is by possible relations amongst sets. But some phenomena, such as inclusion similarity, are not rational, implying that human induction is not entirely consistent with probability theory. Analogously, a theory of induction could appeal to general principles of good scientific practice, but such a theory is only as good as scientists' inductions are justified.

One psychological theory of induction assumes that people make categorical inductions on the basis of two principles, similarity and category coverage. Arguments are deemed strong to the degree that premise and conclusion categories are similar and to the degree that premises 'cover' the lowest-level category that includes both premise and conclusion categories. The notion of category coverage is intended to capture phenomena such as nonmonotonicity, by positing that adding a premise category unrelated to other categories makes a higher-level category relevant, thus reducing coverage. For example, by adding a premise about rabbits to ones about crows and peacocks, the superordinate 'animals' becomes relevant even if birds had previously been the lowest-level relevant category. And 'crows and peacocks' covers the category of birds better than 'crows, peacocks, and rabbits' covers the more general category of animals.

Another theory of induction reduces the two principles of similarity and category coverage into a single principle of feature coverage. Instead of appealing to class inclusion hierarchies, this theory appeals to relations amongst the properties of categories. Predicates are projected from premise categories to a conclusion category to the degree that the conclusion category's properties are covered by the premise categories. Feature coverage can explain the inclusion similarity phenomenon. Lakes don't inherit with certainty the properties of bodies of water because lakes' properties are not covered by the properties of bodies of water. Reservoirs show even less inheritance because they have even more distinctive features. The feature coverage view is not as comfortable with nonmonotonicities, because adding a premise category should not decrease feature coverage and therefore argument strength.

Neither category nor feature coverage can explain phenomena that depend on the nature of the predicate, because these theories focus exclusively on the relations amongst categories. Some models of induction focus on the features of a category that are made relevant by a predicate. If told 'Rhode Island has a beautiful autumn', you are likely to project the predicate only to regions close to Rhode Island, not to those that are shaped like it. Determining relevant features requires explaining why the category would support the predicate, and this explanation therefore determines the induction.

CONCLUSION

People use a variety of cognitive frameworks to evaluate inductive argument strength. Sometimes people use logic. For example, if a premise category is observed to include the conclusion category, the conclusion is usually correctly considered certain. Often people reason causally, as when they generate explanations and let those explanations mediate their judgment. The notion of similarity is at the heart of much inductive reasoning; people rely more on their sense of similarity than on anything else to make inductive judgments. But similarity provides only limited explanatory value if a judgment of similarity changes with the prevailing context.

People are very good at generating explanations, and these explanations quickly become part of the cognitive schema we use to understand our experience. The relative success of simple computational models in accounting for the phenomena of inductive argument strength suggests that we are able to make very good inductive guesses using these sophisticated schema in fairly coarse ways. The evidence that our usage is coarse is the systematic errors we make. We often ignore logical or categorical structure in favor of similarity. But when that more fine-grained structure is attended to, people can use it.

Infant Cognition

Introductory article

Amanda L Woodward, University of Chicago, Chicago, Illinois, USA

CONTENTS

Cognition comprises the mind's processes for acquiring, interpreting, and storing information, as well as processes for reasoning and thinking abstractly. The period of infancy in humans is generally agreed to be the first two years of life, a time during which children are largely preverbal.

INTRODUCTION

Since ancient times, those interested in the nature of the human mind have turned to infants when asking fundamental questions. What is essential and immutable in the human mind? What is given by the particulars of experience? The motivation for seeking answers to these questions from infants is that they have little in terms of experience and (presumably) all of what is innately given. It was not until the twentieth century that the scientific study of infant cognition began, with most of the foundational research occurring in the final three decades. This research has shown that the traditional nature/nurture dichotomy is misleading. Development is a process of organism–environment interaction from the beginning, even before birth. It is extremely difficult to isolate the individual contributions of nature and nurture because they do not act in isolation. Nevertheless, it is possible to ask which human capacities emerge early and therefore may serve as foundations for subsequent development. Current studies of infant cognition focus on the nature of infants' abilities at particular ages, and the process of development during the first years of life.

PERCEPTION

Perceptual systems are the mind's point of contact with the world. Human sensory organs take in a limited range of information. The problem of perception is to take this limited sensory data and yield the experience of a coherent, multidimensional environment. William James expressed a long and widely held view when he wrote that the infant's world was a 'blooming, buzzing confusion'. Early theorists assumed that infants lacked the abilities necessary to construct a coherent world from sensory data. Current work contradicts this view. Perceptual systems function from before birth, and constraints present at birth provide even newborns with a basis for making sense of sensory data. During the first year, experience and maturation tune and enrich the infant's perceptual capabilities. Vision and audition are the most well-studied types (or modalities) of perception in humans of any age, and they are the focus here. Smell, taste, touch, and proprioception also function from the beginning of life.

Vision

How can we know what infants see? Beginning in the 1950s, researchers began to devise methodological innovations to probe the perceptual processes and experiences of infants. Behavioral measures, such as patterns of visual attention, as well as brain activity are currently used to investigate infant perception. To illustrate, one measure of acuity exploits infants' preference to look at a pattern rather than a blank field. Researchers present infants with two pictures, one a gray field and the other a grating of black and white lines. If infants look longer at the latter, this is taken to indicate that they can perceive the grating pattern. By varying the size of the grating, researchers can test the limits of the infant's acuity. Studies of this sort have revealed that newborns can see, but their acuity seems very limited. Acuity may approach adult levels by 8 months of age.

Beyond the capacity to take in visual information, infants possess systems for interpreting this information – that is, perceiving a three-dimensional world populated by distinct objects. The data available to the eyes are two-dimensional, yet we perceive a three-dimensional world. Adults draw on many cues to depth relations, including the relative

motions of objects with respect to one another and the observer's own motion, the different viewpoints provided by the two eyes (stereopsis), the physical activity required to focus on objects, and pictorial cues such as shading, overlap, and perspective. When and how do infants become sensitive to this information as specifying depth?

Early theorists proposed that experience reaching for and manipulating objects at different distances was essential to the ability to interpret visual cues to depth. Modern experimental work has challenged this hypothesis. From birth, well before they are able to reach for objects, infants seem to perceive in three dimensions. A striking demonstration of this is that newborns track an object's size as constant as it moves nearer and farther from them. Because the size of an object's projection on the retina varies as a function of its distance from the observer, perceiving depth is important for tracking size constancy. In one experiment, newborns were familiarized to a cube at various distances. Then they were shown the original cube at a new distance and a similar second cube of a different size. The cubes were positioned so that both projected the same sized image on the retina. Infants stared longer at the novel sized cube, suggesting that they could distinguish between the two sizes and that they recognized the original cube as familiar, despite its new position. Other studies have suggested that infants are sensitive to motion-based depth cues from the first month of life. Infants are not sensitive to pictorial depth cues until late in the first year, suggesting that experience may contribute to their development. Stereopsis is not functional at birth, but matures at between 2 and 4 months of age.

A second challenge in visual perception is to determine which pieces of sensory data comprise a single object. Objects are often partially occluded by others (as when a mother's hand holds a bottle), and boundaries between contiguous objects (books on a shelf, or pencils in a jar) may not be obvious. Adults succeed in perceiving discrete objects by drawing on many cues, including patterns of motion (parts that comprise an object move together), and regularities in the shape and texture of objects. Young infants rely heavily on motion as a cue to object unity. By 2 months of age, infants use common motion as a basis for treating two segments emerging from opposite side of an occluder as part of the same object. The ability to use featural information (shape, color, texture) as a cue to object unity emerges at around 4 months, and may be related to developments in the infant's ability to manually explore objects.

Audition

Fetuses respond to sounds prenatally, and remember what they have heard after birth. Prenatal listening may be the source of newborns' preferences for their mothers' voice and for their native language. Speech is central to normal human cognition and development, and therefore much of the research on infant audition has focused on speech sounds. The minimal difference in sound that carries a difference in meaning is called a *phoneme*. For example, in most spoken English *bit* and *pit* differ by a single phoneme. The physical difference between any two phonemes can be described using a continuous metric; for example, it is possible to artificially produce a sound that is halfway between a *bih* and a *dih*. However, people do not perceive speech sounds as varying continuously. Human perception of speech sounds is categorical; that is, physically different sounds that fall within a category are not easily distinguished, sounds that fall in two different categories are readily distinguished, and no 'middle ground' is perceived. Infants seem to perceive speech sounds categorically from birth. Although this might suggest an innate specialization for language, in fact other species, including quail and dogs, also have categorical perception of speech sounds. Language may have evolved to exploit a pre-existing property of the auditory system. Language experience tunes infants' innate categorical perception abilities. Languages differ in the particular sound contrasts they use as phonemic. For example, *r-* and *l-* are different phonemes in English but not in Japanese. Adults find it difficult to perceive non-native phonemic contrasts. Young infants, however, perceive non-native contrasts as well as native ones. By the end of the first year, infants become insensitive to non-native contrasts. Beyond perceiving the elements of language, by 8 months infants are able to learn recurring patterns in language sounds, an ability that probably contributes to their extraction of word units and grammatical patterns.

Speech carries many different kinds of information simultaneously, and infants are sensitive to much of this information. Beyond the level of phonemes, speech has prosodic characteristics including rate, loudness, rhythm, pitch contours, and pauses. The speech that is specifically directed at infants exaggerates these prosodic elements. Infants prefer infant-directed speech and are more sensitive to the exaggerated prosodic cues it provides. By 6 months, infants seem to respond to prosodic features which correlate with clause

boundaries. During the second half of the first year, infants seem to become sensitive to the particular prosodic cues to grammatical boundaries in their native language. Prosody also conveys emotion – revealing, for example, whether the speaker is excited or frightened, or wishes to praise or scold. Infants respond to these emotional messages appropriately, even when they are given in an unfamiliar language.

Perceptual integration

Even at the beginning of life, different perceptual modalities speak to one another, yielding the experience of a coherent world in which sights, sounds, and tactile experiences are integrated. Newborn infants turn in the direction of a sound, a response that can provide a basis for connecting sounds with the visual properties of the objects that produce them. Studies have suggested that young infants spontaneously match information across modalities. When infants see two images and hear a soundtrack, they will look at the image that matches the soundtrack. Young infants can match novel images and sounds based on temporal synchrony, as well as matching familiar stimuli based on knowledge about the noises emitted by different kinds of objects (e.g., colliding sponges versus colliding blocks) and correspondences between speech sounds and the facial configurations that accompany them. Infants seem able to match tactile and visual information. For example, in one experiment, 1-month-old infants who were given either a bumpy or a smooth pacifier to suck looked longer at a picture that matched the pacifier in their mouth.

ATTENTION

For adults, perception is an active process. People actively seek out certain kinds of information, directing their attention to do so. From birth, infants strategically deploy attention in ways that are likely to facilitate information extraction and learning. Infants, like many other organisms, habituate to a repeated stimulus, attending less to it over repeated presentations, and dishabituate, or increase their attention, when a novel stimulus is presented. These responses aid the efficient use of attention, by reducing attentional resources for old information, and increasing them for new information. In addition, studies have suggested that infants seek out information-rich stimuli. They scan for edges and contours, prefer moderately complex patterns to less complex ones, and, as just reviewed, seek to integrate information across modalities. These attentional responses provide researchers with tools for probing other cognitive processes in infants.

For adults, it is important not only to allocate attention effectively to the current environment, but also to anticipate future events and direct attention accordingly. Some researchers have found that, as young as 3 months, infants direct their attention in anticipation of an event. For example, an infant might see pictures appear in alternation on the right and left side of a screen. After exposure to this pattern, infants look to where the next picture will appear before it actually appears. Infants show anticipatory looking for more complicated patterns as well, with performance on these improving during the first year.

The ability to coordinate one's own attention with the attention of a social partner (joint attention) is a critical contributor to cognitive development. Infants depend on social partners not only for survival, but also for instruction in key domains including language and culture. Systematic attention to social partners starts early. Newborns prefer pictures of faces to other patterns, and research suggests they form preferences for familiar voices and faces. Young infants attend preferentially to eyes over other facial features, respond to shifts in gaze direction, and direct their own attention in accord with another at person's gaze. Gaze-following becomes more robust at between 6 and 18 months of age. By 12–18 months, infants use an adult's gaze direction to interpret the reference of the adult's utterances and emotional expressions.

MEMORY

Development depends on the ability to retain information in memory. Many of the findings discussed so far imply memorial abilities in infants. For example, in order for infants to respond differently to familiar and novel stimuli they must have formed memories of the familiar stimulus. Moreover, since infants seem to prefer sounds heard prenatally, memory may begin before birth. Infant memory has been assessed by many other procedures including retention of conditioned responses, search for hidden objects after delays, response to novel and familiar items after delays, and deferred imitation. Infants remember for long periods as well as short ones. Infants in the first few months of life can retain memories for days or even weeks, and studies with older infants indicate retention of new information for many months.

A central debate concerns the nature of infant memories. Do they include declarative representations, or are they limited to procedural representations? The latter claim concerning infants derives, in part, from Piaget's theory that infant intelligence is limited to sensory-motor abilities (that is, organized ways of acting), and does not include abstract, conceptual representations (but see the section on conceptual structure, below). Much of the evidence for memory in young infants seems to be procedural in nature. For example, 3-month-old infants can learn to kick their feet in order to activate a mobile, and retain this response in memory for long periods. While this act of learning clearly involves procedural memory, it is not clear whether infants also form a more explicit memory of the task. The clearest evidence for declarative memory would be verbal report, which is not available from infants. Researchers have used deferred imitation as a measure of declarative memory in infants. Infants are shown a novel toy, on which an experimenter models a novel action. Infants are not allowed to touch the object until they return to the laboratory after a delay. At that point, if they are able to reproduce the modeled actions, this indicates that they could be recalling the prior event, and representing information that is not strictly procedural. Infants as young as 6 months succeed at producing deferred imitations when the task is not very demanding.

CONCEPTUAL STRUCTURE

In the minds of adults, knowledge is organized around a set of basic concepts, which comprise the building blocks of everyday reasoning. We form mental models of objects in the world, their physical properties, and their causal interactions. We distinguish between inanimate objects and intentional agents. We extract and manipulate information about number. Underlying these systems of knowledge is a general ability to form conceptual categories. How is infants' knowledge organized? Does it reflect the basic concepts that organize adult knowledge? Working in the early part of the twentieth century, Jean Piaget was among the first scientists to frame and address these questions, which continue to focus much of the current research on infant cognition.

Recent experiments have yielded evidence for structured knowledge much earlier in infancy than Piaget's observations indicated. There is currently debate concerning the implications of these findings for the nature of the infant mind. Some theorists have taken these findings as evidence for innate concepts or processing modules dedicated to particular core notions in human cognition. An alternative proposal is that innate constraints on information acquisition enable rapid learning in key domains. Others have argued that specific innate concepts are both neurologically implausible and unnecessary to account for infants' abilities. In considering these alternatives, it is relevant to keep in mind that recent experiments also indicate that infants' knowledge representations differ in significant ways from those of adults. Adult concepts are multifaceted because they are embedded in webs of knowledge, or *folk theories*. Infants' knowledge representations may contain parts of or precursors to mature knowledge. The challenge is to specify the nature of these partial representations.

Object permanence

A basis for much of cognition is the ability to form mental models of objects which can be held in mind and used when the object is no longer available to the senses. Mental models are most useful if they represent the physical properties of objects, such as their solidity, location in space, and continuous existence over time, as well as their particular features. Piaget argued that the ability to form such mental models (which he termed *object permanence*) was not achieved until the end of infancy, at around 18 months, based on his robust observations that young infants fail to search for an object that has been hidden from view and that difficulties on search tasks persist well into the second year of life.

However, search tasks impose demands that may mask infants' representational abilities. In particular, they require means–end abilities, which have been linked to prefrontal cortex, an area of the brain that undergoes critical development toward the end of the first year. More sensitive experimental techniques have revealed that young infants form mental representations of objects and their positions in space. To illustrate, in one experiment, 3-month-old infants were shown a screen rotating through 180 degrees until their attention to it had declined (that is, until they had habituated to it). Then a block was placed on the far side of the screen and infants saw one of two events. In one, the screen moved 120 degrees and then stopped. This was a novel stopping position for the screen, but one that was physically possible given the presence of the now hidden block. In the other, the screen continued to move through 180 degrees. Because this rotation was familiar from the habituation event, if infants did not

remember the object hidden behind the screen, it should have been uninteresting to them. However, if infants represented the hidden block, this event should have been surprising because the screen seemed to move through the space occupied by the block. Infants looked longer on the apparently impossible trials than on the possible trials, suggesting that they represented the existence of the block behind the screen. Further evidence for infants' representational abilities comes from studies of reaching: infants reach for an object in the dark, so long as they have been shown the object before the lights go out. Moreover in these studies, infants reach differently depending on the size of the object, indicating that they hold in mind the object's size as well as its continued existence and location.

Physics

During the first few months of life infants are sensitive to two principles that are deeply intuitive to adults – the principles of solidity (an object cannot pass through the space occupied by another object), and continuity (objects exist continuously in time and space). In the experiment described above, for example, infants not only tracked the block's continuous existence behind the screen, but also responded as if both the block and screen were solid. The principle of continuity also provides information about the number of individual objects present in a scene. By 4 months of age, infants seem to be sensitive to this aspect of continuity. In addition, young infants seem to be sensitive to the causal properties of events. When one object moves toward another, contacts it, and then the contacted object immediately moves off, adults perceive the first object as causing the second to move. Infants differentiate between these apparently causal events and similar events that do not appear causal to adults because of a gap between the objects or a delay before the second object is 'launched'.

Infants' representations of physical reality differ significantly from those of adults. Infants seem to be less sensitive to the constraints imposed on object motion by gravity and inertia than they are to the constraints imposed by solidity and continuity. Across a range of physical phenomena, infants seem to begin with an initial all-or-none representation, only later changing their perception to reflect the relative properties of objects. Although young infants use spatiotemporal information to determine the number of individual objects that are present in a scene, they are less able than older infants to use featural information to do this.

Infants also differ strikingly from older children and adults in that their ability to express their physical knowledge is extremely limited. Visual habituation procedures reveal abilities in very young infants, but other procedures reveal apparent deficits in physical reasoning in much older children. This discontinuity has led to a number of hypotheses concerning the nature of infant cognition and its development. It has been suggested that infants' mental representations are inaccessible to general reasoning systems or action systems because they are encapsulated in particular processing modules, are implicit, or are weak. Current work is directed at elucidating and distinguishing between these alternatives.

Intentionality

The abilities to distinguish between inanimate objects and intentional agents, and to interpret the actions of the latter, are critical to human functioning. Adult folk psychology explains human action in terms of the actor's underlying psychological states. Recent experiments have explored the infant precursors to this system of knowledge.

Infants possess several propensities that may facilitate learning about human action. Newborns attend selectively to faces and voices, and are highly responsive to the contingent response patterns that are typical of social partners. They also spontaneously imitate some of the behaviors they observe, including facial gestures and arm movements. By 6 months, infants respond to shifts in other people's gaze direction by directing their own attention in the same direction. This sets the stage for later developments in joint attention.

Beyond these sensitivities, do infants analyze actions in terms of desires, perceptions, and intentions? A number of studies indicate that 18-month-olds interpret the behavior of other people in terms of their intentions and attentional states. To illustrate, on observing a person attempt and fail to complete a novel action, 18-month-olds infer the person's goals and reproduce the intended action. Recent findings suggest that 6- to 9-month-olds understand certain actions as being goal-directed. It has been hypothesized that imitation provides a basis for infants' interpreting other's actions in terms of underlying psychological states by allowing infants to connect their own internal experiences and actions with the actions of other people. This possibility is consistent with recent findings indicating common neural substrates for the perception and production of actions.

Number

Adults extract and mentally manipulate information about number. Observing flowers in a vase, we can represent the fact that there are precisely six flowers. Moreover, we can predict the resulting number of flowers for transformations such as removing two flowers or adding four.

Habituation experiments have revealed infant abilities that may be related to mature number knowledge. First, young infants are sensitive to features associated with exact small (1–3) numbers. Infants habituated to one number of items (e.g. three dots) dishabituate to a new number (e.g. two dots), but not to a novel display with the same number of items. This sensitivity extends to sounds and events as well as visual stimuli. In addition, when 5-month-old infants observe objects added to or subtracted from a hidden display, they look longer when an incorrect number of items is revealed than when a correct number is revealed. Moreover, recent studies suggest that infants form approximate representations for large numbers that allow them to distinguish between sets with large proportionate differences (8 versus 16), but not small proportionate differences (8 versus 12).

Whether these findings reflect sensitivity to number *per se* has been debated. Number is often correlated with other perceptual dimensions, including density and overall amount, and studies with infants do not always successfully control for these features. Moreover, some of the findings concerning small sets could be accounted for by infants' establishing representations of each individual object involved, rather than extracting the number of items in the set.

Categorization

Adults group together perceptually distinct individuals as being the same kind of thing. The resulting conceptual categories provide a means for efficient information storage and retrieval as well as a basis for inferring the properties of new exemplars.

From early in life, infants seem to be sensitive to category structure. Older infants spontaneously sort objects into categories. Young infants manifest a sensitivity to category structure in their patterns of attention. For example, in one experiment, having been shown a series of pictures of cats, 3-month-old infants generalized habituation to new cats and dishabituated to dogs. In addition, like adults, infants seem to structure their categories around the prototype, or most central member, of the category. Having been familiarized to members of a category, infants respond to the category's prototype as if it is highly familiar, even if they have not seen that item before.

Infants categorize artificial stimuli (e.g. dot patterns) as well as real ones (e.g. photographs of animals), and they attend not only to individual features but also to correlations between features in doing so. During the first year of life, infants can group items into relatively broad categories, such as *vehicle* or *animal*, as well as more narrow, basic level categories, such as *dog* or *car*. Different kinds of experiments tap different levels of category sensitivity in infants. In visual attention tasks, infants are sensitive to basic level categories, but on tasks that involve manual manipulation infants sometimes perform better with broad categories than with basic level categories. Infants, like adults, categorize more efficiently when given the opportunity to compare members of a category to one another or to members of a contrasting category.

Adult category knowledge includes not only the perceptual attributes shared by members of a category but also the underlying, often unobservable properties that unite a class. We understand that dogs not only tend to look, smell, and sound alike, but also that they share deeper, important properties including species-typical behaviors and internal structure. A question of long-standing debate is whether infants' categories are exclusively based on perceptual features or instead include more abstract knowledge. Investigating this question has proven difficult, because deep properties are strongly correlated with perceptual attributes, and therefore infants' propensity to group items may not provide unambiguous evidence concerning their knowledge about deep properties *per se*. Nevertheless, as young as 7 months, infants group together items from broad categories which differ from one another on many perceptual dimensions (e.g. a dog, a bird, and a rabbit), and they distinguish between members of different categories which are similar on several dimensions (e.g. a bird and an airplane), suggesting that they base category judgments on more than raw perceptual similarity. Older infants actively seek commonalities beyond the level of surface similarity. By the end of the first year, infants apparently infer that members of a kind share properties that are not immediately observable. By 13 months, infants may begin to understand the link between conceptual categories and language: hearing diverse members of a kind given the same name leads infants to seek out commonalities between them. Finally, by 18 months, infants selectively learn

feature correlations that are meaningful (e. g. having wheels and rolling versus having wheels and squeaking), suggesting that they seek the underlying causal explanations for these correlations.

CONTENTS

The information-processing approach in cognitive science assumes mental architectures with various components that interact in order to manipulate incoming information.

DEFINITION AND HISTORY

Any field of study, in this case cognitive science, always has as a backdrop a kind of super-theory or metatheory, which may itself be rather vague but which provides a philosophy or way of thinking about problems and helps to motivate the theoretical and experimental investigations that are carried out. The information-processing approach is a good candidate for the central metatheory of cognitive science. Cognitive science began to emerge, slowly at first, in the 1950s, and developed rapidly in the 1960s and 1970s, becoming the dominant paradigm in psychology and attracting researchers in linguistics, computer science and philosophy.

A popular introductory text on cognitive science (Ashcraft, 2002) defines the information-processing approach as 'the coordinated operation of active mental processes within a multicomponent memory system'. The essential element of this definition is the specification of 'active mental processes' indicating dynamic ongoing activity. The term 'processes' emphasizes this dynamic aspect, and its early and continued use led to the term 'process model', again suggesting a model or theory that tells what happens cognitively across time. A 'model' is a theory constructed to explain and make predictions about a relatively restricted set of phenomena, while a 'theory' may aim to cover a much wider range. However, the terms 'model' and 'theory' are often used interchangeably. Much of psychology has traditionally been oriented more towards static descriptions (e.g., most personality trait models are static in nature), so the idea of being composed of active processes was a major innovation in the study of human thought and behavior. The words 'coordinated operation' also suggest that the model builder is paying close attention to how the operations of the various components involved in a mental task might start, continue, and stop relative to each other. A notable omission in the above definition of information processing is the arrangement, or architecture, of the processes. Architecture has been the subject of many studies.

In the 1950s, a number of well-known experimental (and early cognitive) psychologists employed information theory (e.g., Shannon and Weaver, 1949) as a theoretical and methodological tool. Claude Shannon, an engineer, invented information theory to measure how much information is contained in messages and how much is transmitted from one place to another. He went on to define the notion of 'channel capacity', the average amount of information transmitted through a communication channel as the time allowed for transmission becomes very large and when an optimal code for messages is constructed. All these notions have entered the domain of perceptual and cognitive psychology, and they strongly influenced the development of the information-processing approach (e.g., Attneave, 1959; Garner, 1962; Luce, 1960). Nevertheless, Shannon's theory of information processing is rarely employed in cognitive science (perhaps unfortunately); and it should not be confused with the more vague, but more globally applicable, information-processing approach.

Other lines of research by engineers, economists, computer scientists, and mathematicians also influenced the early development of cognitive science, and especially the information-processing approach. Cybernetics, the science of feedback control systems and adaptive systems (systems that can evolve their own behaviors and, to some extent, intelligence (Wiener, 1948)), was one of these. Another was the explosion of research in theoretical computer science, particularly with the work of John von Neumann. The fact that computers – in theory, and to a growing extent in practice – could carry out the mental operations about which philosophers and psychologists had long argued, convinced most psychologists and early researchers in artificial intelligence (computer scientists, engineers, biologists, and psychologists who study how to make machines that can think and act like humans) that important progress could be made in the study of human perception, thought, and action simply by basing their models on computer-like concepts, information theory, and similar structures and ideas.

SERIAL AND PARALLEL PROCESSING, FLOW DIAGRAMS, AND CONTINUOUS-FLOW SYSTEMS

Many early computers operated in a sequential, or 'serial', way on the tasks to be accomplished. This means that each task or part of a task is operated on and completed before the next is started. Hence, it was natural for cognitive investigators to hypothesize that certain simple mental activities might be carried out in this way.

Such an arrangement is called an 'architecture'. An obvious alternative architecture is a 'parallel' architecture, whereby all tasks or processes are carried out simultaneously. Parallel and serial systems are probably the simplest nontrivial kinds of architectures, but much more complicated architectures, many of them composed of combinations of serial and parallel processes, can be designed and tested against laboratory data (e.g., Schweickert, 1978; Schweickert and Townsend, 1989).

Many of the early models proposed in the information-processing approach were serial in nature. This trend was probably due to the serial character of many computer operations. Such analogies have often been made in psychological theorizing over the decades (e.g., Roediger, 1980).

The most popular device employed in the information-processing approach is that of the flow diagram. This is a schematic picture that shows as boxes the hypothetical processes thought to be involved in the mental behavior under study. Figure 1(a) shows a typical flow diagram for memory scanning. It represents a serial interpretation of short-term memory search along the lines suggested by Sternberg (1966). Figure 1(b) shows a parallel network supported by facial-feature detection (Wenger and Townsend, 2001). Figure 1(c) shows a hybrid network called a 'bare Wheatstone bridge' (Schweickert, 1978). Note that there exist parallel channels, but that the presence of the 'bridge' allows serial-like activity as well. Schweickert has found that the Wheatstone-bridge structures are required to handle certain kinds of mental processing.

While many cognitive studies have associated quantitative models with the architecture indicated by their flow diagrams, many more have simply relied on intuitive reasoning allied with experimental results to support their conclusions. Needless to say, verbal reasoning in scientific contexts can be hazardous.

All of the kinds of models discussed so far contain the important assumption of 'discrete flow'. This means that each subtask (e.g., identifying an item, performing a calculation) must be entirely completed before beginning the next. Thus, in serial processing, there is no overlap of mental activities taking place in succession. In parallel systems, of course, different subtasks can take place simultaneously, but anything happening next must await a discrete event, such as all of the preceding parallel items being completed.

It is easy to conceive of alternative systems. Even a task whose subtasks take place sequentially might allow overlap in their actual processing. A hybrid system (neither strictly serial nor strictly parallel) could have, say, the second item to be processed begin 50 ms after the first begins, even though the first is uncompleted (e.g., Taylor, 1976; Townsend and Ashby, 1983, pp. 370–371).

We refer to a system that allows total overlap, even though the structure is sequential, as exhibiting 'continuous flow'. Total overlap means that all items or channels in a sequence begin simultaneously even though they are not processed in parallel. This concept may seem strange at first. Actually, many practical systems – for instance, those used to describe electronic networks – closely approximate this situation. As the first process begins its work, it immediately begins sending output to the second process, which immediately sends its output to the third, and so on. McClelland (1979) developed a model obeying this principle and fit it to data usually interpreted as supporting strict serial models. (See also Ashby (1982).) He

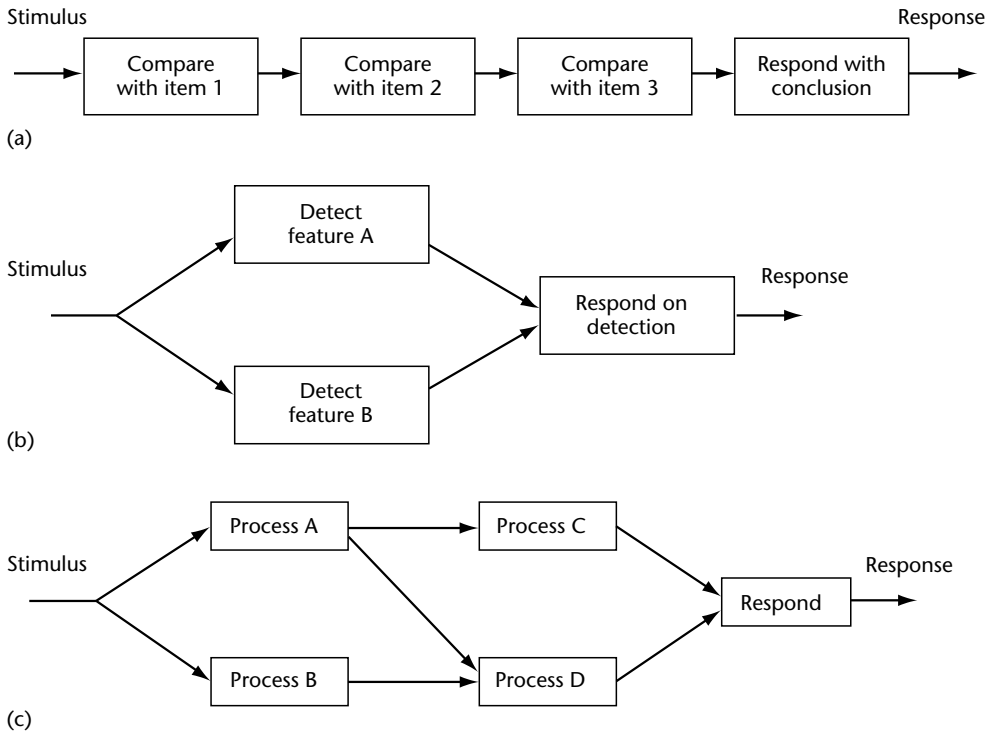

Figure 1. Flow diagrams. (a) A flow diagram of the short-term memory model discussed by Sternberg (1966). It shows a model that compares the stimulus with each item in memory. Each process in the diagram starts only when the previous one is finished, and all processes must be finished before a response is made. At the end, a response is made based on the results of the preceding processes. Note that this diagram does not specify the implementation. For instance, a computer with one central processing unit can perform each process in sequence; or several processing units may be connected in line to perform these processes. (b) A flow diagram of a simplified version of a parallel network investigated by Wenger and Townsend (2001). A 'yes' response is made when one or two features of the stimulus match those of a face in memory. The diagram shows that detection of the two features can be processed simultaneously. A response can be made when either one of the two processes is finished. (c) A flow diagram of a Wheatstone-bridge structure analyzed by Schweickert (1978). In this model, process C cannot start processing until process A is finished; process D cannot start until processes A and B are finished; and a response cannot be made until processes C and D are finished. Schweickert found that these dependencies can be investigated by a generalization of Sternberg's additive-factor method.

called his model the 'cascade model', borrowing terminology from engineering literature.

Naturally, there can exist parallel subsystems, each of which consists of a cascaded (i.e., continuous-flow) sequence of operations. Although such systems are likely to become increasingly popular (e.g., Usher and McClelland, 2001), their formal properties are more difficult to establish in a general manner than those of discrete-flow systems (Schweickert and Townsend, 1989; Schweickert, 1989).

INDEPENDENCE, CAPACITY, AND STOPPING RULES

Besides the architecture issue, the issue of independence versus dependence among the processing times of the items is also important (e.g., Townsend, 1974). Whether two items or channels operate independently is important in terms of both accuracy (Townsend *et al*., 1984; Ashby and Townsend, 1986) and response time (e.g., Townsend and Ashby, 1983). For instance, it is natural, in parallel systems, to assume that the parallel channels are independent of one another – just as, when two different people toss their own coins, we are justified in supposing that the two tosses are independent. It is usually assumed in serial processing that any two successive processing times are independent. Of course, in either parallel or serial systems independence will depend on the particular setting and task.

Another important concept is that of 'capacity', that is, the efficiency, speed and accuracy of processing. It is most often understood in terms of the effect on processing times of the number of

things to be worked on (Fisher, 1982; Townsend and Ashby, 1978, 1983). In parallel processing, it is clearly reasonable to suppose that processing slows down when the number of items to be processed increases (capacity is limited). However, limitations in capacity that are indirect, even with serial processing, can be conceived. For instance, a serial processor might speed up as it goes through the items, due to warm-up effects, or slow down, due to inertia or fatigue of the processor. Even though capacity and independence are logically separate notions, they can interact. For instance, an important type of parallel system, one that can mimic serial processing, assumes that as each item is completed its processing capacity is reallocated to other remaining items (Townsend and Ashby, 1983). This obviously affects the overall 'reaction time' (RT), but it also creates a positive dependency (i.e., facilitation) among the item processing times. And different types of dependency can affect capacity measures in different ways. Thus, it has been shown that positive dependencies across two parallel channels can speed things up.

Another important notion is that of the 'stopping rule'. Depending on the task, it may or may not be necessary for the participant to process all of the items in order to make a correct response. For example, in the memory-search paradigm, if a probe is present, the processing can cease before everything has been processed: an event known as 'self-termination'. However, if no probe is present, it is necessary to process all of the memory items in order to be sure of correctly making a 'no' response: that is, exhaustive processing must occur. In some experimental designs, all the items meet the probe's criterion (for instance, the 'probe' might be specified as 'any vowel' and all memory items might be vowels). In this case there is the possibility of 'first-terminating' or 'minimum time' processing.

Of course, it is an empirical question whether any kind of self-termination can actually take place in high-speed perceptual or cognitive operations. It has been proved that some of the early data from the 1960s that did not distinguish certain classes of parallel and serial models provides strong evidence for or against self-termination (van Zandt and Townsend, 1993; Townsend and Van Zandt, 1990; Townsend and Colonius, 1997).

MATHEMATICAL MODELS OF HUMAN INFORMATION PROCESSING AND COGNITION

The use of mathematical models is a powerful alternative to a flow diagram together with verbal reasoning. Although mathematical models have a long history in psychology, it is only since the 1950s that they have begun to exert a consistent and strong influence on psychology in general, and cognitive psychology in particular. They have been particularly effective within the information-processing approach, since the investigator can immediately begin to work out what a flow diagram purports to do in terms of mathematical expressions. Mathematical models express, in terms of formulae and equations, assumptions and explanations and predictions of psychological ideas.

A large number of mathematical models have been developed within the information-processing approach. Typically, a mathematical model will have some parameters, which are given as symbols that can assume values as numbers. For instance, consider the rather trivial model given by the equation $y = ax + b$. In this model, the constants a and b are parameters, which, in general, can take any numerical value. The term x is the main independent variable (usually not called a parameter, although usage varies), which is manipulated in the model while a and b are held constant. Mathematical models, whether in cognitive science, physics or biology, can be highly complex, but have been of inestimable value.

Mathematical models must be tested against real data. The usual way of testing a model requires us first to find the parameter values that allow the model to come as close as possible to a set of experimental data (the so-called 'fit procedure'), and then to examine how well the model does indeed reproduce the data. Some measures of fit permit statistical testing of the model, to learn whether it differs from the data more than would be expected on the basis of chance. These are called 'tests of significance'. Since the use of sparse or noisy data can sometimes make a model seem to fit data better than it deserves (i.e., where a large representative set of data might falsify the model), many theorists recommend comparisons of models obeying different and often opposing principles (e.g., parallel versus serial principles). This is a survival-of-the-fittest strategy. It has much to recommend it, especially since it is a very human tendency, even among scientists, to want to 'save' one's own model or theory.

However, a rather different strategy has emerged over the past few decades: to attempt to discover broad, qualitative kinds of predictions that a model, or a whole set of models (e.g., the set of all parallel models, that is all models that predict simultaneous processing of the task under study), make for a set of phenomena. For instance, one

model might predict that a certain dependent variable is a linear function of a certain independent variable, while another predicts a concave function. Then graphing the data can falsify one model and support another, even though the investigator does not actually fit either model to the data. A more complex, but much more powerful, qualitative approach is found in 'systems-factorial methodologies', which we describe later.

In recent years, mathematical models have become a part of everyday cognitive and experimental psychology. In the 1950s it was rare to find a mathematical model in a journal of experimental psychology, and most were found in specialist quantitatively-oriented journals. Nowadays, any issue of an experimental journal will typically contain several articles that employ mathematical models.

CODES IN INFORMATION PROCESSING

Since the term 'information processing' explicitly refers to information, it is natural to inquire about the nature and measurement of information, that is, the 'code' used, in various perceptual and cognitive operations by the individual.

The traditional unit of information, namely, the 'bits' (short for 'binary unit', basically equal to the logarithm to base 2 of the number of message possibilities), has rarely been employed in recent models. But there are exceptions. In studies related to perception, such as pattern recognition, where the observer must identify which of a set of patterns (letters, words, faces, etc.) has been presented, or in areas where the coding is an integral part of the science, such as psycholinguistics, researchers do explicitly employ, and sometimes test, the code used in the pertinent operations. An example is the study of perception of letters and letter-like forms, where hypothetical sets of features making up the visually-presented letters are subjected to study (e.g., Townsend and Ashby, 1982). Things like lines and curves, as well as more complicated features such as whether a letter is closed (like an 'O') or open (like a 'C'), have been examined. However, other approaches have sought explanation in terms of the wave forms of light and dark of which any picture is composed (i.e., Fourier analysis): such an approach is akin to the analysis of sounds into frequencies that are related to pitch sensation (e.g., Ginsburg, 1986).

Often, in the absence of any knowledge or hypotheses about the form of the code, one can simply measure the information, or important aspects of the information, by means of parameters in mathematical models. A parameter in a model can represent something that relates to a code, without actually being a code. For example, consider a model of pattern identification that assumes that the likelihood of confusing two items is a function of the similarity between the two items. For instance, in the 'overlap model', the probability of confusing, say, the letter K with the letter R would be given by the parameter c_{KR} (e.g., Townsend, 1971). A very successful model of identification called the 'similarity choice model' (Luce, 1963) also uses similarity parameters.

Note that these models do not try to give the perceptual code of the stimulus patterns. A response-time model may possess a parameter that actually measures the rate of processing of, say, the visual features that make up a letter. However, often the model will simply include a term that represents the likelihood that a sub-process is completed by a certain time, without clear specification of a code or how fast that code is employed or processed.

SYSTEMS-FACTORIAL METHODOLOGIES FOR DETERMINING ARCHITECTURE

One promising general qualitative approach to testing different ideas about mental architecture is based on the notion of 'selective influence' of experimental factors: a notion first employed in tests of strict seriality by Sternberg (1969) in his well-known 'additive-factor method'. All factorial methodologies, like the original Sternberg strategy, depend on the assumption (powerful, if true) that distinct experimental factors affect distinct processing components (i.e., subsystems). This is the assumption of selective influence. The expression $\overline{\mathrm{RT}}(X + \Delta X, Y)$ refers to the mean RT where the X factor has prolonged RT but Y is at base level; and similarly for $\overline{\mathrm{RT}}(X, Y + \Delta Y)$. The fundamental statistic for the original method, and most extensions, is the 'mean interaction contrast', defined as $\mathrm{MIC} = [\overline{\mathrm{RT}}(X + \Delta X, Y + \Delta Y) - \overline{\mathrm{RT}}(X + \Delta X, Y)] - [\overline{\mathrm{RT}}(X, Y + \Delta Y) - \overline{\mathrm{RT}}(X, Y)]$. Schweickert (1978) formulated the first major extension of the additive-factor method involving more complex architectures under the assumption of selective influence, in his 'latent mental network theory'. Townsend and Ashby (1983) found that the mean interaction contrast distinguished parallel and serial stochastic models, when selective influence was assumed, and Schweickert and Townsend (1989) produced general theorems for Schweickert's

latent networks, within a stochastic setting, assuming exhaustive processing. Note that factorial strategies do not demand that the investigator provide a specification of the information codes that the underlying system is using.

Although the early theorems were established in the context of exhaustive processing, analogous results can be found in the case of self-terminating and first-terminating processing times (e.g., Schweickert and Giorgini, 1999; Townsend and Nozawa, 1995). Because Sternberg's original ideas have been extended in so many new directions, it has been suggested that the general approach be referred to as 'systems-factorial technology' (Townsend and Thomas, 1994). For instance, one interesting strategy has been to enlist entire RT distributions in providing more powerful tests of parallel versus serial processing or other related architectures (Dzhafarov and Schweickert, 1995; Roberts and Sternberg, 1993; Townsend, 1990; Townsend and Ashby, 1983; Balakrishnan, 1994).

The assumption of selective influence is critical to the legitimacy of systems-factorial technology, and much is now known about its foundational underpinnings and what may go awry if it is violated (Dzhafarov, 1997; Townsend, 1984; Townsend and Schweickert, 1989; Townsend and Thomas, 1994).

Goldstein and Fisher (1991) have produced a theory and methodology for stochastic networks and processing rules even more general than those based on directed graphs. Miller (1993) and Liu (1996) have proposed theoretical approaches based on the theory of 'queuing processes'. Queuing theory is an approach of great value in engineering. It studies or describes how customers in lines waiting for service in various arrangements are served, and how long it takes with various arrangements. For instance, queuing theory may try to find an optimal architecture to enable lines of partially-finished products to make their way through a factory. The tools of queuing theory, and the general networks of Goldstein and Fisher (1991), may prove of considerable value to the study of human information processing, when appropriately adapted.

CONCLUSION

The information-processing approach has grown in breadth and depth, far beyond the sometimes simplistic early use of computer analogies, flow diagrams, and other concepts and terminologies that were not always backed up by rigorous theory and methodology. With the aid of modern mathematical modelling, theory-driven methodology, and adept experimentation, we can undoubtedly look forward to continued and cumulative progress in the understanding of human information processing.

Information Theory

Introductory article

Zoubin Ghahramani, University College London, UK

CONTENTS

Information theory is a mathematical theory defining the limits and possibilities of communication. It provides a quantitative measure of the information content of a message, which is independent of the meaning of the message, in terms of the reduction of uncertainty resulting from receiving the message.

INTRODUCTION

Information is the reduction of uncertainty. Imagine your friend invites you to dinner for the first time. When you arrive at the building where he lives you find that you have misplaced his apartment number. He lives in a building with 4 floors and 8 apartments on each floor. If a neighbor passing by tells you that your friend lives on the top floor, your uncertainty about where he lives is reduced from 32 choices to 8. By reducing your uncertainty, the neighbor has conveyed *information* to you. How can we quantify the amount of information?

Information theory is the branch of mathematics that describes how uncertainty should be quantified, manipulated, and represented. Ever since the fundamental premises of information theory were laid down by Claude Shannon in 1949, it has had far-reaching implications for almost every field of science and technology. Information theory has also played an important role in shaping theories of perception, cognition, and neural computation. This article will discuss some of the basic concepts in information theory and how they relate to cognitive science and neuroscience.

ENTROPY AND MUTUAL INFORMATION

The most fundamental concept in information theory is entropy. Shannon borrowed the concept of entropy from thermodynamics, where it describes the amount of disorder of a system. In information theory, entropy measures the amount of uncertainty of an unknown or random quantity. The entropy of a random variable X is defined to be

$$H(X) = -\sum_x P(x)\log_2 P(x) \quad (1)$$

where the sum is over all values x that the variable X can take, and $P(x)$ is the probability of the value x occurring. Entropy is measured in *bits*, and can be generalized to continuous variables, although care must be taken to specify the precision level at which we would like to represent the continuous variable. Returning to our example, if X is the random variable that describes which apartment your friend lives in, initially it can take on 32 values with equal probability $P(x) = 1/32$. Since $\log_2(1/32) = -5$, the entropy of X is 5 bits. After the neighbor tells you that he lives on the top floor, the probability of X drops to 0 for 24 of the 32 values and becomes $1/8$ for the other 8 equally probable values. The entropy of X thus drops to 3 bits (by convention $0 \log 0 = 0$). The neighbor has therefore conveyed 2 bits of information to you.

This fundamental definition of entropy as a measure of uncertainty can be derived from a small set of axioms. Entropy is the average amount of 'surprise' associated with a set of events. The amount of 'surprise' of a particular event x is a function of the probability of that event: the less probable an event (e.g. a moose walking down Wall Street), the more surprising it is. The amount of surprise of two independent events (e.g. the moose and a solar eclipse) should be the sum of the amounts of surprise of the events. These two constraints imply that the surprise of an event is proportional to $-\log P(x)$, with the proportionality constant determining what base logarithms are taken in (e.g. base 2 for bits). Averaging over all events according to their respective probabilities, we get the expression for $H(X)$.

Entropy in information theory has deep connections with the thermodynamic concept of entropy and, as we will see, it can be related to the smallest

number of bits it would take on average to communicate X from one location (the sender) to another (the receiver). On the one hand, the concepts of entropy and information are universal, in the sense that a bit of information can refer to the answer to any yes–no question where the two options are equally probable. A megabit is a megabit (the answers to about a million yes–no questions, which can potentially distinguish between $2^{1\,000\,000}$ possibilities) regardless of whether it is used to encode a picture, music, or large quantities of text. On the other hand, entropy is always measured relative to a probability distribution, and for many situations it is not possible to consider the 'true' probability of an event. For example, I may have high uncertainty about the weather tomorrow, but a meteorologist might not. Hence there may be different entropies for the same set of events, defined relative to the subjective beliefs of the entities whose uncertainty we are measuring. This subjective, or Bayesian, view of probabilities is useful when we are considering how information communicated between different (biological or artificial) agents changes their beliefs.

While entropy is useful in determining the uncertainty in a single variable, it does not tell us how much uncertainty we have in one variable given knowledge of another. For this we need to define the *conditional entropy* of X given Y:

$$H(X|Y) = -\sum_{x,y} P(x \,\&\, y)\log_2 P(x|y) \tag{2}$$

where $P(x|y)$ denotes the probability of x given that we have observed y. Building on this definition, the *mutual information* between two variables is the reduction in uncertainty in one variable given another variable. Mutual information can be written in three different ways:

$$\begin{aligned} I(X;Y) &= H(X) - H(X|Y) = H(Y) - H(Y|X) \\ &= H(X) + H(Y) - H(X\&Y) \end{aligned} \tag{3}$$

The mutual information between two variables is symmetric: $I(X;Y) = I(Y;X)$. If the random variables X and Y are independent, that is, if the probability of their taking on values x and y is $P(x \,\&\, y) = P(x)\,P(y)$ for all x and y, then they have zero mutual information. Similarly, if one can determine X exactly from Y and vice versa, the mutual information is equal to the entropy of either of the two variables.

SOURCE CODING

Consider the problem of transmitting a sequence of symbols across a communication line using a binary representation. We assume that the symbols come from a finite alphabet (e.g. letters and punctuation marks of text, or levels from 0 to 255 of grayscale image patches) and, to begin with, that the communication line is noise-free. We further assume that the symbols are produced by a source which emits each symbol x randomly with some known probability $P(x)$. How many bits do we need to transmit per symbol so that the receiver can perfectly decode the sequence of symbols?

If there are N symbols in the alphabet then we could assign a distinct binary string (called a *codeword*) of length L to each symbol, provided $2^L > N$. This suggests that we would need at most L bits. But we can do much better than this by assigning shorter codewords to more probable symbols and longer codewords to less probable ones. Shannon's '*noiseless source coding theorem*' states that if the source has entropy $H(X)$ then there exists a decodable prefix code having an average length L per symbol such that

$$H(X) \le L < H(X) + 1 \tag{4}$$

Moreover, no uniquely decodable code exists having a smaller average length. In a *prefix* code, no codeword starts with another codeword, so the message can be decoded unambiguously as it comes in. This result places a lower bound on how many bits are required to compress a sequence of symbols losslessly. A closely related concept is the Kolmogorov complexity of a finite string, defined as the length in bits of the shortest program which when run on a universal computer will cause the string to be output.

Huffman Codes

We can achieve the code length described by Shannon's noiseless coding theorem using a very simple algorithm. The idea is to create a prefix code which uses shorter codewords for more frequent symbols and longer codewords for less frequent ones. First we combine the two least frequent symbols, summing their frequencies, into a new symbol. We do this repeatedly until we have only one symbol. The result is a tree with the original symbols at the leaves. This is illustrated in Figure 1 using an alphabet of 7 symbols {a,b,c,d,e,o,k} with differing probabilities. The codeword for each symbol is the sequences of left (0) and right (1) moves required to reach that symbol from the top of the tree.

In this example we have 7 symbols, so the naive fixed-length code would require 3 bits per symbol ($2^3 = 8 > 7$). The Huffman code (which is a variable-length code) requires on average 2.48 bits; the

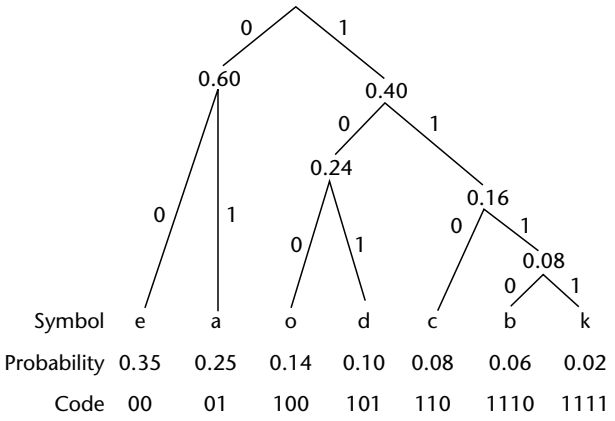

Figure 1. Huffman coding for an alphabet of seven symbols with differing probabilities.

entropy gives a lower bound of 2.41 bits. The fact that it is a prefix code makes it easy to decode a string symbol by symbol, by starting from the top of the tree and moving down left or right every time a new bit arrives. For example, try decoding: 1010011010010100.

If we want to improve on this to get closer to the entropy bound, we can code blocks of several symbols at a time. Many practical coding schemes work by forming blocks of symbols and coding each block separately. Using blocks also makes it possible to correct for errors introduced by noise in the communication channel.

Information Transmission Along a Noisy Channel

In the real world, communication channels suffer from noise. When transmitting data to a mobile phone, listening to a person in a crowded room, or playing a DVD movie, there are random fluctuations in signal quality, background noise, or disk rotation speed, which we cannot control. The noise on a channel can be simply characterized by the conditional probability of the received symbols given the transmitted symbol: $P(r|t)$. This noise limits the information capacity of the channel, which is defined to be the maximum, over all possible distributions over the transmitted symbols T, of the mutual information between the transmitted symbol and the received symbol R:

$$C = \max_{p} I(T;R) \tag{5}$$

For example, if the symbols are binary and the channel has no noise, then the channel capacity is 1 bit per symbol (corresponding to transmitting 0 and 1 with equal probability). However, if 10% of the time a 0 transmitted is received as a 1, and 10% of the time a 1 transmitted is received as a 0, then the channel capacity is only 0.53 bits per symbol.

This probability of error could not be tolerated in most real applications. Does this mean that the channel is unusable? Not if one uses the trick of building redundancy into the transmitted signal in the form of an 'error-correcting code' so that the receiver can still decode the intended message (Figure 2). One simple scheme is a 'repetition code'. For example, encode the symbols by transmitting three repetitions of each; decode them by taking blocks of three and outputting the majority vote. This reduces the error probability from 10% to 2.8%, at the cost of reducing the rate at which the original symbols are transmitted by 1/3.

If we want to achieve an error probability approaching zero, do we need to transmit at a rate approaching zero? Remarkably the answer is negative, as Shannon proved in his '*channel coding theorem*'. This states that all rates below channel capacity are achievable; i.e., that there are codes which transmit at a given rate and have a maximum probability of error approaching zero. Conversely, if a code has probability of error approaching zero, it must have a rate less than or equal to channel capacity. Unfortunately Shannon's channel coding theorem does not say how to design codes that approach zero error probability near the channel capacity. Of course, codes with this property are more sophisticated than the repetition code, and finding good error-correcting codes that can be decoded in reasonable time is an active area of research. Shannon's result is of immense practical significance since it shows that we can have essentially perfect communication over a noisy channel.

INFORMATION THEORY AND LEARNING SYSTEMS

Information theory has played an important role in the study of learning systems. Just as information theory seeks to quantify information regardless of its physical medium of transmission, so learning theory seeks to understand systems that learn regardless of whether they are biological or artificial.

Learning systems can be broadly categorized by the amount of information they receive from the environment in their supervision signal. In 'unsupervised learning', the goal of the system is to learn from sensory data with no supervision. This can be achieved by casting the unsupervised learning problem as one of discovering a code for the system's sensory data which is as efficient as

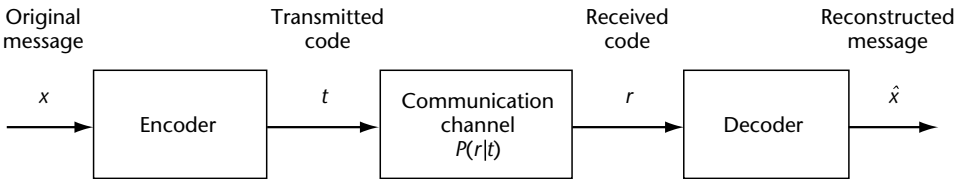

Figure 2. A noisy communication channel.

possible. Thus the concepts of entropy, Kolmogorov complexity, and description length can be used to formalize unsupervised learning problems.

We know from the source coding theorem that the most efficient code for a data source is one that uses $-\log_2 P(x)$ bits per symbol x. Therefore, the problem of discovering the optimal coding scheme for a set of sensory data is equivalent to the problem of learning what the true probability distribution $P(x)$ of the data is. If at some stage we have an estimate $Q(x)$ of this distribution, we can use this estimate instead of the true probabilities to code the data. However, we incur a loss in efficiency measured by the *relative entropy* between the two probability distributions P and Q:

$$D(P\|Q) = \sum_x P(x)\log_2 \frac{P(x)}{Q(x)} \qquad (6)$$

which is also known as the Kullback–Leibler divergence. This measure is the inefficiency in bits of coding messages with respect to a probability distribution Q instead of the true probability distribution P, and is zero if and only if $P = Q$. Many unsupervised learning systems can be designed from the principle of minimizing the relative entropy.

INFORMATION THEORY IN COGNITIVE SCIENCE AND NEUROSCIENCE

The term 'information processing system' has often been used to describe the brain. Indeed, information theory can be used to understand a variety of functions of the brain. A few examples are mentioned here.

In neurophysiological experiments where a sensory stimulus is varied and the spiking activity of a neuron is recorded, mutual information can be used to infer what the neuron is coding for. The mutual information for different coding schemes can be compared, for example, to test whether the exact spike timing is used for information transmission. (*See* **Decoding Neural Population Activity**; **Rate versus Temporal Coding Models**)

Information theory has been used to study both perceptual phenomena and the neural substrate of early visual processing. It has been argued that the representations found in the visual cortex arise from principles of redundancy reduction and optimal coding.

Communication via natural language occurs over a channel with limited capacity. Estimates of the entropy of natural language can be used to determine how much ambiguity or surprise there is in the next word following a stream of previous words, and learning methods based on entropy can be used to model language. (*See* **Natural Language Processing, Statistical Approaches to**)

Redundant information arrives from multiple sensory sources (e.g. vision and audition), and over time (e.g. a series of frames of a movie). Decoding theory can be used to determine how this information should be combined optimally and whether the human system does so.

The human movement control system must cope with noise in motor neurons and in the muscles. Different ways of coding the motor command result in more or less variability in the movement.

Information theory lies at the heart of our understanding of computing, communication, knowledge representation, and action. As in many other fields of science, the basic concepts of information theory have played, and will continue to play, an important role in cognitive science and neuroscience.

Intelligence

Introductory article

Robert J Sternberg, Yale University, New Haven, Connecticut, USA

CONTENTS

Intelligence has been defined variously, across a range of cultures and populations, as encompassing such mental and social phenomena as learning and understanding, reasoning and problem-solving, perception and adaptation.

INTRODUCTION

Intelligence, according to *Webster's New World College Dictionary* (3rd edn), is 'the ability to learn or understand from experience, ability to acquire and retain knowledge; mental ability…' Such a definition captures many facets of the nature of intelligence, but not necessarily those believed by experts to be key.

Two symposia, one in 1921 and the other in 1986, sought to ascertain the key features of intelligence according to experts in the field such as Lewis Terman and Edward Thorndike (in the 1921 symposium) and Ulric Neisser and Douglas Detterman in the 1986 symposium. Critical elements of the definition of intelligence, according to experts, are (a) adaptation in order to meet the demands of the environment effectively, (b) elementary processes of perception and attention, (c) higher level processes of abstract reasoning, mental representation, problem-solving, decision-making, (d) ability to learn, and (e) effective behavior in response to problem situations.

Some experts, however, have been content to define intelligence operationally, simply as what intelligence tests test. This definition, first proposed by Edwin Boring in 1923, relies on tests to define intelligence and ultimately is circular.

Laypeople also can be asked to define intelligence, and it turns out that their definitions differ from expert definitions in placing somewhat greater emphasis on social competence skills. In one study, for example, laypeople defined intelligence in terms of three broad classes of skills: (a) practical problem-solving, (b) verbal ability, and (c) social competence. But how people define intelligence varies across occupations. For example, one study found that philosophy professors tend to stress critical and logical thinking very heavily, whereas physicists tend to place more value on precise mathematical thinking, the ability to relate physical phenomena to concepts of physics, and the ability to grasp quickly the laws of nature.

Definitions of intelligence also vary across cultures. For example, in a study by Yang and Sternberg of Chinese people's conceptions of intelligence in Taiwan, it was found that in addition to emphasizing cognitive skills in their conceptions of intelligence, the Taiwanese also emphasized interpersonal skills, intrapersonal (self-understanding) skills, knowing when to show one's intelligence, and knowing when *not* to show one's intelligence.

FACTOR-ANALYTIC THEORIES

One of the oldest approaches to understanding intelligence is through psychometric theories. These theories seek understanding of intelligence through its measurement.

Among these theories, the earliest major one is that of Spearman, who proposed that intelligence comprises a general factor (*g*) of intelligence common to all intellectual tasks, as well as specific factors (*s*), each of which is unique to a given test of intelligence. His proposal was based on his finding of a 'positive manifold' among intelligence tests: all tests seemed to be positively intercorrelated, suggesting the existence of a general factor. Spearman's theory still has many proponents today, such as Arthur Jensen.

Louis Thurstone disagreed with Spearman, arguing that the general factor was an artefact of the way Spearman analyzed his data. Thurstone suggested that seven primary mental abilities underlie intelligence: verbal comprehension, verbal fluency, number, spatial visualization, inductive reasoning, memory, and perceptual speed. More modern theorists, such as Raymond Cattell and John

Carroll, have attempted to integrate these two kinds of views, suggesting that intelligence is best understood hierarchically, with a general factor at the top of the hierarchy and narrower factors under it. Cattell proposed two such factors: fluid intelligence, which is involved in reasoning with novel kinds of stimuli; and crystallized intelligence, or stored knowledge base.

J. P. Guilford had a very different kind of model. He suggested that intelligence could be understood in terms of 150 separate factors that represented different combinations of operations, products, and contents. Operations included cognition (knowing), memory, divergent production (generation of alternatives), convergent production, and evaluation. Products included units, classes, relations, systems, transformations, and implications. Finally, contents included the figural, symbolic, semantic, and behavioral. For example, solving a verbal analogy such as 'LAWYER is to DOCTOR as CLIENT is to ?' would require cognition of semantic relations. Although this theory was popular at one time, the empirical evidence supporting it was shown by John Horn to be flawed. In particular, using Guilford's methods, Horn found that random data yielded as good a fit to Guilford's model as did real data!

Not all psychometric work on intelligence has been theoretically based. One of the earlier theories of intelligence was proposed by Sir Francis Galton, an Englishman, in 1883. Galton believed that intelligence is the capacity for labor and sensitivity to physical stimuli. Galton and his follower in the United States, James McKeen Cattell, measured intelligence using tests to assess skills such as the rate of arm movement over a distance of 50 cm, the threshold for distance on the skin by which two points need to be separated for them to be felt separately, and the span of letters that could be recalled from memory.

A more plausible inroad into intelligence testing was made by Alfred Binet and Theodore Simon in France. In 1904, the Minister of Public Instruction in Paris appointed a commission to find a means to differentiate truly mentally 'defective' children from those who were unsuccessful in school for other reasons. The commission was to ensure that no child suspected of mental retardation be placed in a special class without first being given an examination to measure the child's intelligence. Binet and Simon created the test, which measured judgment skills. A later test, created by David Wechsler, also measured primarily judgment skills.

Both the Binet and the Wechsler tests are still used in modern versions. What is actually found on such tests? The Wechsler tests (which cover three age ranges from infancy through adulthood) are divided into two major scales, verbal and performance. The verbal scale includes items measuring (1) comprehension, which requires examinees to answer questions of social knowledge; (2) vocabulary, which requires individuals to define words; (3) information, which requires people to supply generally known information; (4) similarities, which requires examinees to say in what ways two concepts are similar; (5) arithmetic, which requires people to solve simple arithmetical word problems; and (6) digit span, which requires individuals to repeat back number series, forward or backward. The performance scale includes items requiring test-takers to solve tasks. The subtests are (1) object assembly, which requires the participant to put together a puzzle by combining pieces to form a particular common object; (2) block design, which requires the individual to use patterned blocks to form a design that looks identical to a design shown by the experimenter; (3) picture completion, which requires an individual to say what is missing from each of a set of pictures; (4) picture arrangement, which requires the individual to put a set of cartoon-like pictures into a chronological order, so they tell a coherent story; and (5) digit symbol, which requires the individual to use a key matching particular symbols to particular numerals to copy a sequence of symbols based on the key of correspondence to the numerals.

KINDS OF INTELLIGENCE

In recent years, scholars seeking to understand intelligence have sought to understand not just factors of intelligence, but also kinds of intelligence. Three major theories have received special attention.

Howard Gardner has proposed a theory of multiple intelligences, according to which intelligence is not just a single entity, but eight separate entities. These are (1) linguistic intelligence – used to read a book, write a paper, or understand speech; (2) logical–mathematical intelligence, used to solve mathematical problems and balance a checkbook; (3) spatial intelligence, used to get from one place to another and to read a map; (4) musical intelligence, used to sing a song or compose a sonata; (5) bodily–kinesthetic intelligence, used to dance or play basketball; (6) naturalist intelligence, used to understand patterns in the natural world; (7) interpersonal intelligence, used to relate to other people; and (8) intrapersonal intelligence, used to understand oneself. So far, there have been no

psychometric tests designed formally to measure the different intelligences in this theory, so it is in need of empirical validation.

Robert Sternberg has proposed that intelligence comprises three aspects. Analytical abilities are used to analyze, evaluate, and critique: for example, they are used to decide whether a certain argument you or someone else has made is a logical argument. Creative abilities are used to create, discover, and invent: for example, you use creative intelligence when you come up with new ideas for a paper topic, a scientific experiment, or a work of art. Practical abilities are used to apply, implement, and utilize: for example, they are used when you decide how you should best say something to someone to convince that person to do what you wish them to do.

According to Sternberg's triarchic theory of human intelligence, intelligence draws on three kinds of information processes. Metacomponents are used to plan, monitor, and evaluate problem-solving. Performance components are used to implement the commands of the metacomponents. Knowledge-acquisition components are used to learn how to solve particular kinds of problems in the first place.

A third theory is the theory of emotional intelligence, originally proposed by Peter Salovey and John Mayer and then popularized by Daniel Goleman. Emotional intelligence is the ability to perceive accurately, appraise, and express emotions; the ability to access and/or generate feelings when they facilitate thought; the ability to understand emotion and emotional knowledge; and the ability to regulate emotions to promote emotional and intellectual growth. Although emotional intelligence is a relatively new construct, there is already some solid evidence suggesting its validity as a psychological construct. Mayer and Salovey have devised tests of emotional intelligence which predict behavior independently of the behavior's relations to conventional cognitive intelligence.

GENETIC AND ENVIRONMENTAL FACTORS

The ancient nature–nurture controversy continues in regard to intelligence. However, today, the large majority of psychologists and behavior geneticists – those who study the effects of genes on behavior – believe that differences in intelligence result from a combination of hereditary and environmental factors. The degree to which heredity contributes to intelligence is often expressed in terms of a heritability coefficient, a number on a scale from 0 to 1, such that a coefficient of 0 means that heredity has no influence on variation among people, whereas a coefficient of 1 means that heredity is the only influence on such variation. This coefficient can be applied to intelligence or to any other trait, such as height or weight.

It is important to remember that the coefficient indicates variation in measured intelligence. The heritability coefficient can tell us only about genetic effects that result in individual differences among people. It tells us nothing about genetic effects when there are no, or only trivial, differences. For example, both how tall you are and how many fingers you have at birth are in large part genetically preprogrammed. But we can use the coefficient of heritability only to assess genetic effects on height, where there are large individual differences. We cannot use the coefficient to understand number of fingers at birth because there is so little variation across people.

It is also important to realize that heritability tells us nothing about the modifiability of intelligence. A trait can be heritable and yet modifiable. For example, height is highly heritable, with a heritability coefficient greater than 0.9 in most populations. Yet heights of Europeans and North Americans increased by over 5 cm between 1920 and 1970. Consider, as another example, attributes of corn. Many attributes of corn, including height, are highly heritable. But if one batch of corn seeds were planted in the fertile fields of Iowa, and another similar batch were planted in the Mojave desert, the batch planted in Iowa undoubtedly would grow taller and thrive better, regardless of the heritability of the attributes of the corn. In this case, environment would largely determine how well the corn grew.

Current estimates of the heritability coefficient of intelligence are based almost exclusively on performance on standard tests of intelligence. The estimates can be no better than the tests and we have already seen that the tests define intelligence somewhat narrowly. How can we estimate the heritability of intelligence (at least that portion of it measured by the conventional tests)? Several methods have been used. The main ones are studies of separated identical twins, studies of identical versus fraternal twins, and studies of adopted children.

Many psychologists who have studied intelligence as measured by IQ believe the heritability of intelligence to be about 0.5 in children and somewhat higher in adults, for whom the early effects of the child-rearing environment have receded. However, there probably is no one coefficient of

heritability that applies to all populations under all circumstances. Indeed, changes in distributions of genes or in environments can change the estimates. Moreover, even if a trait shows a high heritability, we could not say that the trait cannot be developed. For example, as we have seen, the heritability of height is very high – about 0.9 – yet we know that over the past several generations, heights have been increasing. We can thus see how better environments can lead to growth, physical as well as intellectual.

At one time, it was believed that intelligence was fixed, and that we are stuck with whatever level of intelligence we have at birth. Today, many researchers believe that intelligence and the thinking skills associated with it are malleable, that these skills can be shaped and even increased through various kinds of interventions. For example, the Head Start program was initiated in the 1960s in the USA as a way of giving preschoolers an edge on intellectual abilities and accomplishments when they started school. Long-term follow-ups have indicated that by mid-adolescence, children who participated in the program were more than a grade ahead of matched controls who were not in the program. Children in the program also scored higher on a variety of tests of scholastic achievement, were less likely to need remedial attention, and were less likely to show behavioral problems. Although such measures are not truly measures of intelligence, they show strong positive correlations with intelligence tests. A number of newer programs have also shown some success in environments outside of the family home.

Perhaps the best evidence for the modifiability of intelligence comes from research by James Flynn. This research suggests that ever since record-keeping began early in the twentieth century, IQ (intelligence quotient) scores have been increasing roughly 9 points per generation (every 30 years). This result is sometimes referred to as the Flynn effect. From any point of view, this increase is large. No one knows exactly why such large increases have occurred, although the explanation must be environmental, because the period of time involved is too brief for genetic changes to have had an effect. If psychologists were able to understand the cause of the increase, they might be able to apply what they learned to increasing the intellectual skills of individuals within a given generation.

Altogether, evidence now indicates that environment, motivation, and training can profoundly affect intellectual skills. Heredity may set some kind of upper limit on how intelligent a person can become. However, we now know that for any attribute that is partly genetic, there is a reaction range – the broad limits within which a particular attribute can be expressed in various possible ways, given the inherited potential for expression of the attribute in a particular individual. Thus, each person's intelligence can be developed further within this broad range of potential intelligence. We have no reason to believe that people now reach the upper limits in the development of their intellectual skills. To the contrary, the evidence suggests that, although we cannot work miracles, we can do quite a bit to help people become more intelligent.

INDIVIDUAL AND GROUP DIFFERENCES

People in different cultural groups may have quite different ideas of how to behave intelligently. One of the more interesting cross-cultural studies of intelligence was performed by Michael Cole and his colleagues. These investigators asked adult members of the Kpelle tribe in Africa to sort a selection of terms. In Western culture, when adults are given a sorting task on an intelligence test, more intelligent people will typically sort hierarchically. For example, they may sort names of different kinds of fish together, and then the word 'fish' over that, with the name 'animal' over 'fish' and 'birds', and so on. Less intelligent Westerners will typically sort functionally. They might sort 'fish' with 'eat', for example, because we eat fish, or 'clothes' with 'wear', because we wear clothes. Members of the Kpelle tribe generally sorted functionally – even after investigators tried indirectly to encourage the Kpelle to sort hierarchically.

Finally, in desperation, one of the experimenters directly asked one of the Kpelle how a foolish person would do the task. When asked to sort in this way, the Kpelle had no trouble at all sorting hierarchically. He and the others had been able to sort this way all along; they just had not done so because they viewed it as foolish – and they probably considered the questioners rather unintelligent for asking such foolish questions. Why would they view functional sorting as intelligent? Simple. In ordinary life, we normally think functionally. When we think of a fish, we think of catching or eating it; when we think of clothes, we think of wearing them. However, in Western schooling, we learn what is expected of us on tests. The Kpelle did not have Western schooling and had not been exposed to intelligence testing. As a result, they solved the problems the way Western adults might do in their everyday lives, but not on an intelligence test. The Kpelle people are not the

only ones who might question Western understandings of intelligence. Work by Robert Serpell in Zambia shows that Zambians also have conceptions of intelligence quite different from those of North Americans, and research shows that there are many other such differences around the world.

A study by Seymour Sarason and John Doris provides a closer-to-home example regarding the effects of cultural differences on intelligence, particularly on intelligence tests. These researchers tracked the IQ scores of an immigrant population: Italian Americans. Less than a century ago, first-generation Italian American children showed a median IQ of 87, which is considered to be in the low average range, even when nonverbal measures were used and when so-called mainstream American attitudes were tested. Some social commentators and intelligence researchers of the day pointed to heredity and other nonenvironmental factors as the basis for the low IQs – much as they do today for other minority groups. For example, a leading researcher of the day, Henry Goddard, pronounced that 79 percent of immigrant Italians were 'feebleminded'. He also asserted that about 80 percent of immigrant Hungarians and Russians were similarly unendowed with intelligence. Goddard also asserted in 1917 that moral decadence was associated with this deficit in intelligence; he recommended that the intelligence tests he used be administered to all immigrants and that all those with low scores be selectively excluded from entering the United States.

Yet, Italian American students who take IQ tests today show slightly above-average IQs; other immigrant groups that Goddard denigrated have shown similar 'amazing' increases. Even the most fervent hereditarians would be unlikely to attribute such remarkable gains in so few generations to heredity. Cultural assimilation, including integrated education and adoption of American definitions of intelligence, seems a much more plausible explanation. At various times, and in various places, not all children have been encouraged to pursue an education.

Cultural and societal analyses of the concept of intelligence render it particularly important to consider carefully the meaning of group differences in measured IQ. For example, on average, African Americans score somewhat lower than Caucasians on conventional standardized tests of intelligence; but remember, Italian American scores used to be considerably lower than they are now. Scores of African Americans have been showing an increasing pattern over time, just as have scores for other groups. Available evidence to date suggests an environmental explanation for these group differences. Moreover, differences between groups in societal outcomes, such as likelihood of graduating from high school or going on welfare, cannot really be attributed simply to differences in IQ, as some people have tried to do, because after equating for IQ (and thus removing IQ as a source of group differences), African Americans are still considerably more likely than Caucasians to be born out of wedlock, born into poverty, and be underweight at birth. Group differences may thus originate from a number of factors, many of which change over time. The result is that group differences are not immutable: a group that scores, on average, lower than another group at one given time may score, on average, lower, the same, or even higher at another time.

An example of a change in the nature of group differences is that with regard to sex. Overall, males and females do about the same on cognitive ability tests, although differences have been noted on specific ability tests. Analyses of trends over time suggest that sex differences in scores on these cognitive ability tests have been shrinking over the years. Nevertheless, there do appear to be some differences that remain. In particular, males, on average, tend to score higher on tasks that require visual and spatial working memory, motor skills that are involved in aiming, and certain aspects of mathematical performance. Females tend to score higher on tasks that require rapid access to and use of phonological and semantic information in long-term memory, production and comprehension of complex prose, fine motor skills, and perceptual speed. These differences refer only to averages, and there are many individuals of one sex who do better than individuals of the other sex, regardless of the particular skill measured by a given test. In any case, these score differences are not easily interpretable. Claude Steele, for example, has found that when boys and girls matched for general mathematical abilities take very difficult mathematical tests, boys often do better. But when the two groups are told in advance that a particular test will show no difference, on average, scores of boys and girls converge, with girls' scores increasing and boys' scores actually decreasing.

Another group difference is between African Americans and whites. As mentioned earlier, African Americans tend to score lower than do white Americans on conventional tests of intelligence. The available evidence is largely consistent with an environmental explanation of this difference. For example, in one study, offspring of American servicemen born to German women during the

Allied occupation of Germany after World War II revealed no significant difference between IQs of children of African American versus white servicemen. This result suggests that given similar environments, the children of the two groups (African American and white) of servicemen performed equally on tests of intelligence. Another study found that children adopted by white families obtained higher IQ scores than did children adopted by African American families, again suggesting environmental factors contributing to the difference between the two groups. Another way of studying group differences has been through transracial adoption studies, in which white parents have adopted African American children. The results of these studies have been somewhat difficult to interpret, in that both white and African American children who were adopted in the study showed decreased IQ in a 10-year follow-up on their performance.

There are a number of mechanisms by which environmental factors such as poverty, undernutrition, and illness might affect intelligence. One mechanism is through resources. Children who are poor often do not have the resources in the home and school that children from more affluent environments have. Another mechanism is through attention to, and concentration on, the skills being taught in school. Children who are undernourished or ill may find it hard to concentrate in school, so they may profit less from the instruction they receive. A third mechanism is the system of rewards in the environment. Children who grow up in economically deprived environments may note that the individuals who are most rewarded are not those who do well in school, but rather those who find ways of earning the money they need to survive, whatever those ways may be. It is unlikely that there is any one mechanism that fully explains the effects of these various variables. It is also important to realize that whatever these mechanisms are, they can start *in utero*, not just after birth. For example, fetal alcohol syndrome results in reduced IQ and has its initial effects prenatally, before the child even enters the world outside the mother's womb. Thus, couples can help maximize their future children's intelligence by giving those children good prenatal care.

Intermodal Perception, Development of

Intermediate article

Lorraine E Bahrick, Florida International University, Miami, Florida, USA

CONTENTS

Intermodal perception is the perception of unitary objects and events through spatially and temporally coordinated stimulation from multiple sense modalities. Research suggests that the senses are united in early infancy, fostering the rapid development of intermodal perception.

INTRODUCTION

Intermodal perception is the perception of an object or event that makes information available to two or more sensory systems simultaneously. Most objects and events are multimodal in that they can be experienced through multiple sense modalities. For example, a person talking, a fire, or a bouncing ball can all be seen as well as heard and felt. Intermodal perception is thus one of the most fundamental human capabilities and forms the basis for most of what we perceive, learn, and remember. One of the questions developmental psychologists have asked is how and when the child comes to perceive multimodal events as single, unitary events, in the way adults do. For example, without prior experience with objects and events, how does the infant learn that certain patterns of auditory and visual stimulation, such as the sight of the mother's face and the sound of her voice, belong together and constitute a unitary event, whereas other concurrent patterns of sensory stimulation are unrelated? How does the child acquire intermodal knowledge such that the sound of footsteps in the hallway will elicit the expectation of seeing a person in the doorway?

INTEGRATION VERSUS DIFFERENTIATION

Researchers have discovered that intermodal perception develops rapidly during infancy. Infants are intrinsically motivated to pick up new information. Some researchers (e.g., Piaget, 1954) have characterized the development of intermodal perception as a process of integration. According to this view, the senses are separate at birth and the infant must gradually learn to put together or 'integrate' stimulation from the different sense modalities in order to perceive a unitary multimodal event. This 'integration' may occur through associating concurrent information across different modalities. Thus, before integration takes place, infants would perceive only unrelated streams of light, sound, or tactile impressions. A contrasting position is the 'differentiation' view of development (e.g., Gibson, 1969). According to this view, the senses are unified at birth, and perceptual development is characterized by a progressive process of 'differentiation' of increasingly finer levels of stimulation. Thus, in early infancy, information from the different senses must be gradually separated from the global, undifferentiated perceptual array. From this perspective, intermodal perception of some kinds of information is possible at birth and infants continue to show perceptual learning of more complex multimodal relations throughout infancy and early childhood.

Recent evidence has demonstrated that young infants are adept at perceiving a wide array of multimodal objects and events and they do so by detecting information that is common, or invariant, across the senses. This body of research has thus weakened the integration position, especially when intermodal abilities are discovered in very young infants who have had little opportunity to learn to associate or integrate information across the senses. Much infant research has provided support for the differentiation view, particularly the large body of research on young infants' detection of 'amodal

invariants', suggesting that the senses are unified in early infancy.

AMODAL INVARIANT RELATIONS

Amodal information is information that is not specific to a particular sense modality, but is completely redundant or invariant across two or more senses. For example, the sights and sounds of hands clapping share a synchrony relation, a common tempo of action, and a common rhythm. The same rhythm and tempo can be detected by watching or hearing the hands clap. Thus, synchrony, rhythm, and tempo are 'amodal invariant relations' in that this information can be perceived across different sense modalities. Most information that is amodal characterizes how events are distributed in space and time, two of the most fundamental dimensions of our experience. According to the differentiation view, detection of amodal relations focuses attention on meaningful, unitary events and buffers infants from making incongruent, inappropriate associations (e.g., Bahrick and Pickens, 1994). For example, if the infant detects synchrony, shared rhythm, and common tempo between the sight of a person's moving face and the sound of the person's voice, the infant would necessarily be attending to a unitary event: the person talking. In this way, unrelated sounds and movements would not be merged with the event. In support of the differentiation view, research has found that young infants detect a wide array of amodal invariant relations in multimodal events.

In contrast to amodal relations, information can also be nonredundant and arbitrarily related across the sense modalities (e.g., speech sounds and the objects they refer to; particular faces and voices). Information such as color, pattern, timbre, or pitch is 'modality-specific' and can be perceived only through a single sense modality. Research suggests that infants detect amodal relations (such as temporal synchrony) developmentally prior to arbitrary relations, and detection of amodal relations can then guide and constrain learning about arbitrary relations.

AUDITORY–VISUAL CORRESPONDENCE

To assess intermodal perception of auditory–visual relations, sometimes an intermodal preference method is used. In this method, infants view two filmed events simultaneously, along with the soundtrack to one of them coming from a centralized speaker. It is expected that if the infant detects the intermodal relations, he or she will look longer at the film that belongs with the soundtrack played.

Research using these and similar procedures has demonstrated that young infants display a wide array of intersensory abilities in the area of audio-visual perception (see Gibson and Pick, 2000; Lewkowicz, 2000; Lewkowicz and Lickliter, 1994). Neonates turn their eyes in the direction of a sound, demonstrating a basic coordination of audio-visual space. In the first month of life, infants detect the temporal synchrony between sights and sounds of an object striking a surface, and the spatial location common to the sights and sounds of a moving object. By three to five months, infants can match films and soundtracks of moving objects on the basis of their substance (rigid versus elastic) or their composition (single versus multiple objects), as well as the rhythm and tempo of their impact sounds. Further, by four to six months, infants can match faces and voices on the basis of affective expressions, including happy, sad, neutral, and angry (Walker-Andrews, 1997). They can also match faces and voices on the basis of age (adults versus children) and gender of speaker. All these relations are amodal and invariant across vision and audition.

BIMODAL PERCEPTION OF SPEECH

The perception of speech, an auditory–visual event, has traditionally been studied as a unimodal, auditory event. However, speech is produced by a speaker who can be heard and seen, and who typically uses gesture as well. It turns out that the multimodal nature of speech is salient to infants and facilitates its perception (e.g., Meltzoff and Kuhl, 1994). By the age of at least two months, infants are sensitive to voice–lip synchrony during speech. By four months, infants are able to detect the voice–lip correspondence between speech sounds such as '*a*' and '*i*'. When one of these speech sounds is played in synchrony with two films side by side of a speaker's face intoning each sound, infants look more to the face with the matching lip movements. The McGurk effect, an auditory–visual illusion, also illustrates how infants and adults merge information for speech across the senses. When we view the face of a person speaking one speech sound such as '*ga*', while hearing a different speech sound, for example '*ba*', we perceive another sound, '*da*', a blend between the two. Infants show evidence of this effect in the first half-year of life. Visual input appears to have significant auditory consequences.

Amodal information during speech is also important for learning the arbitrary relation between

speech sounds and the objects they denote (Gogate *et al*., 2001). By 14 months of age, infants are able to learn to pair a speech sound and an object during a brief familiarization. However, if amodal synchrony unites the sounds and object movements, for example in showing and naming the object simultaneously, infants can learn the relation as early as seven months of age. Adults even match their teaching style to the infant's needs. They use more synchronous movement with labeling, to highlight object–sound relations, when they are first teaching the names of new objects to their young infants. Their use of synchrony decreases as infants become more linguistically competent. Further evidence for the importance of visual information for perceiving speech lies in the success of teaching speech to deaf individuals using a visual depiction of the lip and tongue movements involved in different speech sounds.

VISUAL–TACTILE CORRESPONDENCE

Amodal invariant relations also unite perception across vision and touch. Information for shape, texture, substance, and size are invariant across visual and tactile stimulation (Rose and Ruff, 1987). One method for investigating perception of visual–tactile correspondence is the cross-modal transfer method. An object is presented to one sense modality alone, and a preference test is then given in another sense modality to determine whether the information transfers across modalities. Using this method, research has shown that, by the age of one month, infants can perceive the correspondence between an object they experienced tactually (on the back or a pacifier) and a visual replica of the object. Infants looked more to the object of the shape and texture that they had previously experienced orally. Infants are also able to transfer information about the substance of an object (rigid versus deforming) across touch and sight.

Evidence also shows that infants can transfer information obtained through manual exploration to vision, and this develops across the first year. One factor determining the extent to which manual information is perceived is whether exploration is active or passive. Tactile exploration develops over the first year. Young infants tend to grasp objects, whereas older infants become more adept at obtaining tactile feedback by moving their hand relative to the object's surface. By four months, infants can perceive whether two parts of objects are connected or separate, by the type of motion they produce during haptic exploration. By six months, infants can recognize the shape of an object visually that they have manually explored, as long as exploration is active.

VISUAL–MOTOR CORRESPONDENCE AND THE SELF

Infants are also able to perceive information specifying the self by detecting amodal invariant relations (Rochat, 1995). Even in the first weeks of life, infants can imitate facial expressions. In order to do this, they must relate the visual appearance of the adult's facial expression with their own production of the expression. This is most probably guided by proprioception: proprioception is information about self-movement based on feedback from the muscles, joints, and vestibular system. Facial imitation reveals evidence of early intermodal coordination between visual information and motor behavior, and this coordination continues to develop over the first year (Meltzoff and Moore, 1995).

Infants also show evidence of self-perception by detecting amodal invariant relations in a procedure where they view their own body moving live in a video display (Bahrick, 1995). By three to five months, infants can distinguish between a live video of their own legs kicking and a video of another infant's legs kicking, a pre-recorded video of their own legs, or a spatially incongruent video of their own legs. They do this by detecting the amodal temporal synchrony and spatial relations common to the visual display of their motion and the proprioceptive experience of their motion.

Infants also demonstrate a phenomenon called 'visually guided reaching', which develops rapidly during the first year. That is, they show continuous adjustments in their reaching and manual behavior as a function of visual input about the size, shape, and position of objects. Infants are even able to contact a moving object by aiming their reach ahead of the object and taking into account the speed and direction of its movement as well as that of their arm motion. Later, infants show an ability to adapt their crawling and exploratory behavior as a function of visual information about the slant and solidity of the surface. These examples illustrate a close coupling between vision and motor behavior and an understanding of self in relation to objects (Gibson and Pick, 2000).

NEURAL BASES OF INTERMODAL PERCEPTION

Behavioral research on the rapid development of intermodal perception during infancy is consistent

with research findings from the neurosciences. Some areas of the brain (cortex, superior colliculus) contain 'multimodal neurons' that respond to inputs from multiple sense modalities, providing a biological basis for the early integration of the senses (e.g., Stein and Meredith, 1993). Further, some cells of the superior colliculus (devoted to attention and orienting) are activated much more by simultaneous auditory and visual inputs than by either auditory or visual information alone. Other cells, however, are modality-specific but can have receptive fields that are spatially coordinated across the sense modalities as a result of experience with multimodal events. Thus, auditory and visual input from the same spatial location can be related. Neurophysiological findings suggest that if input to one modality is somehow modified, the receptive field of cells in the superior colliculus can compensate and realign with those of the other modality to maintain a coherent multimodal spatial mapping. The early plasticity of the brain, its sensitivity to multimodal inputs, and its reliance on experience in the multimodal world to guide neuronal development, appears well tailored to the behavioral findings of the early development of intermodal perception.

CONCLUSION

Infants demonstrate a diverse array of intermodal abilities. These abilities illustrate the close connection between the senses during early development and the rapid growth in intersensory abilities across the first year of life. Development appears to be guided by the detection of amodal, invariant relations, and this promotes accurate and unitary perception of multimodal events.

CONTENTS

Intuitive physics describes the common-sense beliefs that people hold about how the world works. The study of intuitive physics has focused on people's beliefs about biology and physical mechanics.

INTRODUCTION

Intuitions about the natural world are based upon implicit, common-sense beliefs that people hold about the way the world works. It is useful to distinguish between individual and culturally shared beliefs. Intuitive (or naive) beliefs develop within each individual, in the absence of formal training or instruction. Folk knowledge is a belief system reflecting a culture's cumulative understanding of a class of physical phenomena. These understandings may consist of simple compilations of observations, or they may evoke systematic belief systems. In some regards, folk knowledge can resemble aspects of scientific inquiry (Kuhn, 1970), in which practitioners share common concepts and techniques. However, folk knowledge lacks the paradigmatic rigor of science, and its core belief structure is often constrained or defined by a society's religious tenets.

Like intuitive beliefs, folk knowledge tends to explain only a subset of the relevant phenomena in a physical domain. Models tend to be simplistic and are often animistic. Observations that are inconsistent with the prevailing model are either discounted, or explained by *ad hoc* elaborations.

FOLK BIOLOGY: KEEPING THE BODY'S SYSTEMS IN BALANCE AND CLASSIFYING NATURE

Biology is one of the most extensively developed domains of folk knowledge. People are naturally interested in understanding the workings of their own bodies, and in organizing the other living things in their environment into meaningful groups and clusters. Hence, two of the primary foci of folk biology are medicine and taxonomy.

Folk Medicine

Of necessity, virtually every culture has individuals trained to serve as healers. Even today, many societies reject the therapies of modern Western medicine in favor of traditional methods of treatment. Typically, such treatment involves herbal medicines. The therapeutic efficacy of many of these remedies has been scientifically validated (Fontanarosa, 2000). However, folk medicine also involves rituals and totems. In some cultures, these are used to appeal to deities for restorative intervention. Other cultures view these exercises as a means to restore the body to a healthy state of balance. Thus, ancient Greeks and medieval physiologists attributed illness to an excess or deficiency of one of the body's four humors (blood, phlegm, choler, and bile). Similarly, Hispanic folk medicine holds that disease is caused by an imbalance between hot and cold principles (Buhner, 1996).

The practice of folk medicine can be quite sophisticated, with hierarchies of healers and specialists who advise patients on preventative as well as curative measures. The 'four-humors' model emphasized a balanced diet for health maintenance, whereas the 'hot/cold' model stresses the avoidance of exposure to extreme temperature. Should illness occur, treatment is given to restore the body's natural balance (e.g. 'cold' diseases such as pneumonia or colic are treated with 'hot' remedies).

Folk Taxonomy

The manner in which cultures categorize animals and plants reflects their societal needs and priorities. Still, there are some notable commonalities in the taxonomies derived (Atran, 1995). First, in

establishing the defining criteria for a species, certain features are attended to while others are ignored. Usually, the features deemed relevant appeal to what Atran terms the 'underlying essence' of the species. Thus, category structures are teleological, and irrelevant surface features (such as fur color) are ignored.

Second, as Darwin noted (1859) and contemporary researchers have confirmed (Hays, 1983; Brown, 1984), virtually every culture's folk taxonomy is hierarchical in nature: 'groups under groups' (Darwin, 1859, p. 431). As with their scientific counterpart, the categories at each level of these folk taxonomies are exhaustive (every plant or animal can be assigned to a class) and exclusive (no plant or animal belongs to more than one class). Folk taxonomies differ both from one another and from scientific taxonomies in their hierarchical groupings (which species of animals are seen as related) and 'terminal contrast' (the lowest level of grouping recognized) (Lévi-Strauss, 1966). Thus, one folk taxonomy may have a terminal contrast of 'bat' while another groups bats into a terminal contrast of 'flying animals'. Modern science, of course, recognizes 'bat' as corresponding to diverse families, genera, and species in the order Chiroptera.

FOLK NOTIONS OF THE PHYSICAL WORLD: GENESIS MYTHS

The most pervasive folk notions of physics deal with a fundamental cosmological issue: the origin of the earth and universe. The realm of creation accounts is quite diverse. Many are mythic in nature, positing a divine agent (or agents) as creator. In some cultures, the model is closely woven with the society's religion, and there is little effort to reconcile the model with physical evidence. One example of how theology constrained cosmological models can be found in the debate between geocentric/heliocentric models of the solar system. Despite the difficulty of reconciling the geocentric model with astronomical data, religious forces retarded the acceptance of the more parsimonious heliocentric view (Casper and Noer, 1972).

The tendency to maintain a belief in the face of contrary evidence can be observed within individuals as well as cultures. This bias is quite evident when one examines people's intuitive physics.

INTUITIVE PHYSICS: SURPRISING PHENOMENA

The literature on intuitive physics is filled with accounts of people's erroneous predictions about basic mechanical systems. For example, in the problem depicted in Figure 1, people are asked to indicate, by drawing a line, what the orientation of a liquid's surface would be given that it intersects the glass at the spot indicated (Piaget and Inhelder, 1948/1956). About 40 percent of the adult population gets this problem wrong by drawing lines that are inclined more than 5 degrees away from the horizontal in the same direction as the tilt of the container (McAfee and Proffitt, 1991). This is odd and surprising given that people observe liquids in containers every day. Why should people be systematically wrong about something with which they are so familiar? Systematic error in the face of familiarity is the hallmark of the phenomena that define the intuitive physics literature.

One could pick problems in physics that are so complex that almost no one could predict the systems' behavior. Predicting the behavior of spinning-tops is an example (Proffitt and Gilden, 1989). One could also pick physical systems that are so simple that everyone would answer correctly, such as predicting the path of a ball exiting a straight tube. What has captured the imagination of researchers in this field are those problems that garner systematic error as opposed to on-the-spot guessing or correct responses.

Many studies have looked at people's ability to predict trajectories in simple dynamical systems (Champagne *et al.*, 1980; Clement, 1982; Kaiser

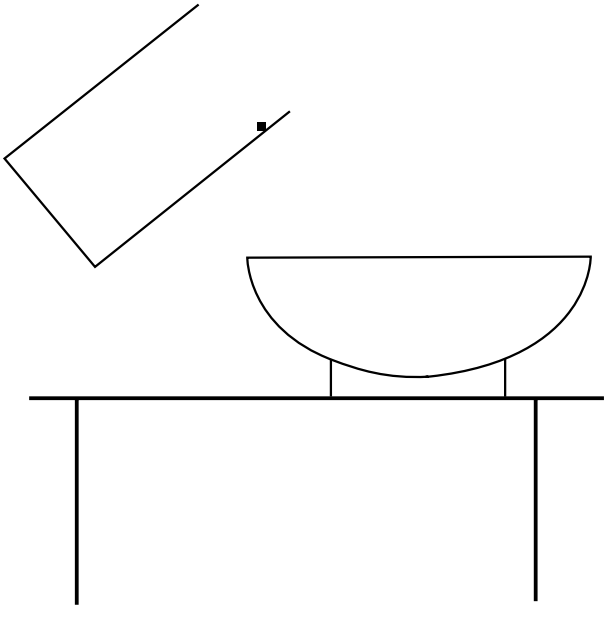

Figure 1. The water-level problem. The participant's task is to draw the surface of water in the tilted glass so that it touches the point on the right side of the glass.

et al., 1986; McCloskey, 1983; McCloskey *et al*., 1980; Shanon, 1976). One of the most extensively investigated problems is depicted in Figure 2 (McCloskey *et al*., 1980). In this problem, a C-shaped tube is shown lying flat on a horizontal surface. Participants are asked to imagine that a ball is made to roll through the tube and then they are required to draw the trajectory that it would take upon exiting the tube. A correct drawing would show the ball following a straight trajectory tangential to the tube's curvature at the point of exit. It has been found that about 40 percent of college students get this problem wrong and draw a trajectory in which the ball continues to curve after exiting the tube. What is interesting about this problem is not simply that people are wrong, but rather that those who make errors produce very similar predictions.

Among the trajectory problems, predicting how an object will fall has been found to elicit systematic errors. Figure 3 shows the pendulum problem. Participants are asked to predict the path that the pendulum bob will take following a break of its tether at one of two phases in its swing. The figure shows one correct trajectory along with some of the common errors. Another problem is that shown in Figure 4, in which a moving carrier drops an object. In this situation, many people predict that the object will fall straight down as opposed to following the parabolic curve that combines its forward movement with the downward acceleration of gravity. Interestingly, if a ball is shown rolling

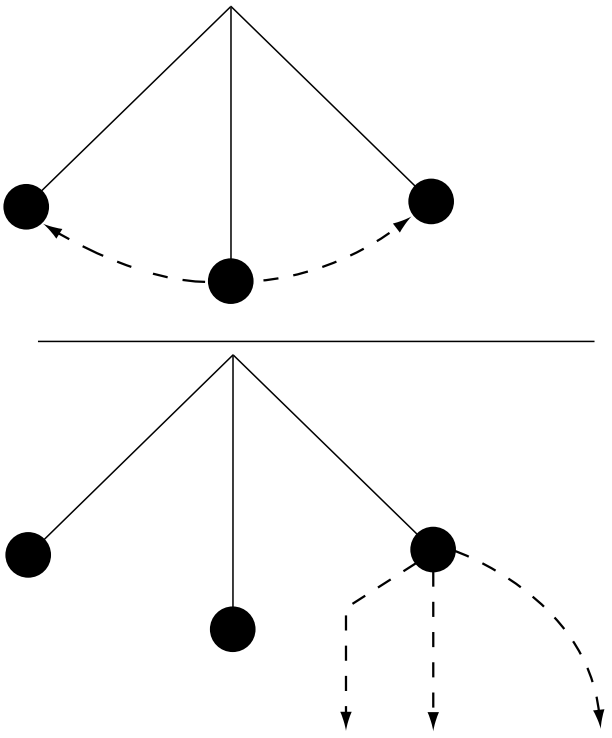

Figure 3. The pendulum problem. The top panel depicts a swinging pendulum. Participants are asked to draw the trajectory that the bob would take if its tether broke at either the apex or the nadir of its swing. The bottom panel shows the correct straight-down path for the apex condition along with two incorrect paths that are frequently drawn.

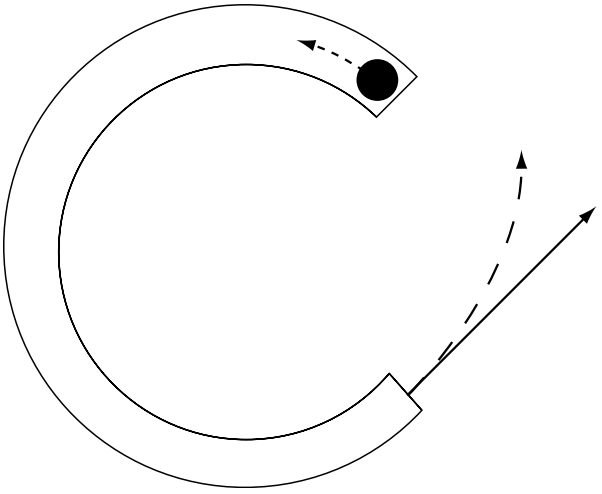

Figure 2. The C-shaped tube problem. The curved tube is to be construed as lying flat on a table and participants are to draw the trajectory of the ball after it exits the tube. (In the problem, the trajectories are not shown.) Although the correct path is straight (solid line), many people draw paths that continue to curve (dotted line).

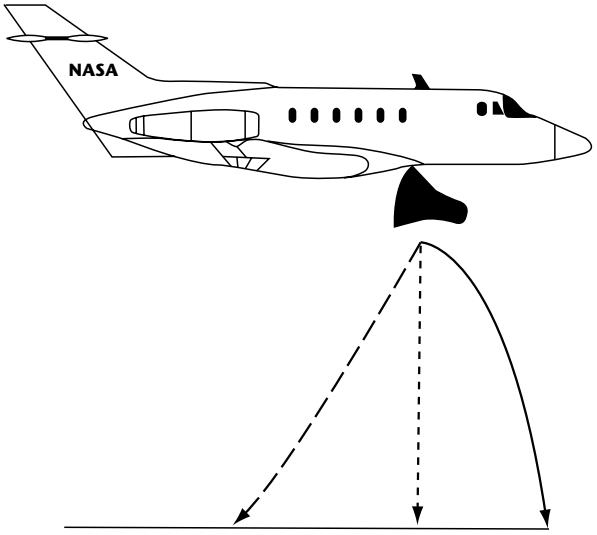

Figure 4. The object dropped from a moving carrier problem. The figure depicts a space capsule being dropped by an airplane. Participants are asked to draw the capsule's falling trajectory. The correct trajectory is a forward parabolic path (solid line). The incorrect paths shown with dotted lines are often drawn.

off a table as in Figure 5, then adults are far more likely to take into account its forward motion. People are also prone to err when making judgments about falling rate. Shanon (1976) found that many people report that objects will fall at a constant velocity proportional to their mass.

Hecht and Bertamini (2000) found that misconceptions about projectile motions are not limited to predictions about the shape of their trajectories. In their studies, people were asked to indicate where in the trajectory of a thrown ball the velocity was greatest. Many participants judged the speed of the ball to be greatest some distance after it was released by the thrower, implying that the ball continued to accelerate after its release.

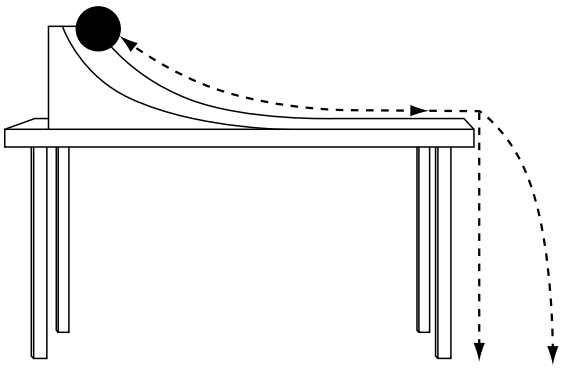

Figure 5. The ball rolling off a table problem. Participants are asked to predict the path of a ball that rolls off a table. Most adults correctly draw parabolic paths, whereas young children tend to draw straight-down paths.

People's intuitions about the dynamics of rotation seem to be especially error-prone. Proffitt *et al*. (1990) asked people to predict whether size (radius), mass, or shape (moment of inertia) would affect the time that it would take a wheel to roll down a ramp (Figure 6). Among these variables, they found that people were most certain that shape would not be an effective variable; in fact, it is the only factor that matters. 'Moment of inertia' describes the distribution of an object's mass relative to its axis of rotation. In the case of the rim-like shape in Figure 6(c), a greater proportion of the wheel's mass is located away from the axis as compared to the standard. Assessments of university and high school physics teachers showed only minimal improvement so long as these individuals were forced to answer quickly and were prohibited from writing down the relevant equations.

Once it is recognized that people predict motions that defy the laws of physics, a natural question follows as to what these people would experience should they see animated events that conformed to their predictions. Would people who erroneously predict that a ball exiting a C-shaped tube continues on a curved path be surprised or accepting when viewing this event? Studies have shown that some problems are penetrated by perception but others are not. When shown animations of C-shaped tube, pendulum, and dropped object problems, people who make erroneous predictions on paper-and-pencil tests view their predicted paths

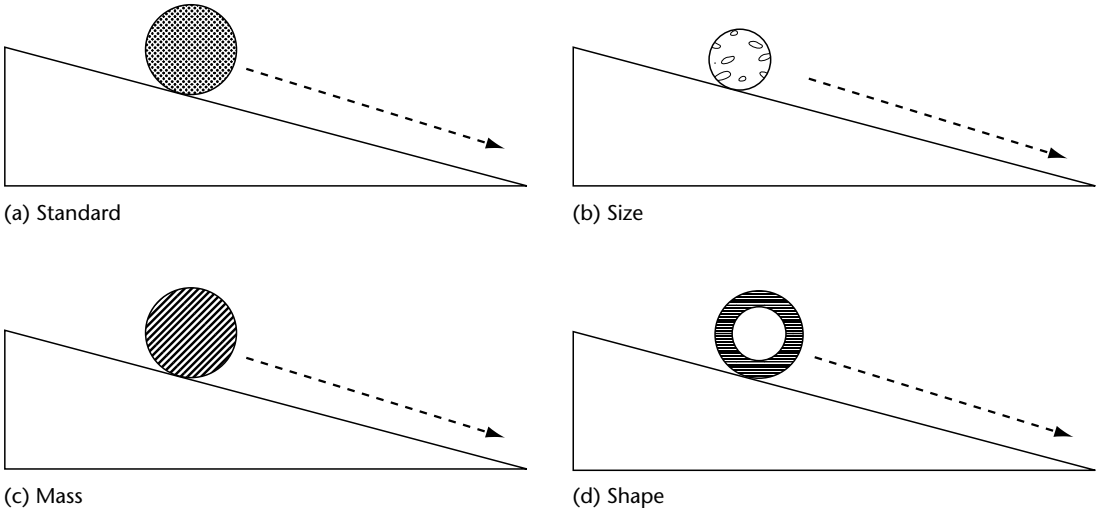

Figure 6. The wheels rolling down a ramp problem. Relative to a standard wheel, participants are asked to judge which of two wheels will arrive at the bottom of the ramp first. The comparison wheels are identical to the standard except for one of the following variables: size (radius), weight (mass), or shape (moment of inertia).

as being anomalous and correctly choose the appropriate trajectories as being natural (Kaiser *et al*., 1985; Kaiser *et al*., 1992). However, animations of the water-level problem shown in Figure 1 (Howard, 1978; McAfee and Proffitt, 1991) and of the moment of inertia problem (Proffitt *et al*., 1990) do not evoke more accurate responses than their static paper-and-pencil versions.

HEURISTICS IN COMMON-SENSE REASONING

The list of surprising phenomena in the intuitive physics literature is long, varied, and could probably be extended indefinitely. What is needed, of course, is a theoretical account capable of predicting when and how people are likely to make accurate or biased judgments and when they are likely to be totally befuddled. The classes of explanation fall into at least three non-mutually exclusive categories.

Implicit Theories

It has been proposed that people develop implicit theories about how the world works. These theories then become evident in the heuristics that people use when attempting to solve intuitive physics problems (Chi and Slotta, 1993; Ranney, 1994; Smith and Casati, 1994). Shanon (1976) and, in his earlier writings, diSessa (1982) proposed that people's reasoning reflected an Aristotelian conception of dynamics. McCloskey (1983) suggested that people's judgments were more consistent with medieval impetus theory. By this account, objects are put into motion by an impetus that dissipates over time. Since both linear and curvilinear impetus persist after their initial application, impetus theory nicely accounts for the common curvilinear predictions made on such problems as the C-shaped tube.

There are a number of problems with implicit theory accounts. First, people are often inconsistent in their judgments from one problem to another (Cooke and Breedin, 1994; diSessa, 1982; Kaiser *et al*., 1992; Ranney and Thagard, 1988; Shanon, 1976). This could mean that people's judgments are not grounded in implicit theory or that they possess multiple theories. A second problem is that people are highly influenced by the surface structure of the problem. For example, no one predicts that water exiting a C-shaped hose will continue to curve upon exit (Kaiser *et al*., 1986). Finally, the implicit theories that have been proposed have limited scope in accounting for the wide variety of intuitive physics problems. Impetus theory, for example, explains why curvilinear trajectories are predicted but is mute with respect to the water-level problem or the belief that a thrown ball will continue to accelerate after it leaves the thrower's hand.

Perceptual Biases

What makes erroneous judgments about nature surprising is that people's intuitions about the way that the world works ought to have been informed by manifest regularities in everyday experience. A possible explanation for this conundrum is that judgmental biases reflect biases that are inherent in perception itself. In the case of the object being dropped by a moving carrier, Kaiser *et al*. (1992) proposed that the bias to predict a straight-down motion is due to the perceptual bias to notice and attend to relative motions. Relative to the carrier, the object does indeed move straight down. A similar frame of reference argument has been applied to the water-level problem (Hecht and Proffitt, 1995; McAfee and Proffitt, 1991). If the water level's orientation is related to its container instead of the environment, then a perceptual bias is evoked in which the horizontal is misperceived to be inclined slightly in the direction of the container's tilt. As with implicit theories, perceptual bias accounts suffer from a lack of scope. They account for a few phenomena well but not the others.

Problem Complexity

As previously noted, physics problems range in their difficulty from laughably easy to stupefyingly difficult. As a first approximation towards defining problem complexity, a distinction has been made between particle (easy) and extended body (difficult) motions (Proffitt and Gilden, 1989). Particle motions are those that can be described adequately by treating the object as if it were a point particle located at the object's center of mass. Freefall is a particle motion if air resistance is ignored. Extended body motions make relevant other object properties such as shape. A wheel rolling down a ramp is an extended body motion because its shape (moment of inertia) is of dynamic relevance. This distinction predicts that particle motions will be easier to construe than extended body ones, and this prediction is fairly well borne out by research findings (Proffitt and Gilden, 1989; Proffitt *et al*., 1990). For example, all rotations are extended

body motions – a point particle cannot rotate – and as noted above, the dynamics of rotations are especially difficult to appreciate.

It would be desirable to have a general account that could predict performance across the whole range of intuitive physics problems. That no account currently meets this goal may reflect the current state of theory development, or the plurality of means by which people attempt to solve the different sorts of problems that comprise the intuitive physics literature. The latter possibility is probably more likely.

Judgment

Introductory article

Jonathan Baron, University of Pennsylvania, Philadelphia, Pennsylvania, USA

CONTENTS

A judgment is an evaluative response to a stimulus. Judgments are often based on rules of thumb, or heuristics, which may cause systematic errors. Often judgments can be improved with the use of algebraic formulas.

INTRODUCTION

We make judgments when we evaluate stimuli with respect to some set of criteria. Classic examples of judgments are the ratings given in Olympic sports events such as diving and gymnastics. The stimulus might be a dive, a half gainer, say, and the criteria are the list of properties that a good half gainer should have, such as coming close to the board, entering the water at a 90-degree angle, and so on. Other examples are grades given to students' examinations or papers, ratings of movies, and ratings of stock offerings (buy, hold, sell, etc.). Judgments need not be expressed numerically, but they are always expressed in terms of some ordered scale along a better–worse continuum.

Judgments are not the same as decisions, but decisions may depend on judgments. In making consumer purchases, we may first make judgments of price and quality. Judgments about the future are predictions. Weather forecasters make judgments about tomorrow's temperature.

Psychology researchers learn about judgments by presenting stimuli to subjects and asking for judgments as responses. By varying features of the stimuli, we can learn what affects the response. For example, in a typical experiment on judgment, a psychologist might present a set of stimuli like that shown in Table 1, one row at a time. The stimuli are in the first three columns.

The judgment in this case is a rating of suitability of each of these eight students for graduate school in psychology. Can you tell from this table what the judge is doing? (We will come back to this example.)

NORMATIVE AND DESCRIPTIVE ACCOUNTS

One way in which researchers study judgments is to compare them to a standard for how the judgments should be made. This is called a *normative* standard, or a normative model. A simple normative model of predictions of tomorrow's temperature is what that temperature turns out to be. Often we cannot specify the normative model exactly because we have no obvious right answer to the question of what the judgment should be. But we can often specify normative criteria. For example, in the case of giving grades to essays, it is good, other things being equal, to give the same grade to the same essay presented at another time. If a grader gives different grades to the same essay, we can use the difference to estimate a certain kind of error, an error of inconsistency.

Often we find that judgments show some sort of systematic error. They tend to depart in a predictable way from some normative standard. Such a systematic error is called a bias. When a bias is discovered, researchers often try to explain it. The explanation is called 'descriptive' as opposed to normative.

Explanations are typically of two types, which are not incompatible. One is in terms of a mathematical model of the judgment process. The other is a verbal description of the rules that the judge is using. These rules are often *heuristics*. A heuristic is a weak method.

Interestingly, the term 'heuristic' was coined (by the mathematician George Polya) to explain how mathematicians solve problems when they cannot rely on procedures (algorithms, such as the procedure for long division). Heuristics were thus seen as good things. The psychologists Daniel Kahneman and Amos Tversky adopted this term to explain biases, which produce departures from normative models. Did Kahneman and Tversky completely turn the meaning of the term on its head, so that

Table 1. Hypothetical predictors of suitability for graduate school

Grade average in psychology	*Grade average in science*	*Letters of recommendation*	*Judgment response*
4.0	4.0	4.0	20
4.0	4.0	3.0	19
4.0	3.0	4.0	17
4.0	3.0	3.0	16
3.0	4.0	4.0	10
3.0	4.0	3.0	9
3.0	3.0	4.0	7
3.0	3.0	3.0	6

heuristics were now seen as bad rather than good? Not really. Kahneman and Tversky, and others who follow their heuristics-and-biases approach, still think of heuristics as fundamentally useful short-cuts. We use heuristics exactly because they are usually useful. We have trouble when they are less useful than normal.

REPRESENTATIVENESS

An example is the representativeness heuristic. When people make judgments of the probability that a case belongs to a category, they often base these judgments on similarity of the case description to their concept of the category. For example, Kahneman and Tversky presented subjects with a paragraph description of 'Tom W.', a graduate student, which characterized Tom as intelligent but uncreative, with a need for order, with a writing style that was 'dull and mechanical, occasionally enlivened by somewhat corny puns and by flashes of imagination of the sci-fi type', among other features. The subjects judged the probability that Tom was in several different fields of study.

Subjects judged the description to be more typical of the category of computer science students than of social science students, and other subjects judged Tom as more likely to be a computer science student. Usually, such use of similarity would be a good heuristic for a judgment. But a normative model of probability judgments also says that the judgments should take into account the sizes of the categories. When this study was done, the category 'social science students' was many times larger than 'computer science students'. Yet the subjects completely ignored the relative sizes of the categories.

In this example, the normative model was the theory of probability, and the descriptive model was that subjects use the representativeness heuristic, judging probability on the basis of similarity alone, and ignoring the base rates of the categories. The judgments were unaffected by the sizes of the categories, and, in this way, they were biased. The representativeness heuristic has been found in many other situations.

ANCHORING AND ADJUSTMENT

Another well-studied heuristic is found in numerical judgments. Tversky and Kahneman asked subjects to estimate certain quantities, such as the percentage of African countries in the United Nations. For each quantity, a number between zero and 100 was determined by spinning a wheel. The subject was instructed to indicate whether that number was higher or lower than the value of the quantity, and then to estimate the value of the quantity. The number the subject started with, determined solely by the spin of a wheel, strongly affected the final estimate. Subjects who were given high numbers gave higher estimates than those given low numbers.

Descriptively, subjects use a heuristic of anchoring their judgment on the number they are given and then adjusting it, but the adjustment is insufficient. Normatively, the judgment should be unaffected by the number they are given. The anchoring-and-adjustment heuristic can distort a great variety of real judgments and predictions. We can reduce this effect by avoiding the use of anchors, even though they often make the judgment easier. We cannot stop people from making up their own anchors, however. If you are asked the proportion of African countries in the United Nations, you might well start by asking yourself whether it is more or less than 50 percent. As a result, your final judgment will be too close to 50 percent.

RATIONALITY

Are biased judgments irrational? The concept of 'rational' is much more difficult to define than that of 'normative', and the two are not the same. One view of rationality is that it involves doing the best we can, all things considered. Among the things to be considered are the time and effort involved in using methods that will reduce biases and errors. Often, in daily life, our biased judgments are much better than nothing and good enough for the purpose at hand. It would not be worth the time and effort to try to avoid biases, so the biases would not, in these cases, be irrational.

In other cases, much more hinges on our judgments, and it is worth making an effort to improve

them. An example is the use of the anchoring-and-adjustment heuristic in the estimation of how long it will take to complete a project. Typically, people imagine how long it would take to carry out each step if nothing goes wrong, and then they adjust for the possibility that something will go wrong. Typically, they underadjust, so they underestimate completion times. If the time in question is that for cooking dinner, the dinner may be a little late, but that is not a grave matter. However, the same problems seem to occur in estimating the cost and time of larger projects such as the Sydney (Australia) Opera House or the tunnel under the English Channel.

HUMAN JUDGES VERSUS FORMULAS

One way to improve judgments is to use algebraic formulas. This is especially useful in the case of prediction, when formulas can be discovered by examining past cases. Such formulas have been discovered for predicting the future price of a wine crop on the basis of the weather conditions under which the grapes were grown, suicide attempts by depressed patients, college student grades, and defaults on bank loans. In principle, formulas of this sort ought to be useful in predicting the success of employees, so they could be used in hiring decisions, but they are rarely used in this way.

Many useful formulas are simply a weighted sum. We have various attributes of the object in question, such as the student's high-school grade average, high-school class rank, and test scores, to predict college grades. We multiply each of these numbers by its weight, which depends on which kind of number it is (grade average, class rank, etc.), and then we add up the results. This is called a linear model because a graph of the result as a function of any of the attributes is a straight line. Linear models make sense when each attribute is better at one end of its scale and worse at the other end. For wine, 'total rainfall' might not work this way, because there can be too much rain as well as too little. But there can't be too high a test score, in the same sense.

Researchers have compared linear models with human judges. In situations where linear models make sense, the judges are never more accurate than the linear models. Why is this? The answer is that the models always give the same answer to the same item presented twice, but human judges give different answers. Human judgments are variable. We can compensate for this variability by using the average of several judgments made by different judges, but usually it is less costly to use a formula.

Notice that the variability in judgment will occur even when we have no way of determining the right answer. In the example in the table, we have no final right answer to a student's 'suitability for graduate school'. This is a subjective judgment. Still, we can remove the variability in judgment by finding a formula for the judgments themselves. In the example in the table, the judgments are well fit by the formula: $10(psychology) + 3(science) + letters - 36$.

Ordinarily, the fit is not so good, because the judgments are higher or lower than those predicted by the best-fitting formula. Still, we can find the formula with the smallest errors in predicting the judgments, and we can use that formula. We can get a few hundred judgments, then dismiss the judges and use a formula based on their judgments.

When we have a right answer (such as employee performance), formulas derived in this way have never been found to do worse than the judges themselves. This implies that the cost of judges' errors is greater than any gains that could be made from the ability of judges to consider special patterns or exceptions to the rules. We have reason, then, to use formulas even without an objective normative criterion. They will at least lead to consistent judgments.

The errors in judgments that cause this effect are not always biases. Sometimes they are random, occurring equally often in both directions. The bias is in our overconfidence, thinking that we can do better by considering individual cases. In fact, in every case so far, the linear model of the judge does better than the judge.

Knowledge Representation, Psychology of

Introductory article

Arthur B Markman, University of Texas, Austin, Texas, USA

CONTENTS

'Knowledge representation' is an umbrella term for the methods by which information is stored in the mind for later use.

THE BASICS OF REPRESENTATION

From the beginning of the study of psychology, philosophers and psychologists have been interested in the way information is stored in the mind. In his *Theaetetus*, the Greek philosopher Plato described memory as a wax tablet, in which information is stored as impressions in the wax. In this proposal, the information remained in memory for as long as the impression remained in the wax. Later in the same work, Plato suggested that memory is like an aviary with birds flying around it. Retrieving information was like grabbing a bird from the aviary.

The philosopher David Hume realized that one problem with proposals about the nature of representation was that they required someone (or something) to look at them to interpret the information in them. He searched for some form of self-interpreting representation, which led him to speculate about the various ways that ideas can be related to each other. The idea that there must be some kind of person in the head to interpret representations – called a homunculus ('little man') – baffled psychologists and philosophers until the development of computers. Computers process information by defining processes (or algorithms) that manipulate the structure (or syntax) of the information stored in representations. Computers are able to process information without needing a homunculus, because they need to attend only to the structure of the information presented to them, without needing to understand the content. (*See* **Knowledge Representation**)

Since the late 1950s, psychologists have operated with a computational view of mind. This view assumes that the mind is like a computer in that it carries out algorithms using representations. It is important to bear in mind that this view does not assume that the mind is constructed using the same components as a computer (such as having a central processing unit). The mind is like a computer only in the way that information is processed. (*See* **Knowledge Representation**)

Based on the computational view of mind, a definition of representation can be developed that has four parts: (1) a represented world, (2) a representing world, (3) a set of representing rules, and (4) processes for using the information in the representation. These ideas are illustrated in Figure 1. The represented world is the situation that is going to be represented. For example, the represented world might be information about the outside world. In Figure 1(a), the represented world is the heights of three people. In complex systems, the represented world for one representation might be another representation inside the system. (*See* **Symbol-grounding problem**)

The representing world is the system used as a representation. In Figure 1(b), the representing world is a set of lines that vary in length. The represented and representing worlds are related by a set of representing rules that specify how aspects of the represented world are encoded in the representing world. These relationships determine how information is carried by the representation. For example, the rules might state that larger heights (from the represented world in Figure 1(a)) are represented by longer lines (from the representing world in Figure 1(b)). The representing rules may be arbitrary. For example, Figure 1c shows a symbolic representation for heights using familiar Arabic numerals. In order for these symbols to represent heights, a set of rules relating these symbols to quantities must be established.

Finally, in order for something to be used as a representation, there must be some process that makes use of the information. This last part of

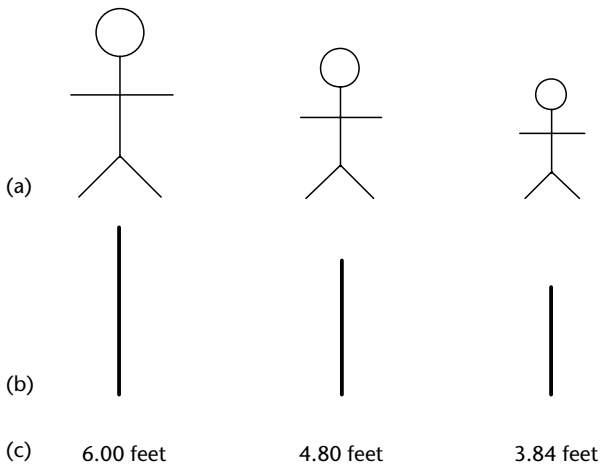

Figure 1. Sample representations: (a) a represented world; (b) a representing world in which the height of the line represents the height of the people; (c) a symbolic representing world in which numbers are used to represent the height of the people.

the definition is quite important. Often, proposals about psychological representations are accompanied by figures that depict the representation. When someone looks at the picture, it seems obvious what information is there. However, if no process is specified that can use the representation, then it is as if the information were not part of the representing world at all.

As an example of a very simple system that uses representations, consider a common thermostat attached to a home heating system. The thermostat has a bimetal strip that curls more as the temperature rises. Attached to the end of the bimetal strip is a glass bulb filled with mercury. When the bimetal strip loses its curvature (because of a decrease in room temperature), the mercury collects in the bottom of the tube, connecting a pair of electrical contacts that completes a circuit and turns on the heater. When the temperature rises, the strip curves more, the mercury pools in the end of the bulb, the circuit is broken, and the heater shuts off. In this system, the represented world is the temperature in the room. The representing world is the shape of the bimetal strip. These worlds are linked by physical laws that determine how changes in temperature affect the shape of the strip. Finally, the bulb of mercury allows the thermostat to use the information to turn the heater on and off.

A thermostat does not have a deep psychology. Nonetheless, according to the definition given earlier, it does have simple representations (though some philosophers reserve the term 'representation' for more complex forms of information-carrying systems). What separates such simple systems from more complex ones like people is the additional properties that can be added to the representations that enable them to carry out more complicated processes. The following sections will describe some important types of representations used in cognitive science.

TYPES OF REPRESENTATIONS

There are a number of different types of representations that have been proposed in cognitive science. These representations differ from each other in two ways. First, representations can be distinguished by virtue of the kinds of information that can be stored in them. Second, each type of representation has its own set of processes that can naturally be applied to it. The processes that can be applied to a representation determine what can be done easily and what can be done with difficulty. This section looks at four types of representations: (1) spatial representations, (2) featural representations, (3) semantic networks, and (4) structured representations.

Spatial Representations

Spatial representations use a space as a representing world. For example, Figure 2 shows a diagram of a basketball play. The positions of the players in this diagram are meant to represent the positions of the players in space on a real basketball court. Thus, in this example, the representing world is a two-dimensional space, and the represented world is the two-dimensional surface of a basketball court. In this case, one space is being used to represent another. However, it is possible to use spatial representations for a variety of different kinds of represented worlds.

A space is a geometric entity that satisfies certain conditions. It can be described by a set of dimensions, where each dimension is a line that points in an independent (or orthogonal) direction. For example, in Figure 2, the space has two dimensions. To see that it has two dimensions, look at the top left corner of the box surrounding the diagram. There are two perpendicular lines that emerge from this corner. If you move along the line moving downward, then you are not moving at all in the left–right direction. Similarly, if you move along the line emerging to the right, you are not moving at all in the up–down direction. Thus, these lines are orthogonal.

Any other line that you draw in the plane of the paper will move at least partially in the direction of

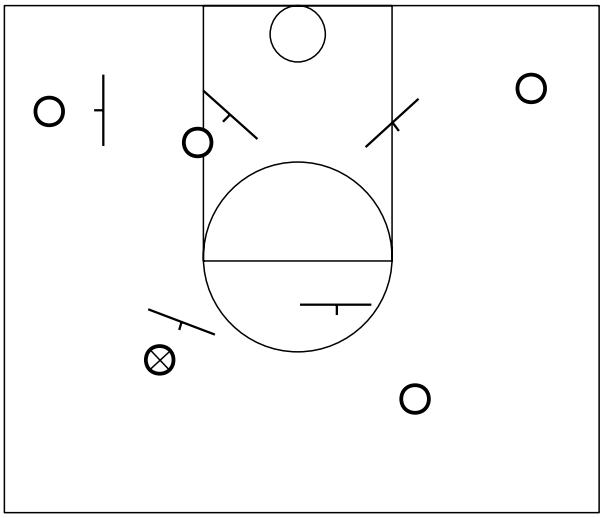

Figure 2. An example of using a spatial representation to represent a space. In this case, the basketball diagram represents the positions of players on the two-dimensional surface of the court using their position within a two-dimensional rectangle. The circles represent offensive players, the circle with the x is the player with the ball, and the lines represent defensive players where the small line indicates the front of the player.

one or both of the lines. The space has two dimensions, because you can put at most two orthogonal dimensions into the space. Physical space has three dimensions, but a psychological space can have any number of dimensions. While it might be difficult to imagine a space with 1000 dimensions, the mathematics that defines the concept of a space can still be used. (*See* **Spatial Representation and Reasoning**)

Distance measured in a space must obey the metric axioms. The three metric axioms are minimality, symmetry, and the triangle inequality. Minimality states that the distance between any point and itself is zero. The symmetry axiom states that the distance between any two points is the same regardless of which point you start from. Finally, the triangle inequality states that the distance between two points is less than or equal to the sum of the distances between those two points and a third point. These metric axioms are important, because they provide a set of characteristics that the representing world must have, which in turn places constraints on what a spatial representation can be used for.

Finally, in a spatial representation, distance can be measured in many ways. The measure that is most familiar from our everyday experience is the Euclidean metric. In a Euclidean space, the distance between any two points is simply the length of the line between the two points. Another way of measuring distance that is often used in spatial representations is the 'city block metric', in which the distance between two points is equal to the distance you would have to travel to get from one point to the other moving only in the direction of the dimensions of the space. For example, if you were in New York City, and wanted to get from 10th Avenue and 50th Street to 8th Avenue and 63rd Street, you could not simply walk straight from one point to the other. Instead, you would have to follow 10th Avenue to 63rd Street and then walk along 63rd Street to 8th Avenue. Often, the Euclidean metric is used for spaces that represent psychological dimensions that are integral (such as the saturation and brightness of a color). Integral dimensions are ones for which people have difficulty attending selectively to one but not the other. In contrast, the city block metric is often used for spaces that represent psychological dimensions that are separable (such as the color and size of a shape).

The easiest process to carry out in a space is the determination of distance, and so many psychological models that use spatial representations focus on cases in which the distance in the representing world corresponds to a salient property of the represented world. For example, a concept space can be developed in which the points in the space represent categories of objects (such as different animals). The distance between points is then inversely proportional to the psychological similarity of those animals. Thus, the closer a pair of objects, the more similar they are.

Spaces have been popular as the basis for models of mental representation, because there are many ways to create spatial representations. One popular technique is multidimensional scaling (MDS). Multidimensional scaling takes a set of distances between points and creates a spatial map of those points. For example, if an MDS program is given the flying distances between 10 European cities, it generates a two-dimensional map of the relative locations of those cities. MDS programs can also be given conceptual distances. For example, a program could be presented with pairwise similarity ratings among a set of concepts obtained from a group of subjects, in which case the output would be a map of the conceptual space. (*See* **Multidimensional Scaling**)

Multidimensional spaces can also be derived from analyses of text. Techniques such as latent semantic analysis (LSA) and the hyperspace analog to language (HAL) take large corpora of text (sometimes with millions of words) and perform

statistical analyses on the co-occurrences among words. Using these techniques, a space is generated in which words that often appear in the same language contexts are represented by points that are near to each other in space. These representations often have hundreds or thousands of dimensions. Analyses of these spaces suggest that they capture a number of aspects of word meanings, like the degree of association among words and their grammatical class. (*See* **Lexicon, Computational Models of**; **Language, Connectionist and Symbolic Representations of**)

Finally, many distributed connectionist models use spatial representations. In a connectionist model, there are many simple units that are interconnected. Each unit, which is roughly analogous to a neuron in the brain, has some degree of activation. The pattern of activation across a set of units is assumed to represent information. These patterns of activation are often written mathematically as vectors. A vector may also be interpreted as a list of coordinates of a point in a multidimensional space. The processes that allow input units in a connectionist model to give rise to patterns of activation on output units can also be interpreted as spatial operations. (*See* **Connectionism**; **Distrubuted Representations**)

In sum, in a spatial representation, items are represented as points (or vectors) in space. The primary operation carried out on pairs of points is a determination of distance between them. The distance between points often has a psychological interpretation. In many cases, distance is assumed to be inversely proportional to psychological similarity.

Spatial representations are not suitable for all kinds of cognitive models. In particular, there is no way to refer to specific items in a space, because a space has no symbols in it that can serve as labels. Thus, whenever a cognitive process requires access to symbols, a purely spatial representation is a poor candidate as an underlying representation. In those cases, one of the representations described in the following sections should be used.

Featural Representations

As mentioned in the previous section, it is often important to be able to refer to a particular aspect of a mental representation, as opposed to merely knowing the similarity of a pair. For example, language involves using labels for objects and for properties. These labels are symbols. (*See* **Symbol Systems**)

The philosopher Pierce distinguished between icons, indexes, and symbols. An icon represents something by physical resemblance. For example, a portrait of Thomas Jefferson is an iconic representation. An index represents something through a causal relation. For example, smoke indexes a fire, because smoke is caused by fires. A symbol has an arbitrary relation to the thing it represents, where that relation is fixed by convention. For example, the word 'hat' is related to the concept 'hat' by arbitrary convention (as evidenced by the fact that other languages may use very different words for the same concept).

In a featural representation, the represented world is a collection of features that are used to describe concepts. In the simplest featural representations, the features are treated as independent of each other. This assumption of independence eases the processes that can be carried out on the representation.

For example, a featural model of similarity (as shown in Figure 3) assumes that each object is represented by a set of features. Then, elementary set operations can be used to determine the common and distinctive features of the objects. The common features are those in the intersection of the feature sets representing the two objects. The distinctive features are those that are not in the intersection. Studies of similarity have demonstrated that the rated similarity of a pair increases with the number of common features of the pair and decreases with the number of distinctive features of the pair. (*See* **Analogical Reasoning, Pscychology of**; **Similarity**)

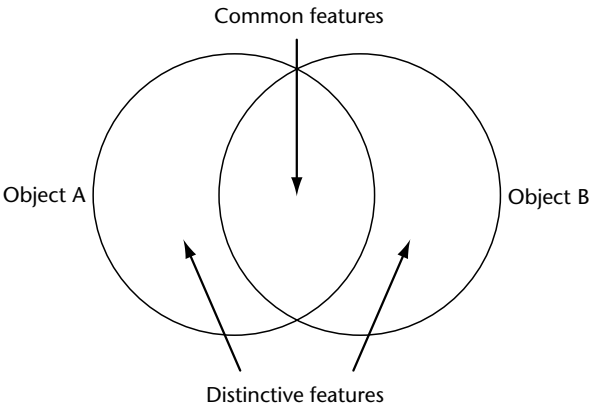

Figure 3. Sample feature sets for two objects, illustrating that the intersection of the feature sets is the set of common features, and that the remaining features are distinctive features.

For featural models, as well as more complex kinds of representations, it is important to consider what the basic (primitive) elements of the representations are going to be. Attempts to generate the primitive elements for representations have been made in research on object recognition, word learning, and text comprehension. Each of these theories tried to posit a small set of basic elements that could be used to construct the remaining concepts in the representational system. For example, Schank's conceptual dependency theory of text comprehension proposed that there are 11 primitive actions, and that verb meanings involve combinations of these actions. Attempts to specify primitives have failed because, for any set of primitives posited, there are many exceptions that require additions and modifications to the initial set. (*See* **Distinctive Feature Theory**; **Prototype Representations**)

Featural representations are the simplest form of symbolic representation. They are simple, because they represent only a set of properties that an object might possess. For example, the concept 'bird' might have the features {wings, flies}. However, this simple representation does not have any information about how the features are related. For example, this representation could not capture a belief that having wings enables a bird to fly. A number of extensions of featural representations have been developed, however. These extensions are designed to account for the way people represent and process relations among aspects of mental representations. In the following sections, two such representations are discussed: semantic networks and structured representations. (*See* **Conceptual Representations in Psychology**)

Semantic Networks

Semantic networks capture relationships among concepts. A small piece of a semantic network is shown in Figure 4. This network consists of nodes (shown as ovals in Figure 4) and links (shown as arrows). The nodes represent concepts in the domain, and the links represent relations among the concepts. If you were to state the relation as a simple sentence, then the arrow points from the subject of the sentence to the object (e.g. an animal has the part 'cells'). Many different kinds of relations among concepts can be represented. Even in the simple example in Figure 4, there are three different kinds of relations. (*See* **Semantic Networks**; **Representations, Abstract and Concrete**)

There are two kinds of processes that are typically associated with semantic networks: marker passing and spreading activation. Marker passing is used by networks for language processing. When interpreting a sentence, a scout is sent to the nodes for concepts mentioned in the sentence. At the first time step, the scout walks along every link leaving a node (i.e., for which the arrow points out of the node), and marks the node. At each subsequent time step, the scouts move further away from the original nodes down the links from the nodes they visited. When scouts starting from two different places mark the same node, an intersection has been found, and an interpretation is formed of the path between the nodes where the scouts originated. (*See* **Implicit and Explicit Representation**)

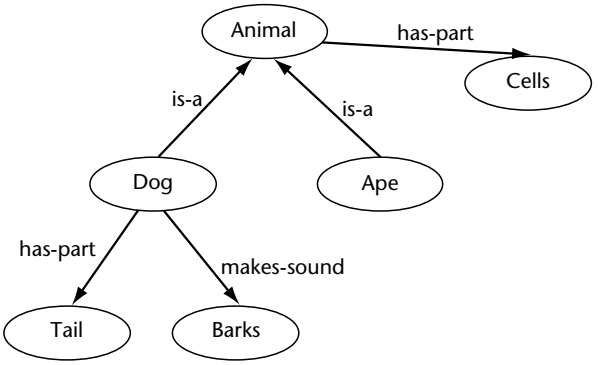

Figure 4. A piece of a semantic network. The ovals are nodes, which represent concepts, and the arrows are links, which represent relations between pairs of concepts.

For example, if a model were trying to verify the sentence 'dogs have cells', then it would send scouts to the 'dog' node and the 'cells' node. Scouts would leave the 'dog' node and walk to the 'tail', 'barks', and 'animal' nodes. At the next time step, the scout would leave the 'animal' node and reach the 'cells' node. At this point, this scout would intersect with a marker from the other scout, and the marker passing process would stop. Analyzing the path between these nodes suggests that dogs do have cells, because dogs are animals and animals are known to have cells.

The second prominent process carried out on semantic networks is spreading activation. Models such as Anderson's ACT (Adaptive Control of Thought) assume that each node can have a degree of activation that corresponds to its current prominence in working memory. In addition, each link has a weight that determines the influence of activation of one node on the activation of another. If a link has a positive weight, then activation of one node will increase the activation of the node to

which it is connected. If a link has a negative weight, then activation of one node will decrease the activation of the node to which it is connected. (*See* **ACT**)

Spreading activation models are used to account for patterns of associative relatedness in memory. For example, a classic finding is that the time taken to determine that a string of letters is a word (i.e. to make a lexical decision) is faster if the string of letters is preceded by a related word than if it is preceded by a neutral string of asterisks. In the present example, if the string of letters DOG was preceded by the word 'barks', activation from 'barks' would spread to the concept 'dog', which would in turn speed the recognition of the word 'dog'.

Semantic networks are quite useful for modeling simple comprehension processes and effects of semantic relatedness. They have difficulty with more complex processes, however. For example, in sentence verification, it is difficult to determine when a property is not true of an object, because the scouts would not intersect for properties that are not possessed by an object. In addition, in semantic networks, the links can connect only pairs of objects. In contrast, there may be times when a cognitive process must relate two or more relations to each other. In this circumstance, more complex structured representations are needed.

Structured Representations

Semantic networks are a constrained form of a more general type of representation called a structured representation. The key aspect of a structured representation is the concept of binding in which the scope of a relationship is determined by items it connects (or binds). For example, we could rewrite the relationship that a dog is an animal from Figure 4 using the following structured representation:

$$\text{is-a}(\text{dog}, \text{animal}) \quad (1)$$

In this simple example, the term 'is-a(*?x*,*?y*)' is a predicate, and the items 'dog' and 'animal' are constants. The *?x* and *?y* in the predicate are variables that can be filled by constants or other predicates. These variables specify the scope of the relation. In the example, when the variables are bound to constants, the predicate specifies that the first item is a type of the second. Variables that specify the scope of a relation are called 'arguments'. When the arguments to a predicate are specified, then the statement is called a 'proposition', because it can be evaluated as being true or false about the represented world. (*See* **Binding Problem**)

Structured representations permit efficient representations of relational information. In general, if we are able to represent a relation like 'kiss (John, Mary)', then we can also represent the same relation with the arguments reversed, 'kiss(Mary, John)'. Thus, we can use the same three elements (kiss(*?x*,*?y*), Mary, and John) to represent two very different concepts. It would be quite difficult to represent these relations with a featural representation, because there is no way to bind features to each other. (*See* **Representations Using Formal Logics**; **Syntax**)

Structured representations are more general than semantic networks in two ways. First, in semantic networks, all links relate two items (i.e., there are only predicates with two arguments). In contrast, in structured representations, it is possible for a predicate to have only one argument or for it to have more than two arguments. For example, predicates with one argument are often used to represent specific attributes of an object such as:

$$\text{red}(?x) \quad (2)$$

Predicates with more than two arguments may be used to represent complex actions, such as:

$$\text{give}(\text{?giver}, \text{?recipient}, \text{?item-given}) \quad (3)$$

The second way in which structured representations are more general than semantic networks is that semantic networks relate only concepts specified by nodes, but structured representations permit predicates to take other whole propositions as arguments. These more complex predicates are often used to represent causal relations, such as:

$$\text{cause}\,[\text{love}(\text{John}, \text{Mary}), \text{kiss}(\text{John}, \text{Mary})] \quad (4)$$

In this example, the fact that John loves Mary causes him to kiss her, where the predicates 'love(*?x*,*?y*)' and 'kiss(*?x*,*?y*)' serve as arguments to the cause relation. (*See* **Causal Reasoning, Psychology of**)

The processes that act on structured representations can be quite complex, because they must be sensitive to the way predicates take arguments. For example, when a process that calculates the similarity of a pair of structured representations finds a relation in each representation that corresponds, this process must then ensure that the matching relations have matching arguments.

Making use of this argument structure increases the complexity of the processes that act on structured representations relative to processes that act on featural representations.

USING REPRESENTATIONS

The diversity of approaches to representation in psychology reflects that there are a variety of goals that cognitive processes must satisfy. Some processes must run quickly and efficiently. These processes are likely to use spatial or featural representations or perhaps a semantic network, because procedures such as distance calculation, feature set comparison, or spreading activation can be carried out quickly. In contrast, the procedures that operate on structured representations are often computationally intensive, and thus require time to complete. (*See* **Computablity and Computational Complexity**; **Computation, Philosophical Issues about**)

There are also situations in which a cognitive process requires the ability to represent complex information (such as language comprehension or causal reasoning). In these cases, efficiency may not be an issue, as the process may have seconds or minutes to be carried out. In this case, the greater expressive power of structured representations outweighs the complexity of the processing.

This analysis leads to an important topic in current research on knowledge representation, which is the way that different types of representations are integrated during processing. As an example, the ACT model mentioned above uses a spreading activation process to allow concepts to be retrieved from memory. Because memory retrieval requires the potential consideration of many different pieces of information, it is important to have processes that run efficiently. The ACT model also uses structured representations for carrying out reasoning processes where there is sufficient time to permit the use of complex representations. Work that tries to integrate representations has also been done in the areas of object representation and analogical reasoning. There is much still to be learned, however, about the way different representational systems can be incorporated into a single model. (*See* **Connectionist Implementations and Hybrid Systems**)

Language and Cognition

Introductory article

Catherine L Harris, Boston University, Boston, Massachusetts, USA

CONTENTS

Cognitive scientists have long debated whether language and cognition are separate mental faculties, or whether language emerges from general cognitive abilities.

INTRODUCTION

What is the relationship between language and cognition? Do people who speak different languages think differently? Is a certain level of cognitive development required for language acquisition? These questions were of keen interest to thinkers in the early twentieth century and remain important in anthropology, linguistics and psychology. However, the cognitive revolution of the 1950s raised a new question about the relationship between language and cognition: is language the same type of mental entity as other cognitive abilities, or is it fundamentally different?

A hallmark of modern cognitive science is the goal of developing a theory of cognition powerful enough to encompass all human mental abilities, including language abilities. A long-standing controversy concerns two ways of conceptualizing the architecture (or basic design) of cognition. One approach proposes that general-purpose processes and mechanisms provide a foundation for all varieties of human intelligence. We can refer to this as 'general purpose' cognition. Examples of possible universal processes are the ability to induce a category from exposure to examples (category induction), and the ability to mentally complete a known pattern when confronted with a piece of it (pattern completion). Cognitive scientists frequently attempt to precisely specify their proposed mechanisms by implementing them as computer algorithms which can be tested in artificial intelligence (AI) programs. Researchers have tried to use AI programs to show that the same principles that can explain general problem solving can also explain aspects of language acquisition and processing.

The second way of conceptualizing human cognition emphasizes the differences between language and other abilities. A key idea is that many distinct domains of cognition exist and must be learned separately, using different mental mechanisms. This approach is referred to as the 'modularity of cognition' or 'mental modules' approach. At first glance it may seem contrary to the interdisciplinary spirit of cognitive science and to the possibility of a unified theory of cognition. However, the unifying theory is the thesis of distinct mental modules, which are believed to have evolved to accomplish specific tasks relevant to mammalian evolution, such as visual exploration, or relevant to human evolution, such as language use. Much of the appeal of this approach comes from findings in neuropsychology showing that distinct areas of the brain serve distinct functions such as vision, language processing, motor coordination, memory, and face recognition. The interdisciplinary spirit is maintained because advocates of this approach reach out to biological scientists and evolutionary theorists. Those favoring modularity embrace the principle of converging methodologies: a theory must have explanatory power in the distinct academic disciplines that compose the cognitive sciences. These two approaches to the architecture of cognition developed out of different philosophical traditions, and have evolved considerably during the half-century history of cognitive science.

CONCEPTS OF COGNITION AND LANGUAGE

Why are there two different views on the relationship between language and cognition? At the dawn of the cognitive revolution, in the late 1950s, there were two distinct ideas about the nature of mind.

Discussed first are the views of linguist Noam Chomsky and the field of generative linguistics which he developed, because the underlying philosophy has remained fairly constant over the intervening years.

Chomsky's major innovation was to conceive of language abilities as akin to a mental organ. According to this view, children are born with a 'language acquisition device' and with specific linguistic knowledge. This knowledge is thought to include the concepts of noun, verb, grammatical subject, and structures that constrain possible grammatical rules. In contrast to the views of the dominant psychological paradigm of the 1950s, behaviorism, Chomsky argued that children do not learn to speak by imitating adults. His key evidence was that children spontaneously use incorrect forms they could not have heard, like 'goed' and 'breaked'. Linguistic overregularizations like these suggest that children are extracting rules from the language they hear, not merely imitating. Theorists at that time found it noteworthy that parents do not generally tell children that their utterances are ungrammatical. Because the language input to children is full of mistakes, stops and restarts, Chomsky felt that children could not learn language using general purpose problem-solving or regularity-extraction skills. They needed to come to the task with a rich set of expectations about the nature of language. These expectations were believed to be specific to language, and thus did not share commonalities with other aspects of cognition. This set of language-specific abilities has been variously called the 'language acquisition device' (the historically early term) and 'universal grammar' (a more recent term). Chomsky's approach to linguistics is called 'generative linguistics' because its early goal was to describe mental structures that can generate all the grammatically valid sentences of a language.

Chomsky felt that the aspect of language that is unique is syntactic ability. An example of specifically syntactic knowledge is illustrated by the sentence, 'Colorless green ideas sleep furiously'. Although the words in this sentence contradict each other and do not correspond to a possible reality (green is not colorless, ideas cannot sleep furiously), speakers nevertheless recognize the sentence as having a correct grammatical structure. Chomsky used this sentence as an example of how syntactic structure represents information independently from the meaning of the words in the sentence. He argued that syntax is a unique, independent human capacity and not derivative from other abilities. The proposal that syntax is not influenced by the meaning of the words in the sentence or speakers' communicative goals came to be called the 'autonomy of syntax' hypothesis.

Chomsky's innovations developed in tandem with the dawn of the cognitive revolution. With the birth of computer science a new way of conceptualizing human cognition arose, using the metaphor of the brain as a computer and the mind as software. Much of Chomsky's early work depended on these metaphors: he conceived of grammar as a set of rules for generating novel combinations of words, just as a computer program could generate a string of symbols according to a formula. Thinking of mental operations as akin to steps in a computer program allowed psychologists and workers in the new field of artificial intelligence to begin to subdivide mental tasks, such as arithmetic or language comprehension, into a series of steps in a computer program. Their research evolved in a different direction from Chomsky's. Computer scientists and psychologists such as Alan Newell, John Anderson, Roger Schank and Patrick Winston began to describe a range of human abilities – from visual object recognition and general problem solving, to metaphor use and story understanding – in terms of a set of internal representations and processes that transform those representations. A key aspect of this approach to cognition was that the theorist could write computer programs that would provide a formalizable theory of mental operations. A rigorous test of the theory could be performed by running the program and seeing if output matched human output.

Many of the early successes of this field involved language, including sentence comprehension, story understanding and metaphor use. An important aspect of the language and cognition relationship is that the AI models of language did not draw on language-special algorithms or knowledge structures. The new AI tradition and the information processing movement within psychology emphasized learning, particularly general-purpose learning, and was thus opposed to the emphasis on innate knowledge structures that was part of Chomsky's new linguistics. Psychologists drawn to the information processing movement were frequently inspired by the work of Swiss psychologist Jean Piaget, whose works began to be translated into English in the 1960s. Piaget also emphasized the commonalities between language and cognition, and proposed that language emerged out of the same broad cognitive changes that transform the sensorimotor processing of infants into the formal and logical mind of adults.

Table 1. Theoretical perspectives on the language–cognition relationship

Timeline	*Movement*	*Main source of constraints*	*Language/cognition*
1957–present	Chomskyan linguistics	Innate	Language unique, unlike cognition
1960s–1990	Artificial intelligence	Learned	Subject to same principles
1980s–1990	Connectionism	Learned	Subject to same principles
1980s–present	Modularity of mind	Innate	Language unique, unlike cognition
1990s–present	Cognitive neuroscience	Dynamical interaction	Complex similarities and differences

In the 1970s and 1980s, among those researchers who aligned themselves with the interdisciplinary field of cognitive science, there was a tendency for linguists to emphasize the specialness of language and cognition, and for psychologists to emphasize commonalities between language and cognition. However, there was considerable variation in viewpoint within psychology and linguistics, which continues to this day. Three scientific developments during the 1980s and the 1990s had implications for theories of the language–cognition relationship: connectionism, cognitive linguistics, and the cognitive neuroscience movement. The development of these movements is summarized in Table 1.

CONNECTIONISM

The 'connectionist revolution' was launched in the mid 1980s. A new computational metaphor emerged to explain both language and cognition, based not on the Von Neumann computer, but on the idea that sophisticated computations emerge from massive networks of simple processing units, in which the units are akin to idealized neurons.

In the early 1980s several groups of cognitive scientists became dissatisfied with the AI systems being used to model cognition. These rule-governed systems employed databases containing knowledge of common situations, such as what one does at a restaurant; 'if–then' rules specified the action that an expert would take in a specific situation. This expert knowledge thus constituted intelligent reasoning. Critics noted that these expert systems were brittle and frequently failed to generalize beyond the bounds of their circumscribed database. Real human cognition seemed intuitively to involve not the application of fixed rules to a specific situation, but the satisfaction of many soft constraints, some of which could be ignored. Categories were not logical sets of necessary and sufficient conditions, but were graded groupings which shared 'family resemblance', as had been argued earlier in the century by Wittgenstein. To the mathematical and cognitive psychologist David Rumelhart, flexible and creative reasoning seemed to be similar to the motor process involved in reaching for a cup behind a pencil-holder on one's desk – or at least, more similar to this type of planning than to rule-governed algebraic reasoning.

Rumelhart and other cognitive scientists such as Terrence Sejnowski and Stephen Grossberg agreed that mental functioning involves computation, but asked what type of computation would be carried out by an organic structure like the brain, composed of massive numbers of simple processing units (neurons), linked together in a complex network of fiber tracts, with many units firing simultaneously. This movement was labeled 'connectionism' because intelligent behavior was posited to emerge from large numbers of neuron-like processing units, connected together into networks in ways that fostered parallel processing. One early success story was a connectionist model that could learn English past tense forms given the present tense of a verb. The domain of English past tense was provocative because it contained both rule-like behavior (past tense forms are generated by adding '-ed' to a present tense form), and exceptions which themselves congregated into patterns, such as that emerging from considering 'grow/grew', 'blow/blew', 'know/knew'. Both connectionist networks and adult second-language learners are likely to make the error of generating 'glew' for the past tense of 'glow', presumably through analogy with this subregularity within the past tense system. Other connection language models explored how ambiguous words are understood in their sentence context (such as 'bat' in 'The boy hit the bat'), and how abstract categories such as noun and verb can emerge from distributional regularities in text (such as the fact that nouns tend to occur in similar sentence positions). Because the basic system of processing units under these connectionist language models was the same as those used to model visual and motor behavior, successes like the past tense model were taken as support for a

common computational architecture underlying both language and cognition.

COGNITIVE LINGUISTICS

A subset of linguists disagreed with Chomsky's emphasis on the uniqueness and specialness of language, then generally accepted. The field of cognitive linguistics emerged in the late 1980s and helped initiate a flood of work connecting language and cognition. One source for the cognitive linguistics movement was an older tradition within linguistics called 'functionalist' linguistics. This held that constraints on the form of language (where 'form' means the range of allowable grammatical rules) derive from the function of language. The goals of using language include serving efficient communication. Thus the function of diverse syntactic forms, such as subject versus object and main clause versus subordinate clause distinctions, serve communicatory goals such as conveying which information is most important and which is background or context. However, the goals of conveying the relevance and background/foreground structure of the message are outside the language system. The proposal that the form of grammatical rules is influenced by communication is thus inconsistent with the autonomy of syntax hypothesis. That hypothesis specified that syntax was its own system, not shaped by the need for efficient processing or other exigencies of communication.

Functionalist linguists as well as other linguists were dissatisfied with the range of linguistic phenomena excluded by generative linguistics. They rejected the Chomskyan view that the most important aspect of language was a mechanical device for generating only legitimate grammatical sentences. They wanted to understand language in all its diversity, including narrative, discourse, dialects, sociocultural influences on language use, and metaphor. Some functionalist linguists even proposed that rule use is just a minor aspect of language. Linguists such as Dwight Bolinger and Charles Fillmore argued that speech utterances, not rules for generating utterances, are what is mentally stored. They noted that every language speaker has memorized huge numbers of odd coinages, colloquialisms, idioms and collocations, many of which share patterns. An example is the phrase 'know by heart' which has the variation 'learn by heart'. Rules, partial regularities and rule exceptions appear to differ in degree, occupying a continuum from fully idiosyncratic, to partially regular, to fully rule-governed. This idea made researchers in this nascent linguistic movement sympathetic to the connectionist movement, although the commonalities have not yet been fully explored.

Although trained in the generative grammar tradition, linguists such as George Lakoff and Ronald Langacker noted that one could not describe which sentences are syntactically valid and which are invalid without reference to nonlinguistic concepts. They pointed to the tendency for the same words describing movement in space to be used to describe movement in time ('This meeting runs until 3 o'clock'), and emphasized the necessity of incorporating the cognitive psychology of human category formation into linguistics. This approach to linguistics came to be called 'cognitive' linguistics because aspects of general cognition – such as how we construe the meaning of a grammatical construction – were proposed to be important for describing linguistic structure. For example, one descriptive problem of grammar is to account for why some sentences, but not others, can undergo the 'passivization' transformation. The sentence 'John was hit by Mary' sounds fine, but 'John was known by Mary' does not. To fully describe which transitive sentences can undergo passivization, one needs to invoke the notion that the subject and direct object are in dynamic interaction with each other. Thus, one cannot passivize a sentence like 'John left the auditorium' because John is not acting on the auditorium in a way that has consequences for it; but the sentence 'John left the auditorium unguarded' can be transformed into 'The auditorium was left unguarded by John', presumably because John's action affects the status of the auditorium.

By 2000 the cognitive linguistics movement had grown into an enduring subfield, but it has remained outside the mainstream of linguistics. While some cognitive linguists have remained focused on specific linguistic questions, others have addressed questions in an interdisciplinary manner, drawing on experimental psychology, brain science, and category induction performed by artificial neural networks.

THE COGNITIVE NEUROSCIENCE MOVEMENT

The field of cognitive neuroscience emerged from work in neuroscience and cognitive science. Cognitive neuroscience differs from basic neuroscience by having the goal of explaining complex cognitive abilities, but rejects the tradition of artificial intelligence (and much of cognitive science) that one can understand cognition abstractly, without reference to its neural underpinnings.

In the 1990s some cognitive neuroscientists argued that basic aspects of the language–cognition relationship, such as the autonomy of syntax hypothesis and the innateness and modularity of language, could be evaluated from the neuroscientific point of view. Neurobiologists have noted that developing neural tissue is very plastic. For example, the auditory association areas of the brain frequently represent visual and gestural language in individuals who are born deaf. The regions of the brain that mediate language use appear to be especially malleable. Like other aspects of cognition, language acquisition is heavily dependent on experience.

Ralph-Axel Mueller has remarked that regional specialization in the brain is beyond doubt, but modularity of cognitive functions, including language, is highly debatable from the view of neurobiology and evolution. Functional specialization of brain areas most probably emerges because some brain areas are near to the site of sensory input, such as sensory systems for vision and audition. Scientists such as Jeffrey Elman, Elizabeth Bates and their colleagues note that however closely one looks at the anatomy and physiology of the brain, there is no evidence of cortical structures unique to language or unique to humans. These researchers argue that language has an 'epigenetic' not a 'genetic' origin. Epigenetic development is the proposal that behavior results from a complex dynamic evolution of genes and environmental forces during prenatal and postnatal development. The concept of epigenesis dates back to psychologist Jean Piaget, who argued that cognitive abilities emerge from a biological structure which evolves, both before and after birth, in tandem with environmental forces. Contemporary researchers who embrace the epigenetic view point out that there are too few genes in the human genome to code directly for outcomes such as the ability to use language. Like other brain regions, the language areas in the adult brain are the end product of complex chains of interactions with internal and external environments. These sequences of events are based probabilistically on genes rather than being rigidly determined by the genome.

The neurobiological evidence thus may run counter to what would be expected under the autonomy of syntax hypothesis. There is no known way that genes could encode for concepts like 'subject' and 'verb'. Thus the most parsimonious perspective is that language is similar to other aspects of cognition in terms of emerging out of a brain which evolved to have an oversized frontal cortex (relative to other primates) and an elongated period of childhood, which privilege the role of learning.

Cognitive neuroscientists share a view of language that resonates with the cognitive linguists: they emphasize the joint development of language and perceptuomotor processes, with language acquisition understood to be semantically driven and embodied. The neurological representation of grammar is continuous with the representation of other language 'components' and the neural substrate.

CONCLUSION

In the first half of the twentieth century the main question about the relationship between language and cognition was whether the grammatical structure or vocabulary of our language influenced thought processes. Cognitive science introduced a new question: are language and cognition similar or distinct human abilities? The last 50 years have seen considerable controversy on this question, mirroring the development within cognitive science of two fundamentally different conceptions of the cognitive architecture. The tradition of artificial intelligence emphasized general-purpose problem-solving abilities, while the tradition of linguistics and philosophy led to an emphasis on distinct mental modules.

The different theoretical perspectives on the language–cognition relationship are summarized in Table 1. The view at the beginning of the twenty-first century appears to be best captured by the idea that cognition and language have complex similarities and differences, and both develop over the human life span from genetic factors constrained by environmental input and cultural learning. New possibilities for synthesis continue to emerge, especially as cognitive scientists pay more attention to evolutionary, neurobiological and cultural factors. It may be possible to set aside the question of whether language is distinct from cognition and whether the brain is composed of distinct mental modules. The theorist Howard Gardner has noted a growing consensus about the importance of a new set of questions about how to divide up the grand areas of mind and brain. Scientists are emphasizing the distinction between areas of human ability that are available to all humans and played a part in the evolution of our species (such as language and basic number use), and areas requiring cultural elaboration (such as algebra and the ability to play musical instruments). The era of simplistic statements about the language–cognition relationship is drawing to a close, as cognitive scientists begin to deliver on the promise of a truly interdisciplinary approach to understanding the mind–brain.

Language Comprehension and Verbal Working Memory

Introductory article

Gloria S Waters, Boston University, Boston, Massachusetts, USA
David Caplan, Massachusetts General Hospital, Boston, Massachusetts, USA

CONTENTS

Working memory is considered to be a specialized component of memory that is responsible for the temporary storage and manipulation of information necessary to accomplish a cognitive task. Language processing is an example par excellence *of a task that requires temporary storage and manipulation of information, and that therefore provides a domain in which ideas about working memory can be explored.*

OVERVIEW OF WORKING MEMORY

Alan Baddeley and his colleagues are generally credited with introducing the concept of 'working memory' into contemporary cognitive psychology and neuropsychology. They argued that the concept of 'short-term memory' (STM) as a system that retains information for short periods of time was too restrictive. They suggested that a combination of a short-duration storage function and a computational capacity was necessary for performing many mental functions. Thus was born 'working memory' (WM). Baddeley and his colleagues went on to elaborate a model of working memory that postulated the existence of a 'central executive' responsible for both computations and information storage, and 'slave systems' responsible for information storage when the capacity of the central executive was exceeded (see Figure 1).

It is now commonly accepted on the basis of both behavioral and neurological evidence that there are different working memory systems for verbal and nonverbal (e.g. visuospatial) tasks. There is considerable controversy concerning whether there are further subdivisions within each of these systems.

WORKING MEMORY AND LANGUAGE COMPREHENSION

The concept of a limited resource system that determines computational capacity and efficiency is a powerful one with many potential applications, and it has been widely utilized. Language is a natural domain in which this concept might apply, because virtually all language processing – from recognizing spoken words on the basis of their phonemic content to participating in a conversation – requires storage of representations and performing computations on these representations over some period of time.

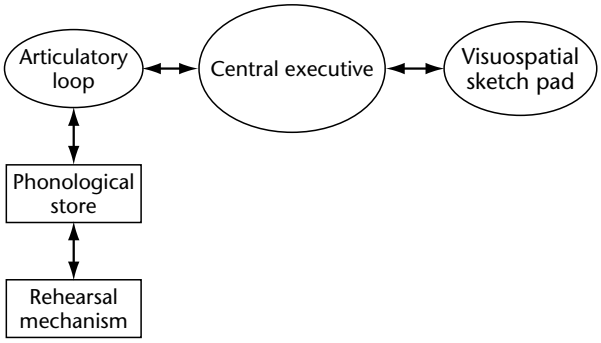

Figure 1. A schematic of Baddeley's model of working memory. Working memory is composed of the central executive, which is responsible for computations and information storage, and slave systems, such as the articulatory loop and the visuospatial sketch pad, which are responsible for information storage when the capacity of the central executive is exceeded.

Measurement of Working Memory Capacity

To relate WM to language, we have to be able to measure both the capacity of the WM system and the speed and accuracy of various language functions. A fair number of WM tests have been developed (see Figure 2).

Probably the most widely used is the 'reading span' measure. In this task, subjects read aloud increasingly longer sequences of sentences and

Daneman and Carpenter Reading Span Task

Subject reads aloud the following:
I imagine that you have a shrewd suspicion of the object of my early visit.
I'm not certain what went wrong but I think it was my cruel and bad temper.
Filled with these dreary forebodings, I fearfully opened the heavy wooden door.

Subject recalls sentence-final words:
visit, temper, door

Waters and Caplan Sentence Span Task

Subject reads the following sentences silently, making an acceptability judgment after each. Reaction times for judgments are measured.

It was the gangsters that broke into the warehouse.	*Acceptable*
It was the pillow that clenched the man.	*Unacceptable*
It was the cat that climbed the tree.	*Acceptable*

Subject recalls sentence-final words:
warehouse, man, tree

Alphabet Span Task
Experimenter reads aloud the following:
tree, arm, vest

Subject recalls the following:
arm, tree, vest

Subtract 2 Span Task
Experimenter reads aloud the following:
3-7-4

Subject recalls the following:
1-5-2

Running Item Span Task
Experimenter reads aloud the following:
1-7-9-3-4-5-6-2-8
'*Now tell me the last three numbers.*'

Subject recalls the following:
6-2-8

Figure 2. Sample items from several tests of verbal working memory (span size = 3).

recall the final word of all the sentences in each sequence. A subject's working memory capacity is defined as the longest list length at which he or she can recall the sentence-final words on the majority of trials. This task is thought to involve both a processing and a storage component, and therefore is thought to be a better measure of WM capacity than STM tasks, such as digit span, that simply require the recall of a list of items and so do not have a processing component.

There are close to a dozen WM tasks to choose from today (see Figure 2 for examples). Many of these tasks are similar to the reading span task in that the processing operation involves sentences. However, other types of WM tasks have been developed that require quite different processing operations, for example, to arrange a list of words alphabetically. Thus, while these different tasks share the characteristic of requiring both storage of some information and some sort of computation, they differ quite radically in their specifics. These differences might lead to different estimates of WM capacity. Indeed, studies of these tasks show that they are not always well correlated with one another. In addition, one cannot always be confident in the stability of a measurement of WM over time in an individual subject.

Thus we are at the uncomfortable point of having many WM tasks to choose from, which correlate only modestly with one another and are often unstable over time, and on which it is often unclear what cognitive functions determine a subject's performance.

CONTROVERSY OVER HOW/WHETHER WORKING MEMORY CONSTRAINS LANGUAGE PROCESSING

Researchers have nonetheless studied the relationship of WM to performances on many language

tasks and to language impairments, and found that measures of WM capacity have predictive value both for performances of normal subjects and for the presence of abnormalities of language functions. The simplest, and most common, account of these relationships is that WM is involved in language functions and that differences in WM capacity give rise to differences in performances on language tasks.

Given the above concerns about what tests of WM measure, however, it is advisable to examine the relationship between performance on WM tests and performance on tests of language functions more closely, and to ask whether any such relationships reflect the reliance of a language function on the WM system measured by these WM tests.

Measurement of Language Functions

One starting point for this examination is to deconstruct tests of language functioning, as we have those of WM. There are two ways to do this. One is to consider language tests in relationship to the nature of the linguistic representations that they require. This approach looks to linguistic analyses that describe the structure of language as a multilevel code that relates meanings to forms, where the levels include lexical, morphological, sentential, and discourse representations. The second is to consider these tests in relationship to the psychological processes they involve. For example, one could describe the processing requirements of language tasks in terms of their computational and memory requirements, and relate WM capacity to task performance as a function of these measures.

Relationship between Language Functions and Working Memory Capacity: Evidence from Individual Differences and Brain-damaged Populations

Beginning with representations, the strongest case for a relationship between a specific type of linguistic representation and WM has been made by Gathercole and her colleagues in the area of lexical phonological representation. They have argued that the 'articulatory loop' – the part of the verbal WM 'slave system' responsible for rehearsing phonological representations – is involved in lexical phonological processing. More specifically, these researchers have made the case that the articulatory loop is involved in learning new words.

On the surface, this pattern is surprising, since one might expect *a priori* that processing lexical phonological representations, which are made up of phonemes and distinctive features that are adjacent to one another and that extend over a relatively small temporal interval, would be expected to require relatively little WM capacity. This invites a deeper look at this finding.

Such a look shows that the evidence for a relationship between the articulatory loop and new word learning consists of high correlations between subjects' performances in repeating nonwords and in learning new words. It is not surprising that the ability to repeat nonwords is predictive of the ability to learn new words since, at the time they are first presented, new words are like nonwords with respect to their phonological familiarity. It is also unsurprising that the ability to repeat nonwords is related to the ability to rehearse. This suggests that it is the considerable overlap between the representations that need to be processed in a particular task (repetition) that is the basis of the relationship between the articulatory loop and new word learning.

This analysis suggests that the relationship between this one component of the WM system and this language function is not that the capacity of this part of the WM system determines the efficiency of an aspect of language functioning, but rather goes in the opposite direction. The capacity to repeat – a language function that partially underlies learning new phonological representations – is utilized by the WM system. WM recruits language, rather than vice versa.

Where WM tasks and measures of language function do not both emphasize processing the same linguistic representations in the same task, the relationship between WM and language processing is hard to demonstrate. Processing syntactic representations is an interesting case, because syntactic relationships are often established over elements that are much more discontinuous than the phonological units that constitute words, and their processing requires considerable computational activity. For example, working memory would seem to be needed to relate 'the boy' not 'the girl' to 'fell' in a sentence such as 'The boy who chased the girl fell'. Nonetheless, in many studies performance on WM tests does not correlate with performance on tests of the ability to process complex syntactic structures. For example, patients with dementia of the Alzheimer type who have severely reduced WM capacity have in many cases been found to have little difficulty in structuring syntactically complex sentences. The same can be said for populations with less extreme reductions in WM capacity – such as elderly individuals and college students with low WM spans.

Looking at the relationship between WM and language functions in psycholinguistic terms gives us another perspective. As noted above, there are many studies that document significant correlations between performance on a WM task and language functions. In many studies moderate correlations are found between measures of verbal WM and 'global, standardized' measures of comprehension (such as the verbal Scholastic Achievement Test (SAT) or the Nelson–Denny Reading test). Moderate correlations have also been found between measures of verbal WM and more specific tests of integration such as making inferences or abstracting the main theme. However, although it is clear from this literature that there are reliable correlations between many psycholinguistic functions and WM performance, it is not clear that WM capacity will predict performance on many of these tasks as a function of their storage and computational requirements.

Finally, we can look at psycholinguistic tasks in a qualitative manner. What is interesting about the language tasks on which performance bears a relationship to a measurement of WM capacity is the extent to which these tasks require conscious, controlled processing of language. It may be important to draw a distinction between those processes that are responsible for the recovery of linguistic forms and meanings from the acoustic signal to yield a meaning for an utterance, and those processes that use the products of language comprehension. The first set of processes, which is sometimes referred to as 'language interpretation', is largely unconscious, obligatory once initiated, fast, and accurate. The second set, which is sometimes referred to as 'post-interpretive processing', is more accessible to conscious awareness, not obligatory, and often slower than language processing. In general, performance on WM tasks is poorly correlated with the efficiency of interpretive processing and better correlated with that of post-interpretive processing.

The lack of a correlation between performance on WM tests and the efficiency of interpretive processing is not due to the fact that interpretive processing is so automatic that it does not require processing resources. Nor is it the case that interpretive processing does not require temporary storage and manipulation of information. Rather, the information storage and manipulation requirements of interpretive processing appear to be supported by a system that is not well measured by WM tests. This suggests that there may be several systems devoted to the temporary storage and manipulation of linguistic representations, one of which is responsible for language interpretation.

A specialization within verbal WM may have developed to support language interpretation because of a combination of factors. One is that language interpretation involves a set of related operations that always compute items within the same restricted set of representational types. A second is that these operations have the qualities of obligatoriness, unconscious operation, and speed noted above. A third is that these operations are among the most highly practiced of human cognitive functions. Because of their integration and degree of over-practice, one system for storage and manipulation of linguistic representations may be utilized by all the processes that constitute the interpretation process.

Performance on post-interpretive processing and WM tasks correlates much better than performance on interpretive processing and WM tasks. Post-interpretive processing and WM tasks share the basic psychological characteristics of being conscious, controlled functions. Such functions involve a large number of cognitive operations, including the ability to sustain, focus, and shift attention, to retrieve relevant information from long-term semantic and episodic memory, to reason, to assess likelihood, and others. The ability to store and manipulate linguistic and other symbolic representations – at least to do so consciously – is one functional ability that is found in both WM tests and these tasks; but the extent to which it, rather than other shared capacities, is responsible for the relationship between performance on the two types of tasks remains to be explored. Certainly, the simplest view, that differences in WM – the capacity to store and manipulate linguistic and other symbolic representations – are responsible for differences in performance on language tasks, needs to be replaced by a much more nuanced and detailed analysis of the determinants of performance on both these types of tasks.

Language Development, Critical Periods in

Intermediate article

EL Newport, University of Rochester, Rochester, New York, USA

CONTENTS

First language acquisition typically occurs in infancy and early childhood. An important question concerns whether the acquisition of a first or a second language shows a critical or sensitive period: that is, whether acquisition displays a normal course and leads to full proficiency in the language only when it begins early in life.

INTRODUCTION

In many species, including humans, important and species-typical behaviors develop through an intricate combination of innate and experiential factors. One hallmark of such systems is the appearance of a critical or sensitive period for normal development.

A critical period is a maturational time period during which some crucial experience will have its peak effect on development or learning, resulting in normal behavior attuned to the particular environment to which the organism has been exposed. If the organism is not exposed to this experience until after this time period, the same experience will have only a reduced effect, or in extreme cases may have no effect at all. Well-studied examples of species-typical behaviors showing peak plasticity within a critical or sensitive period include the identification of a species member as an attachment object (called 'imprinting') in ducks and birds, the acquisition of the species mating song by finches and sparrows, and the spatial tuning of auditory localization in barn owls. In contrast, in other domains and systems, there may be plasticity uniformly throughout life (open-ended learning), or plasticity may increase with age as experience or higher-level cognitive skills increase.

In his seminal book *Biological Foundations of Language*, Eric Lenneberg (1967) hypothesized that human language acquisition was an example of biologically constrained learning, and that it was normally acquired during a critical period, beginning early in life and ending at puberty. Outside of this time period, he suggested, language could be acquired only with difficulty or by a different learning process. He also suggested a neural mechanism for this developmental change: he hypothesized that the critical period for language acquisition ended with the establishment of cortical lateralization of function, as the brain reached its mature organization in late puberty.

Since the time of Lenneberg's book, an extensive research literature has asked whether there is indeed a critical or sensitive period for human language acquisition. These studies have provided strong support for the existence of such a critical or sensitive period (particularly for acquiring the phonology and grammar of language), though not for Lenneberg's specific hypothesis about the relationship between lateralization and the end of the critical period.

The term 'critical period' is sometimes used when there is an abrupt decline in plasticity and no residual plasticity after this period is over, whereas the term 'sensitive period' is used when there is a more gradual decline and some (reduced) plasticity remaining throughout life. However, recent research has shown that most critical periods show more gradual offsets and more complex interactions between maturational and experiential factors than the original concept of a critical period had anticipated. The terms are therefore often used interchangeably, as will be done in the present article.

EVIDENCE FOR A CRITICAL OR SENSITIVE PERIOD FOR LANGUAGE ACQUISITION

A number of lines of research, both behavioral and neural, suggest that there is a critical or sensitive period for language acquisition. Case studies of

individual feral or abused children, isolated from exposure to their first language until after puberty, have shown extreme deficits in phonology, morphology, and syntax resulting from this deprivation. The best studied of these cases is a girl named Genie, who was followed closely for a number of years after her discovery and placement in a normal linguistic environment at age 13 (Curtiss, 1977). While Genie did successfully acquire some English after puberty, her phonology was abnormal, and her control over English syntax and morphology was limited to only the simplest aspects of the language.

However, in cases of isolated children, general physical and cognitive status may be a concern. In studies of populations of normal individuals, one can systematically examine proficiency in relation to age of linguistic exposure without concern about the physical status of the learning brain. These studies show a strong relationship between the age of exposure to a language and the ultimate proficiency achieved in that language (Johnson and Newport, 1989; Krashen *et al*., 1982; Long, 1990; Newport, 1990), though typically with many fewer extreme deficits in adult learning than those found in the case studies of isolated children. Learning during the first months or year of exposure may show an advantage for adult learners, particularly in the acquisition of vocabulary and the speed of using certain complex sentence forms; however, long-term outcome clearly favors those who start learning the language during childhood. Peak proficiency in the language, in control over the sound system as well as the grammatical structure, is displayed by those whose exposure to that language begins in infancy or very early childhood. Such early learners show not only flawless control over the accent and rhythm of the language but also full and productive control over the syntax and morphology. With increasing ages of exposure there is a decline in average proficiency, beginning as early as ages 4 to 6 and continuing until proficiency plateaus for adult learners (Johnson and Newport, 1989; Newport, 1990). Learners exposed to the language in adulthood show, on average, a lowered level of performance in many aspects of the language, though individual variation also increases with age (Johnson and Newport, 1989), and some individuals may approach the proficiency of early learners (Birdsong, 1992).

These effects have been shown for both first and second languages, and for measures of proficiency including degree of accent, production and comprehension of morphology and syntax, grammaticality judgments for morphology and syntax, and syntactic processing speed and accuracy. For example, Johnson and Newport (1989) have shown that Chinese or Korean immigrants who move to the United States and become exposed to English as a second language show strong effects of their age of exposure to the language on their ability to judge its grammatical structure many years later, even when the number of years of exposure is matched. These effects are not due merely to interference of the first language on the learner's ability to acquire the second language: deaf adults, acquiring American Sign Language as their primary language, show effects of age of exposure on their grammatical skills in ASL as much as 50 years later, even though they may not control any other language with great proficiency (Newport, 1990; Mayberry and Eichen, 1991).

While there are effects of age of acquisition on both first and second languages and on both spoken and signed languages, an important question is how these effects compare. Does the acquisition of a language early in life reduce the effects of age on later language learning? This question has been examined by comparing hearing and deaf individuals' acquisition of English or American Sign Language as either a first or a second language, and (if as a second language) after early exposure to either a spoken or a signed language (Mayberry *et al*., 2002). The results show that age of first language onset has a significant effect, while language modality does not: late first language acquisition results in lower performance than does late second language acquisition, regardless of whether the languages in question were spoken or signed. According to one recent finding, even overhearing a language during early childhood, without producing it or hearing it again for many years, can result in learning to pronounce that language with a more native accent as an adult (Au *et al*., 2002).

However, age of exposure does not affect all aspects of language learning equally. The acquisition of vocabulary and semantic processing occur relatively normally in late learners. Critical period effects thus appear to focus on the formal properties of language (phonology, morphology, and syntax) and not the processing of meaning. Even within the formal properties of language, though, various aspects of the language may be more and less dependent on age of language exposure. For example, late learners acquire the basic word order of a language relatively well, but more complex aspects of grammar show strong effects of late

acquisition (Johnson and Newport, 1989; Newport, 1990). Further research is needed to characterize the structures that do and do not show strong effects of age of learning.

Age of exposure also affects the way language is represented in the brain, with similarities between the behavioral and neural effects. PET (Positron Emission Tomography), fMRI (functional magnetic resonance imaging), and ERP (event-related potential) studies all show strong left hemisphere activation for processing the native language, in bilinguals as well as monolinguals. However, when second languages are learned after age seven, the regions and patterns of activation are partially or completely nonoverlapping with those for the native language. Neural organization for late-learned languages is less lateralized and, like proficiency itself, displays a high degree of variability from individual to individual (Perani *et al*., 1996; Weber-Fox and Neville, 1996; Kim *et al*., 1997). The few studies that have observed early bilinguals or highly proficient late bilinguals report congruent results for native and second languages (Perani *et al*., 1998), though more refined techniques in the future might be expected to show neural differences whenever there are behavioral differences.

As with linguistic behavior, there is considerable specificity in these neural effects. In particular, age of acquisition appears to have more pronounced effects on grammatical processing and its representation in the brain than on semantic processing (Weber-Fox and Neville, 1996). When native speakers of English, respond to the appropriateness of open-class content words, ERP components distributed over the posterior regions of both hemispheres; and these same patterns appear in Chinese–English bilinguals who have acquired English as late as age 16. In contrast, when judging English syntactic constructions or responding to the placement of closed class function words in sentences, only early learners show the characteristic anterior left hemisphere ERP components; learners with delays of even 4 years show significantly more bilateral activation (Weber-Fox and Neville, 1996). Similar effects appear for signed languages (Neville *et al*., 1997).

Taken together, these results provide fairly strong evidence for a critical or sensitive period in acquiring the phonological and grammatical patterns of the language and in organizing the neural mechanisms for handling these structures in a proficient way. Nonetheless, the question of whether there is a critical period for language acquisition continues to be controversial.

QUESTIONS CONCERNING A CRITICAL OR SENSITIVE PERIOD FOR LANGUAGE ACQUISITION

Several questions have been raised about whether these age effects represent the outcome of a critical or sensitive period, or whether they might arise from variables correlated with age but not with maturation. One set of questions concerns whether the behavioral function has the correct shape for a critical or sensitive period. Must a critical period involve an abrupt decline and a total loss of plasticity at the end? Some investigators have argued that, in order to support a critical period hypothesis, age effects must coincide with the onset of puberty (though neural maturation continues throughout the teenage years and does not cease at ages 12 to 13). Other investigators have suggested that, if there were a critical or sensitive period for acquisition, no adult learners should achieve native proficiency. Finally, investigators have noted that it is difficult to distinguish a critical or sensitive period for learning from an interference effect.

However, many of the strong or absolute characteristics expected or demanded by these investigators are not true of critical or sensitive periods in other domains. Critical or sensitive periods in most behavioral domains involve gradual declines in learning, with some (reduced but not absent) ability to learn, and greater individual variation, in mature organisms. Critical periods in other domains also exhibit more learning during the waning portion of the critical period if the organism is presented with extremely salient or strongly preferred stimuli, or with learning problems similar to those experienced early in life. It should therefore not be surprising that a critical period for language in humans would show some continuing ability to learn, with individual variation, during adulthood. If such complex phenomena are routinely found within critical periods in other domains, they should also be expected for language learning.

Latent Semantic Analysis

Advanced article

Thomas K Landauer, University of Colorado, Boulder, Colorado, USA

CONTENTS

Latent semantic analysis (LSA) approximates human understanding of relations between word and passage meanings in a wide variety of ways.

DERIVING SEMANTIC RELATIONS FROM LARGE TEXT CORPORA

Literate adults know the meaning of many tens of thousands of words. It is clear that much of this knowledge comes from reading, if only because a large fraction of the words that adults read are rarely if ever used in oral communication. However, before the mid-1990s, no artificial method could simulate the human ability to extract word meaning directly from text. The first successful model, latent semantic analysis (LSA), was made possible by large electronic text corpora, advanced computational power, and newly sophisticated algorithms (Landauer and Dumais, 1997). (LSA is also known as latent semantic indexing (LSI) in information retrieval applications.) LSA is not a complete model of language: it ignores word order within passages, and cannot produce sentences. Nevertheless, it approximates human understanding of relations between word and passage meanings remarkably well and in a wide variety of ways.

Computational Basis of LSA

The meaning of a passage must be a function of the meanings of its words and context. If m is meaning:

$$m(\text{passage}_i) = f(m(\text{word}_{i_1}), m(\text{word}_{i_2}), \ldots m(\text{word}_{i_n}), m(\text{context}_i)) \quad (1)$$

LSA divides a corpus into passages and treats them as a system of simultaneous equations, which it solves for the meanings of the words. To make this feasible, LSA ignores context and assumes that passage meaning is a linear sum of word meanings:

$$m(\text{passage}_i) \approx m(\text{word}_{i_1}) + m(\text{word}_{i_2}) + \ldots + \text{m}(\text{word}_{i_n}) \quad (2)$$

It is interesting to note that 'composionality', a property of language often posited and debated in linguistics and computational linguistics, is expressed in a very strong and simple form in eqn 2. The representation of a passage is composed by the sum of representations of its components.

Computing LSA by Singular Value Decomposition

LSA is given a corpus of text as close as possible in size and kind to language sources from which simulated humans commonly learn large parts of their vocabulary. The resulting huge and 'ill-conditioned' system of equations is solved by singular value decomposition (SVD), a form of factor analysis. After SVD, each word or passage is represented by a vector in a 'semantic space' defined by hundreds of abstract dimensions. Any old or new passage is represented as the vector sum of its words, as in eqn 2 and Figure 1. Similarity of meaning between two words or passages is usually estimated by the cosine of the angle between their vectors. The representation of a word specifies its average effect on passages, in a way reminiscent of Wittgenstein's (1953) conjecture that linguistic meaning lies in the relations of all words to all others. LSA can also be formulated as a neural net model, but training is more difficult. A related model is HAL (Lund and Burgess, 1996). LSA is fundamentally different from semantic network models based on human judgments (e.g. Lenat and Guha, 1991) rather than machine learning.

DATA COMPRESSION

One effect of LSA is representational economy. LSA dimensions are orthogonal, so there is no

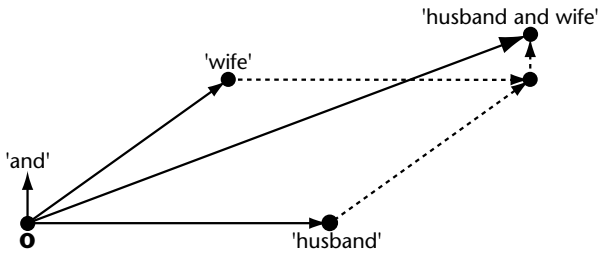

Figure 1. In LSA, passages are composed by the vector addition of words.

redundancy. Ignoring word order gains about another 20 percent. But the most important economy comes from dropping most of the dimensions: usually fewer than 500 are kept, rather than the tens of thousands that might be required to solve the original equations exactly. A typical paragraph requires only about a quarter of the bits of the original text.

The Value of Dimension Reduction

However, LSA is not used primarily for data compression, but for its powerful capacities for language representation. Through dimension reduction, similarities of the (roughly 98 percent of) word–word pairs that never co-occur in the same passage in a typical corpus are estimated. In one experiment, removing all such co-occurrences of tested words produced only modest decrements on a standard vocabulary test taken by LSA. The common belief that associative mechanisms cannot account for human learning of word meaning (e.g. Bloom, 2000; Chomsky, 1987) assumes a mechanism that depends entirely on local sequential or contextual co-occurrence. LSA extracts qualitatively different and quantitatively much greater amounts of associative knowledge.

The Quality of LSA Meaning Representation

Several of LSA's interesting properties are illustrated below. Table 1 shows cosine similarities ('cos') between representative pairs of words based on LSA learning from a 12.6 million word representative corpus of general English. Random word pairs have cos values in the range 0.02 to 0.03 with standard deviation in the range 0.06 to 0.12.

In LSA, different senses are not separately represented, and word forms are usually significantly related to the texts of all their dictionary definitions. Thus 'swallow' has a cos value of 0.57 with 'the process of taking food into the body through the mouth by eating', and a cos value of 0.30 with 'small long winged songbird noted for swift graceful flight and the regularity of its migrations'.

Table 1. Cosine similarities between pairs of words based on LSA learning from a 12.6 million word representative corpus of general English

Word pair		*cos*
love	life	0.35
man	woman	0.37
should	ought	0.51
chemistry	physics	0.65
sugar	sucrose	0.69
sugar	sweet	0.42
mouse	mice	0.79
come	came	0.71
doctor	physician	0.61
doctor	doctors	0.79
man	men	0.41
go	went	0.71
office	self	0.03

Because words combine their effects with their linguistic contexts, significant ambiguity does not necessarily arise from the fact that a single representation carries a complex of meanings. For example, adding the word 'swallow' itself to the two definitions above does not appreciably alter the LSA-meaning of either. (For the two definitions above, the cosine values are 0.99 and 1.00 between the definition and the definition prefixed with 'swallow'.)

Even short phrases containing a word with one of two apparently unrelated common meanings may show no appreciable distortion by the alternative meaning, as shown in Table 2.

In the first three pairs of phrases in Table 2, 'lead' has almost exactly the same effect as 'direct' when combining with 'army'; in the second three pairs of phrases it has very nearly the same effect as 'heavy' when combining with 'weight'. The last pair shows that the two contextual meanings involved are far from the same. Thus, the multiple meaning components of 'lead', which are not first 'disambiguated' by sense, do not interfere with its appropriate influence on meaning in the different contexts.

Another interesting property is that phrases sharing no words can sometimes have high similarities, while ones with many words in common can be dissimilar. Thus, 'the radius of spheres' has a cos value of 0.55 with 'a circle's diameter', but a cos value of 0.01 with 'the music of spheres'.

Table 2. Cosine similarities between pairs of phrases. The word 'lead' has two apparently unrelated common meanings

Phrase pair		*cos*
lead the army	direct the army	0.87
lead the army	desert the army	0.91
direct the army	desert the army	0.89
a lead weight	a heavy weight	0.92
a lead weight	a light weight	0.57
a heavy weight	a light weight	0.61
a heavy weight	direct the army	0.14

Correspondence with intuition is usually good for words and paragraphs, but is often poor for phrases and sentences, especially where local syntactic effects are large. The examples above serve to illustrate phenomena that can occur in LSA representations, but those phenomena do not always occur.

Quantitative evidence of how well LSA represents human meaning comes from simulations of human performance. For example, after training on general English, LSA matched the scores of successful college applicants from foreign countries on multiple-choice questions from the Test of English as a Foreign Language. After learning from an introductory psychology textbook it passed the same multiple-choice final exams as university students. Differences in knowledge between before and after reading a technical article, and between undergraduates and graduate students, were reflected more sensitively by measures based on LSA than by grades assigned by professional readers.

Of course, LSA must be applied judiciously. Modeled human performance must match its capabilities; and words and knowledge in the training corpus must match the human task. For example, LSA does not represent idioms correctly if they are not treated as single 'lexemes' in the input, and it will not represent text in one domain correctly if trained only on another domain. Misuse aside, it is clear that LSA has limited ability to simulate language comprehension: it is best suited to simulating semantic relations among single words and among paragraphs or longer texts, where syntactic and local context effects are minimized.

LSA AS A RESEARCH AND APPLICATION TOOL

LSA's approximation to human semantics is sufficiently good for many scientific and language engineering purposes.

Research Uses

Some researchers use LSA instead of human judgments of semantic similarity, free associations, or experimenter intuition in cognitive models and for equating verbal materials for experiments; others to measure recall accuracy or differences in semantic content of written responses. These uses have included, for example, models of sentential predication and metaphor (Kintsch, 2001).

Practical Applications

LSA is used in artificial intelligence systems to replace or augment 'handmade' lexicons, ontologies, and semantic rules with automatic evaluation of conceptual similarity between texts. For example, systems using LSA score essay content as accurately as professional readers, link people with jobs and training, support assessment and interactive dialogue in intelligent tutors (Hearst, 2000; Graesser *et al*., 2000), and form the basis of comprehension measures. LSA is used in content analysis and information retrieval. In the latter, it finds documents with similar meanings to a query despite containing different words, and is especially useful for routing and topic spotting tasks. LSA applications are language-independent, and with special forms of training can match documents in one language with those in another. Successful matching of paragraphs in Chinese characters with English translations, for example, gives additional evidence that LSA's additive model yields a good approximation of passage meaning.

LSA AS A THEORY OF COGNITION

LSA offers a computational model for investigating certain long-standing puzzles of cognition. One of these, called Plato's problem or the poverty of the stimulus, is that people have greater knowledge, in particular about language, than appears to be learnable from experience. Another is acquired similarity: what makes stimuli psychologically equivalent? These phenomena are often attributed to instinctive knowledge, rules, or primitive features. As exemplified in word meaning, which cannot be innate, LSA strongly suggests that an alternative explanation can be found in the form of a sufficiently powerful learning mechanism.

In LSA, similarity arises from experience, not from biologically defined relations among predetermined features. Inductive mechanisms like LSA's could apply in all kinds of recognition and

generalization: elementary variables could be neural events at any level and related in highly complex, perhaps holistic, ways. The psychological properties of LSA exhibit their power best in full-scale simulation of human learning from human-like quantities of experience. LSA's inferential mechanism evades Goodman's (1972) accusation that 'similarity is an imposter' by showing how it arises rather than using it as a primitive in explanations of other phenomena.

LSA has many human-like cognitive properties. It can learn nearly the same meaning or represent nearly the same idea (a point in semantic space, which may or may not correspond closely to any verbal statement) in an unlimited number of different ways. Meanings are slightly different for each person and in each context, yet are sufficiently stable and sharable to support communication and mutual comprehension. LSA's knowledge is implicit, resembling intuition rather than declarative propositions.

Philosophers and psychologists may be concerned that LSA has no contact with perception or action, the so-called 'grounding' that has often been thought to be essential to learning word meanings (Bloom, 2000). Given LSA's ability to mimic a variety of human linguistic performances, it can no longer be sensibly argued that nothing about language can be learned without such sources. Nonetheless, LSA certainly must miss something by its complete reliance on vicarious experience. An interesting question is whether the same basic mechanisms applied to experience with words in natural perceptual contexts would close the gap, or whether additional factors unique to human cognition make important contributions. Also, LSA does not model important aspects of meaning that depend on order, matters of syntax which have long been a primary focus of linguistics.

Overcoming these limitations is a major scientific challenge. However, even with these limitations, LSA's success, by showing that much human use of language can be mimicked without sources and processes that had been believed to be necessary, raises deep theoretical questions about the nature of language.

Learning and Memory, Models of

Introductory article

David M Eagleman, Salk Institute, La Jolla, California, USA
P Read Montague, Baylor College of Medicine, Houston, Texas, USA

CONTENTS

Learning is the process of acquiring knowledge, and memory is the retention of knowledge. Both have their roots in the biochemistry and anatomy of the brain, and are commonly studied by investigating the connection between brain cells, the synapse.

INTRODUCTION

Animals interact appropriately with the world through their ability to learn and remember the specifics of their environment. Learning and memory are possible only because of the changeable properties of the vast networks of cells in the brain. In this way, neural activity can dynamically modify the brain's organization. Learning and memory can be studied at many levels – biochemical, cellular and systems – and even by investigation of perturbations that decrease learning and memory, from genetic (Down syndrome) to pathological (Alzheimer disease).

What do we mean by learning and memory, and how do we detect when it happens? The answer seems complicated by the fact that memory is not a monolithic entity, but comprises many different types. Memory can be divided into declarative learning (names, facts) and nondeclarative learning (riding a bicycle), and within these categories are scores of subtypes. What neural processes could underlie such a variety of different types of memory?

Specialized Brain Areas

Examples of brain damage demonstrate that different areas of the brain are involved in different subtypes of learning and memory. For example, injury to the medial temporal lobe of the cerebral cortex affects declarative memory but not nondeclarative memory. The cerebellum, on the other hand, seems to be important in learning certain motor skills, especially those involving balance and coordination. The basal ganglia are evidently important in learning that links rewards with motor activity. The list of brain structures and their involvement with learning and memory is large and ever-increasing, and it is interesting to note that the integrity of a particular subsystem is not always essential to the functioning of others. That is, one can lose the ability to learn dates and facts (as in amnesia), but this has no bearing on the ability to learn and remember new motor skills. Much of what we will discuss here will be distilled from data concerning two main areas: the cortex and hippocampus.

The hippocampus (and its surrounding regions) seems to be a central organ of learning, and its structure makes its physiology very amenable to laboratory study; it is perhaps the best-studied area of the brain. In 1953, a 27-year-old patient referred to as HM had his hippocampus and surrounding areas surgically removed to relieve intractable epilepsy. Thereafter, HM lost his ability to form new memories or learn new facts, and although he could acquire new skills, he had no memory of having acquired them.

General Cellular Principles?

While learning and memory can be different in specialized structures, it is possible (although by no means proved) that general learning mechanisms underlie all these different types of learning. It is notable that the different brain areas have many properties in common: short-term and long-term memory, one-trial and multiple-trial learning, similar cellular mechanisms and biochemical pathways, and activation of particular memory genes. This suggests the possibility of general

learning principles at the cellular and subcellular levels.

Almost all current theories of learning and memory involve some variant of the idea that efficacy of the connections between cells can be modified based on their previous activity. Such theories urge us to seek biophysical – as well as computational – descriptions of what happens at the synapse. Although the synapse has received the most experimental attention, we should begin with the caveat that the full picture of learning and memory is largely unknown (the final section of this article reviews other forms of change in the brain that could have a role in learning and memory).

The Synapse

Over a century ago, the idea that neural tissue is a continuous network, or reticulum, was challenged by the proposal that the nervous system is an intricate network of discrete cells. The great Spanish neuroscientist, Ramón y Cajal, proposed this 'neuron doctrine', which ushered in an important new idea: separate cells influence each other primarily through specialized connections called synapses. Rámon y Cajal is credited as the first to suggest that learning and memory might occur by changes in the connections between neurons.

FORMS OF SYNAPTIC PLASTICITY

What is plasticity? A plastic system is one that is changeable, and able to retain change (hence, when a manufacturer moulds a cup out of a lump of plastic, it is useful only because it retains its new shape). A nonplastic system would be unable to store memories of anything, being unchanged by its experiences.

The brain comprises both plastic and nonplastic components. The brain's control of respiration and heartbeat is not thought to be plastic, just as a bird's knowledge of how to build a nest is not something learned, but hard-wired. However, many parts of the brain are plastic, and this is what allows an animal to learn about and interact with its environment. Born in one country, you might learn to forage for food from particular broad-leafed shrubs; in another, you might learn to satisfy your cravings from a refrigerator. This learning of the proper location for the food could only be accomplished because parts of your brain were plastic. In general, plasticity is much greater in the developing animal, and decreases with age.

Associative Learning

Many classic experiments in psychology demonstrate the role of association. Every student knows about Pavlov's dogs, who salivated when they heard the bell that signaled the presentation of meat powder. The behavioral psychologist B. F. Skinner found that particular stimuli caused an organism to repeat an act more frequently. He called stimuli with this effect 'reinforcers'. Other psychologists found that by providing reinforcement in a systematic way one could shape an animal's behavior in desired directions.

What underlies these fundamental learning paradigms is the notion of 'association' – in these cases, the association of the bell and the meat, or the association between a stimulus and reward, or between a particular behavior and a punishment. An appealing idea in neuroscience has been that if an association is established between two stimuli, perhaps there is a neural substrate that should directly reflect this; but what cellular mechanisms could possibly underlie association?

In 1949, the neuroscientist Donald Hebb outlined the following hypothesis:

> When an axon of cell A is near enough to excite cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased.

In other words, if a presynaptic cell (A) consistently participates in driving a postsynaptic cell (B), the connection between them is strengthened (potentiated) (Figure 1). Hebb's hypothesis goes on to prescribe that if A consistently fails to drive B, the connection is weakened (depressed). Systems that display this behaviour are said to follow a Hebbian, or correlational, learning rule. This rule can be written as

$$\Delta w(t) = \lambda x(t) y(t) \qquad (1)$$

where, at time t, $w(t)$ represents the efficacy (weight) between two neurons, and $x(t)$ and $y(t)$ are measures of pre- and postsynaptic activity (a common measure is the rate of action potential generation, or 'firing rate'); λ is the learning rate, as it specifies how quickly the weights will react to changes in $x(t)$ and $y(t)$. The rule states that if the presynaptic and postsynaptic cells are both firing more than normal (i.e. are co-active; assume $x(t)$ and $y(t)$ represent firing rates above baseline, and hence are both positive numbers in this example), then the weight change will be positive (potentiation). If the activity $x(t)$ is high and $y(t)$ is low,

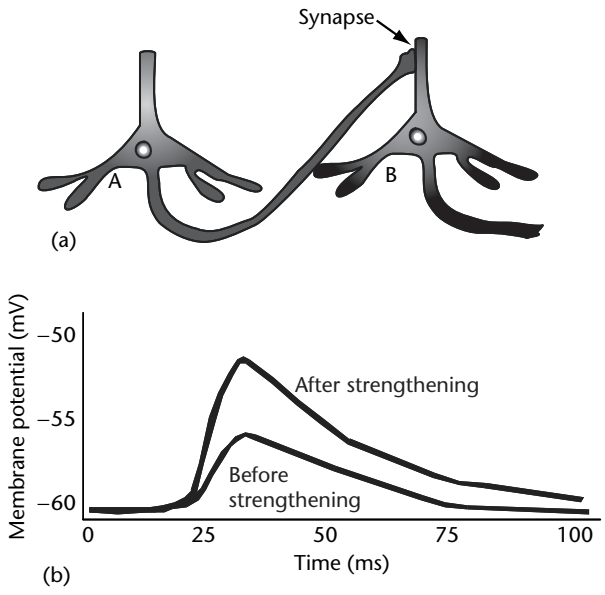

Figure 1. Learning and memory at a synapse. (a) According to Hebb's postulate, if neuron A consistently causes neuron B to fire, then the connection between them will strengthen. (b) When neuron A releases neurotransmitter on B, an excitatory postsynaptic potential (EPSP) can be measured in B. If long-term potentiation is induced by tetanic stimulation of A, the EPSP measured in B is now larger, so the connection has been strengthened.

then the connection between them will weaken. To date, most models of neural function employ such a rule.

At the time Hebb proposed his hypothesis, there was no direct experimental demonstration that could be marshaled for support. Then, in a famous experiment in 1973, researchers stimulated a bundle of nerve fibers in a rabbit's hippocampus. Trains of electrical stimulation were administered at 15 Hz for 10–15 s, and it was shown that one or two such exposures were enough to 'condition' (potentiate) an increased electrical response from the postsynaptic cell for up to 10 h. In other words, this was a direct demonstration that connections could be modified based on the history of the activity of the cells involved.

Although this experiment galvanized thousands of researchers in the ensuing decades, it is still unclear whether the results of this experiment completely and accurately represent the neural changes that take place during learning and memory. Our current understanding suggests that some of the stimuli employed in such experiments are unlikely to be seen in the real animal *in vivo*. However, other stimuli do appear to be biologically feasible; for example, it was later discovered that an optimal stimulus to induce this sort of modification is at a frequency of 5 Hz – which is the frequency of electrical rhythms seen in the hippocampus when animals explore a novel environment.

In general, the biological relevance of the correlational learning rule has been supported by decades of research into the detailed biophysical properties of synapses. It is clear from developmental neuroscience that appropriate neural activity is required for establishing the proper connections between brain areas. This developmental self-organization is consistent with the hypothesis that changes in synaptic efficacy are controlled by processes resembling Hebbian rules. However, such activity-dependent properties of cells are not limited to the developing animal: many experiments have now revealed the reorganizational plasticity of the adult brain. It is widely hypothesized that the cellular rules that account for large-scale self-organization and reorganization (in both the developing and adult brain) may be the same rules that account for learning and memory.

Different Timescales of Synaptic Plasticity

Animals display learning and memory over many different timescales; it may be significant that changes in synaptic efficacy, or strength, similarly occur over different timescales.

Short-term changes

Sometimes the modification of synaptic efficacy is short-term, lasting on the scale of seconds to minutes. The two most commonly studied examples of this are short-term potentiation and short-term depression (also known as fast synaptic depression). The former can be induced by increased levels of intracellular calcium in an axon terminal due to recent activity. This leads to a higher probability of neurotransmitter release with successive activity, and thus the connection between the cells is considered potentiated. Short-term depression can come about by a depletion of the readily releasable pool of neurotransmitter vesicles, which take time to be repackaged and docked. When high activity levels cause increased vesicle release, the terminal becomes temporarily less able to respond to future activity, and is thus considered depressed.

Such fast modifications in synaptic activity can cause rapid dynamic changes in the behavior of networks, modifying their function as a result of recent activity.

Long-term changes

Long-term potentiation

In the 1973 synaptic modification experiment mentioned above, the changes lasted for many hours, and thus the phenomenon was labelled 'long-term potentiation' (LTP). We now know that the phenomenon of LTP is common to many brain areas. It is studied most extensively in the neocortex and hippocampus, the latter because of its crucial role in memory formation.

In most cases, LTP is induced only when the activity in the postsynaptic cell (depolarization) is associated with activity in the presynaptic cell. Depolarization alone or presynaptic activity alone is ineffective. Additionally, LTP is synapse specific, which means that each individual synapse on a cell could, in principle, strengthen or weaken according to its own personal history (although this view is questioned by some).

What goes up must come down: long-term depression

If a connection is able to potentiate, it also needs the ability to depress, otherwise the system will become saturated, and be unable to store anything new. Long-term depression (LTD) is obtained by using low-frequency repetitive stimulation (e.g. 1 Hz instead of 15 Hz). After this conditioning, the connection between two cells is weakened. There are other ways to achieve LTD, as will be seen in the section on timing, below. Long-term potentiation and depression are part of the same phenomenon; LTD is found at the same synapses as LTP and also depends on the same mechanisms.

In general, it is suggested that LTP and LTD could mediate one-trial associative learning, since pairing of two events (presynaptic and postsynaptic activity) creates a long-term change in synapses. The biophysical mechanisms underlying long-term changes are still a subject of intense investigation, but the differences between LTP and LTD are mainly thought to involve differences in the concentration (and temporal dynamics) of postsynaptic calcium ions. Although it may turn out to be inadequate, a current hypothesis is that lower calcium concentrations lead to depression, whereas higher concentrations lead to potentiation.

The NMDA Receptor

For the induction of memory, one of the most important biophysical mechanisms is a subtype of glutamate receptor called the NMDA receptor (NMDA-R), so named because it is selectively stimulated by *N*-methyl-D-aspartate. How does this receptor work, and why does it enjoy such prominence in the research literature?

In most systems, the NMDA-R is crucial for induction of LTP. An animal can be taught a behavioral task, but with the infusion of NMDA-R antagonists, the ability to remember the specifics of the task disappears.

At resting potentials, the NMDA-R is blocked by magnesium. Depolarization of the postsynaptic cell expels the magnesium ions and opens up the channel. Many postsynaptic membranes contain NMDA as well as non-NMDA glutamate receptors. During normal low-frequency stimulation, only the non-NMDA channels will open, owing to Mg^{2+} blockage of the NMDA ion channels. In contrast, high-frequency presynaptic input resulting in depolarization of the postsynaptic membrane displaces the magnesium ions, making the NMDA receptors sensitive to subsequent release of glutamate. In this way, the NMDA-R can act as a coincidence detector, sensing coincidence of presynaptic and postsynaptic activity. Thus, NMDA synapses are the quintessential biological Hebbian synapses, and thus may be crucial to the storage of associations.

The fact that NMDA receptors have a particularly high permeability for calcium allows them to stimulate a second-messenger system that results in long-term structural changes to the postsynaptic cell. Interestingly, one cannot bypass the NMDA channel by depolarizing the cell to allow calcium influx. It is not simply the amount of calcium influx that matters, but also the exact spatial location: the influx must occur in close proximity to the NMDA receptors at the synapse. This highlights the specificity of computations that are performed on spatial scales smaller than we can resolve.

Traditionally, it has been thought that strong presynaptic input is sufficient for local depolarization of the membrane in which the NMDA-R sits, but we now know that when a cell generates an action potential, this potential can (under the right circumstances) propagate back into the dendritic tree. Thus, a back-propagating action potential could act as a global dendritic signal, depolarizing thousands of synapses (and their NMDA-Rs) at once.

Certain forms of LTP induction are known to depend on postsynaptic burst firing. Hippocampal burst firing is presumed to be associated with memory induction *in vivo* (it occurs during active exploration of novel environments).

Note that the NMDA-R is only necessary for the induction of most forms of LTP and LTD; other

mechanisms underlie the maintenance of the changes – most generally, new protein synthesis is required at the nucleus of the cell. An animal can be trained to associate two stimuli (say, pairing an electric shock with a bright light) in the short term, but if protein synthesis is blocked, no long-term memory develops.

How Do Synaptic Efficacy Changes Take Place?

The common observation with plasticity studies is that after conditioning, the presynaptic cell gives a stronger or weakened electrical input to the postsynaptic cell. Mechanistically, how does the strength of an individual synapse change?

A synapse, like most elements of a cell, has many modifiable parameters. Since we know the induction of most forms of conditioning to be dependent upon the NMDA-R, and since the NMDA-R is postsynaptic, this hints at postsynaptic changes. It is known that calcium ions flow in and trigger a postsynaptic biochemical cascade involving protein kinases, and that blocking specific kinases stops LTP: some kinases that have been implicated are calcium–calmodulin kinase II (CaMK-II) and protein kinase C (PKC). These cascades eventually lead to the genome, and to the synthesis of new proteins which solidify the changes – for example, by the expression of more postsynaptic neurotransmitter receptors. Recently, it has been shown that certain receptors appear to increase in concentration after LTP. Other structural changes (such as the formation of new dendritic spines) also appear to occur minutes after LTP induction.

Presynaptic changes and retrograde messengers

Changes at the presynaptic terminal could also lead to greater synaptic efficacy; for example, an increase in probability of transmitter release. There is a raging debate as to whether the changes take place pre- or postsynaptically, and as in most great debates in biology, the answer will probably turn out to be both.

Whatever the case, any presynaptic changes will of necessity require a signal passing back from the postsynaptic to the presynaptic side. Such a signal has been labeled a retrograde messenger. There are several good candidates for biologically realistic second messengers. For example, the influx of calcium (and the subsequent activation of CaMK-II) induces synthesis of nitric oxide (NO), the molecules of which are so small that they effortlessly diffuse through cell membranes to presynaptic terminals (thus acting as a retrograde messenger) to induce the presynaptic neuron to enhance transmitter release.

Very long-term storage (compression)

It is speculated that associations formed in a subset of hippocampal neurons (area CA3) are built into more economical form in another part of the hippocampus (CA1 neurons). The hippocampus itself may function by building more economical storage (long-term memory) in the cerebral cortex. In this view, the hippocampus functions as a transient intermediary in the formation of long-term memories in the association areas of the cerebral cortex. From the point of view of psychology, such long-term storage may go hand-in-hand with the observation that we improve our learning and perform tasks faster as they become proceduralized (i.e. with practice, a skill becomes faster until it is virtually automatic).

IMPORTANCE OF TEMPORAL ORDER IN SYNAPTIC PLASTICITY

Timing: More than Coincidence?

For a long time Hebb's rule was summarized as 'neurons that fire together, wire together'. In other words, if two cells fire within some small window of coincidence, the connection between them is strengthened. However, this rule turns out to be insufficient. Hebbian rules are good for forming associations, but one theoretical shortcoming is that such rules are insensitive to the order of events. Experiments have long shown that animals are strictly sensitive to the order of sensory inputs – such that, for example, Pavlov's dog will not learn an association if the meat is presented before the bell. Similarly, many animals develop strong aversion to a tasty food following a single experience of nausea after eating it, but reversing the order (nausea and then the food) does not lead to an aversion.

It is now becoming appreciated how the relative timing of presynaptic and postsynaptic activity may be crucial at the cellular level. An interesting rule has emerged about the timing of synaptic change, at least in some systems. If an input from cell A contributes to driving cell B, then the synapse is strengthened. If an input from A comes after cell B has fired, the synapse is weakened. The importance of this timing can be seen in Figure 2. This learning rule is commonly called a 'temporally asymmetric Hebbian rule', and has expanded our view of the importance of exact spike timing.

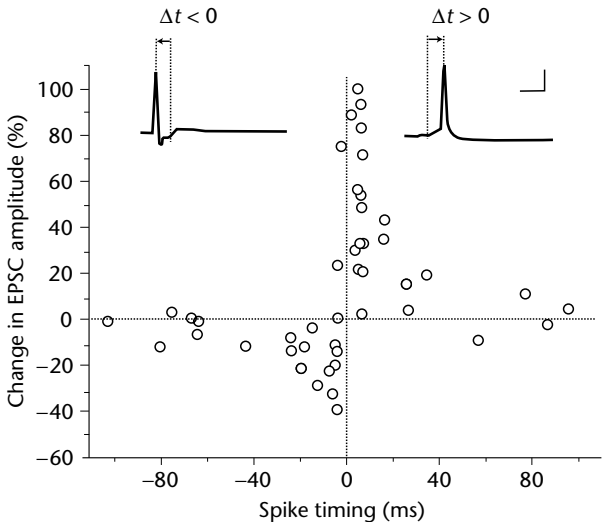

Figure 2. Timing for synaptic potentiation and depression. In this plot, reproduced from Bi and Poo (1998, *Journal of Neuroscience*), $\Delta t > 0$ means that the postsynaptic spike occurred after the presynaptic spike. In such cases the presynaptic spike has a role in the activation of the postsynaptic spike and the connection between the two neurons strengthens, as measured by the percentage change in the excitatory postsynaptic current (EPSC). If the postsynaptic spike arrives before the presynaptic spikes ($\Delta t < 0$), the connection between the two neurons weakens.

Most generally, the temporally asymmetric rule strengthens connections that are predictive; if A consistently fires before B, it can be viewed as a successful prediction, and will be strengthened. (As a caveat, it should be noted that the data in Figure 2 were obtained under specialized and perhaps biologically unrealistic circumstances. It is not yet known what would happen at a synapse with a more realistic barrage *in vivo* of pre- and postsynaptic spikes.)

THE ROLE OF CONTEXT IN LEARNING AND MEMORY

No discussion of learning and memory can take place in the absence of considerations of context – both the context into which new information can be stored, and the situational context of the animal.

Informational Context

Much of what we learn is in terms of what we already know. When you read this article, the points made here would be meaningless unless you were already equipped with an idea of how to operate a book, how to read this language, and what a brain is. Two people might look at a list of important dates in Mongolian history; if one of them already commands a richly developed cognitive model of Mongolia, the new facts are much more readily incorporated into that person's network of knowledge. At the simplest levels, this reflects associational mechanisms, as discussed above. By associating one new concept with others already known, it can be more readily stored and retrieved. Associative neural networks display this sort of property: items can prime webs of association, in the same way that the smell of coffee can immediately conjure associations with the sight of the black liquid, the sensation of warmth on the hands, the bitter taste, and so on.

Situational Context

Neural wiring can dictate which experiences result in learning and which do not. Many birds learn to form a strong emotional bonding at birth to any nearby distinctive and animate object – a process known as imprinting (this is a good example of one-trial learning). Many neural network models fail at such learning, requiring many thousands of trials for the learning of even simple tasks. More recent neural network models have therefore begun to include context as an important variable. The notion that particular types of learning are triggered to occur at certain times – 'schematic' learning – is an expression of an important philosophy that has emerged in neuroscience: the brain is not a *tabula rasa*, a blank slate upon which the world imprints itself. Instead, the brain comes preequipped for certain types of learning, and learning in particular situations. Experience is more likely to result in learning when it has relevance to the life of the organism – especially when it is connected to pleasure or pain, fear or satisfaction.

One way that context is likely to be expressed, biophysically, is through neuromodulatory systems, which are generally global neural systems that signal reward, punishment, alertness, and so on. Neuromodulatory systems have a crucial role not only in developmental plasticity, but also in the synaptic plasticity of learning and memory in the adult. Among other functions, neuromodulators can turn synaptic plasticity on and off, and influence the presynaptic/postsynaptic communication pathways. In this way the plasticity of synapses can be gated, so that learning takes place only at the appropriate time instead of each time activity passes through the cell – which could, in theory, overwrite previous learning. It has been demonstrated in the adult animal that reorganization of

parts of the cortex can occur only when paired with the release of particular neuromodulators.

Lastly, there has been a recent surge of physiological experiments in awake, behaving animals to study the role of attention. It was known by the ancient Greeks that learning and memory are most reliable when a student is paying attention. Recent experiments have shown that the firing rates of individual cells can be highly modulated by the attentional state of the animal. Since the number and timing of spikes seem to be important, it is easy to see how changes in firing rate could modify the dynamic changes in synaptic modification in the networks of cells.

OTHER FORMS OF PLASTICITY

Although synaptic transmission has been favored as the major means of communication between nerve cells, it is almost certainly an incomplete description. Signals of synaptic or nonsynaptic origin can diffuse through large volumes of neural tissue to affect signal-readers, even at distant sites. This mode of communication, 'volume signaling', can function between neurons and also between neurons and glial cells. The consideration of signaling that extends beyond the synapse allows the three-dimensional arrangement of neural elements to play a part in information processing. Such a hypothesis would predict that if one could reproduce the synaptic connections of the brain on a two-dimensional circuit board, the resulting machine would be insufficient for the functional simulation of neural tissue. This is increasingly becoming appreciated as researchers attempt to form models with explicit representations of the three-dimensional composition of neural tissue.

Although this discussion has centered on changes at chemical synapses, certain types of synapses are electrical. Electrical synapses, or 'gap junctions', are increasingly being discovered in the mammalian brain, especially within networks of inhibitory cells. In essence, they are ion channels running through one cell membrane to the cell membrane of an adjoining cell. Gap junctions permit rapid and bidirectional flow of ions between cells, and it is possible that they could exhibit plasticity or other properties that give synapses a central role in learning and memory.

There are many other possible substrates in which to store activity-dependent changes. Researchers are now studying what they call 'intrinsic' (or nonsynaptic) changes in cells: changes in the excitability of the cell, changes in the distribution of ion channels, changes in the shape of dendritic trees, changes in the phosphorylation states of intracellular proteins, and so on. With so many degrees of freedom in biological systems, the possibilities are vast for discovering different storage strategies for learning and memory.

Additionally, in many cases memory can be stored (at least short-term) in reverberating circuits of activity. For example, a form of short-term memory referred to as 'working memory' is associated with the ability to store contemporary representations of the outside world. The apparent locus for working memory is in the prefrontal area of the cerebral cortex. Monkeys shown that food is hidden behind an obscuring object, but who are restrained from immediately taking the food, maintain their knowledge of the whereabouts of the food, and will find it after a delay, once restraints have been removed. Monkeys who have had areas of their prefrontal cortex surgically removed will forget about the food as soon as they can no longer see it ('out of sight, out of mind'). The mechanisms that underlie this working memory may be in circuits of reverberating activity, which keep the information temporarily stored without the need for synaptic change.

CONCLUSION

Many features of neural plasticity in learning and memory seem consistent with Hebbian rules. This convergence of experimental and theoretical approaches provides a powerful example of the modern approach to neurobiology. Future experiments will continue to elucidate the extent to which synaptic learning rules account for the properties of learning and memory, and will contribute to expanding neural models to encompass issues of timing and context.

Learning and Memory, the Ecology of

Introductory article

Bennett G Galef Jr, McMaster University, Hamilton, Ontario, Canada

CONTENTS

Specialized learning and memory mechanisms have sometimes evolved in response to the particular demands of the ecological niches occupied by different species.

INTRODUCTION

For most of the hundred or so years that scientists have studied how animals learn and remember, investigations of these topics have been carried out without attention to differences in the environments in which different species evolved. For example, one of the twentieth century's foremost investigators of animal learning, B. F. Skinner, when discussing the behavior of animals given food rewards, expressed unambiguously the prevailing view of how learning should be studied: 'Pigeon, rat, monkey, which is which? It doesn't matter.'

Skinner, of course, realized that different animals behave in different ways. However, for half a century and more behavioral scientists focused on the many features of animal learning in laboratory situations (for example, in mazes or in boxes where levers had to be pressed to obtain food) that were similar in all species. Such an approach to the study of animal learning, emphasizing similarities across species, is often referred to as a 'general process' approach, because it is based on the assumption that there are one or two basic learning mechanisms (or general processes) that are responsible for all learning by all animals.

A different view of animal learning and memory proposes that specialized learning and memory processes have evolved in response to differences in the selective pressures acting on different species; after all, differences in the physical characteristics and sensory systems of animals are known to be products of natural selection acting in different ecological situations. There is no reason why learning and memory mechanisms should not also have evolved to respond to the different environmental demands faced by members of different species. According to this view, animals would not only learn and remember in general, but also learn and remember particularly well things that are especially important to their survival and reproduction in the natural world.

TASTE-AVERSION LEARNING

In 1966, John Garcia discovered that learning not to eat substances that are associated with illness might be very different from learning in other situations. Garcia was looking at the effects of radiation on feeding behavior, an issue of potential importance both for patients receiving radiation therapy and to the military whose members might have to survive in radioactive areas in the event of war.

Garcia was studying the feeding behavior of rats exposed to X-irradiation while eating a type of food that they had never before eaten. He discovered, quite unexpectedly, that even though the illness resulting from X-irradiation did not start until some time after the rats had finished eating, the rats later refused to eat that type of food a second time. In most situations, in order for an animal to learn to associate two stimuli (in this case the taste of the unfamiliar food and the illness resulting from exposure to radiation), the stimuli have to occur within tenths of a second of one another. Many pairings of stimuli are often needed before learning is observed. Garcia had discovered a situation in which learning of an association between two stimuli occurred in a single trial, and despite the fact that the stimuli to be associated were separated by many minutes. Indeed, later experiments were to show that learning of an aversion to an unfamiliar taste followed by illness could occur in one trial even when taste and illness were separated by several hours.

In a now-classic second experiment, Garcia demonstrated that, although rats would learn to avoid the taste of a food associated with illness, they would not learn to avoid either visual or auditory properties of a food that had been associated with illness. In this second experiment, rats drank a sweetened solution from drinking tubes wired so that each time the rat's tongue contacted the sweet solution (and the rat experienced a sweet taste) a bell rang and a light flashed. Members of one group of rats received X-irradiation whenever they drank this 'sweet, bright, noisy' water; members of a second group received a mild electric shock to their feet whenever they drank it. A day later, half of each group of rats (one that had been X-irradiated and the other with shocked feet) were tested to determine whether they had learned to avoid drinking a sweet solution. The other halves of each group were tested to determine if they had learned to avoid drinking plain water when licking caused a bell to ring and a light to flash.

Garcia found that rats that had been exposed to X-irradiation after drinking 'sweet, bright, noisy' water avoided ingesting sweet water, but did not avoid 'bright, noisy' water. On the other hand, rats that had received foot shock after drinking 'sweet, bright, noisy' water drank sweet water, but avoided 'bright, noisy' water.

These results were a surprise, because in most other situations learning proceeds equally well regardless of what stimuli are paired with one another. Garcia's rats, on the contrary, associated only taste with illness and only audiovisual cues with shock. Even worse, from the general process point of view, it was soon discovered that birds such as quail more readily learned to avoid the visual properties than the tastes of foods associated with illness.

The general process view of animal learning was faced with a serious challenge because learning about the consequences of eating foods seemed to be different from other kinds of learning: it occurred faster, it occurred with longer delays between the stimuli to be associated, and different species seemed to learn to use different cues to avoid potentially dangerous foods. Pigeon, rat, monkey, which is which? It did seem to make a difference.

It was soon pointed out that there was some biological sense to animals being able both to learn to avoid a potentially dangerous new food after a single pairing of that food with illness and to tolerate long delays between eating a food and becoming ill. After all, eating spoiled food or poisonous substances can result in illness delayed by many hours, and repeated ingestion of toxic substances can have fatal consequences. So, if animals are to be able to learn to avoid ingesting poisons in nature, they would have to be able to learn rapidly to associate properties of substances they ate with consequences of ingesting those substances, even if the consequences of ingestion were long delayed.

It also seemed to make some biological sense for rats to depend on taste cues and birds to depend on visual cues to identify potential poisons. Birds select foods largely on the basis of the food's visual properties, whereas rats tend to eat at night, and use their senses of taste and smell to select things to eat. So, if animals preferentially learn to associate with illness only stimuli in the sensory modality that they use when choosing foods (taste for rats and sight for birds), one might expect the differences among species found in learning associations to illness.

The results of studies of taste-aversion learning clearly suggested that all animal learning might not reflect one or two basic processes. Rather, learning might be in some way modular, with evolution producing a variety of specialized learning and memory systems each of which facilitated learning about biologically important relationships in the natural environment. If so, there should be special processes for learning things other than poison avoidance.

LANDMARK LEARNING

Bee-hunting Wasps

Early students of animal behavior had already shown that some animals whose general ability to learn did not seem particularly impressive could learn surprisingly well those few things most important to the animals' survival and reproduction. Niko Tinbergen, who was later to win a Nobel prize for his work on animal behavior, conducted extensive studies of bee-hunting wasps of the genus *Philanthus*, which lived in Tinbergen's native Holland.

Philanthus is a solitary wasp that lives in small burrows excavated in sandy soil. After stinging and paralyzing a honeybee, a female *Philanthus* returns with her paralyzed prey to her burrow where she stores the bee along with her maturing larvae. The paralyzed honeybees serve as food for the developing young wasps.

The problem that a *Philanthus* female faces after capturing prey, often thousands of meters from home, is how to find her nest entrance, a hole less

than a centimeter in diameter. Tinbergen, in his best-known experiment, waited until rainy weather kept wasps in their nests for a couple of days, and early in the morning of the first fair day, just before a wasp emerged from her nest to go hunting, placed a ring of pine cones around her burrow entrance. When the wasp first emerged from her burrow, she circled above her nest entrance for 6–12 s before flying off to hunt for honeybees. While the wasp was gone, Tinbergen moved the circle of pine cones, which the female had seen only once in her life, a few tens of centimeters from its original position around the nest entrance. He then waited for the wasp to return with a paralyzed bee for her young.

If, during the brief flight she made near the nest entrance before leaving to hunt honeybees, the wasp learned the location of the nest entrance with respect to the pine cones, then she should have landed inside the displaced circle of pine cones when she returned with a honeybee to provision her young. In fact, wasps were four times as likely to land in the ring of pine cones (and at a distance from the true nest entrance) than at the nest entrance itself. Clearly, the wasps had learned about the pine cones in the few seconds between coming to the surface and flying off to hunt for bees.

Of course, it is just possible that wasps are more intelligent than is generally suspected. That turns out not to be the case. This same wasp, *Philanthus*, hunts bees by first approaching any bee-sized moving object, and then flying downwind of it. If the wasp detects honeybee scent while hovering downwind of the object it is inspecting, the wasp lands on the object. If the object feels like a honeybee, the wasp stings it and takes it back to its burrow.

Tinbergen conducted another experiment in which he tethered both a dead honeybee and a honeybee-sized piece of wood on separate threads suspended from a clothes line. The piece of wood was hung a few centimeters downwind of the bee. A wasp would, as usual, approach the objects and then fly downwind of them. Because the smell of the scent of a honeybee was on the wind, the wasp then landed. However, it landed on the piece of wood downwind from the suspended, dead honeybee, not on the honeybee itself. Because the piece of wood did not feel like a bee, the wasp then ended its attack without stinging. The wasps never learned to recognize wooden dummies by sight and avoid attacking them. Instead, the wasps repeatedly attacked the piece of wood, rather than the honeybee just a few centimeters upwind of the wooden decoy, and would land on the decoy dozens of times. So here, in a single animal, one sees both a striking ability to learn about landmarks around a nest and a striking inability to learn to use visual cues to distinguish bees from sticks.

Of course, in the natural world, there are rarely if ever inanimate objects hovering in midair between a bee and a hunting wasp. On the other hand, all bee-hunting wasps have to learn the location of their burrow entrances, if they are to raise their young successfully. *Philanthus* wasps appear to be specialized to learn just those things that they need to learn in the natural environment.

Clark's Nutcracker

Many species of bird and mammal create hoards of food to eat during times of food shortage. Some, like chipmunks or dormice, create a single large cache of food. Others, like squirrels or chickadees, called 'scatter hoarders', create a number of food caches in different locations.

Clark's nutcracker (a middle-sized bird about the size of a blue jay but without a crest, and colored gray and black with white wing and tail patches), is probably the champion among scatter-hoarding birds. In late summer, a single Clark's nutcracker will place twenty to thirty thousand pine seeds in six to eight thousand separate caches. During the next winter and early spring, when relatively little food is available on the mountainsides, each nutcracker recovers the seeds it has cached. The cached seeds, rich in protein and fat, enable nutcrackers to breed far earlier in the spring than other birds that live in the same area but either do not cache seeds or cache far fewer seeds than do the nutcrackers. Nutcrackers are also different in having special pouches that open under their tongues (sublingual pouches) where they can place ninety seeds or more, thus easing transport of seeds to caching sites.

The scrub jay is phylogenetically closely related to and lives in the same area as Clark's nutcracker. However, scrub jays are considerably less dependent than nutcrackers on cached food, and do not have specialized pouches for carrying seeds.

The fact that nutcrackers must remember the locations of thousands of seed caches for weeks or even months suggests that, along with a physical structure for transporting food to caches, nutcrackers might have evolved a specialized system of learning and memory to keep track of the cache sites they have created. Indeed, in natural circumstances, after a nutcracker lands and begins to dig in the ground, more than 70 percent of the time it

recovers pine seeds cached there. This level of accuracy is truly remarkable considering that a nutcracker spends only about 30 s hiding each cache, has to remember thousands of caches, returns to harvest its caches months after creating them, and recovers caches from areas which may have changed considerably in appearance since caching took place: nutcrackers cache seeds in the late summer, when the ground is free of snow, but retrieve them in winter and early spring, when the ground is often snow-covered.

It is, of course, possible that nutcrackers do not really remember where they have cached seeds at all. Perhaps they simply locate caches by their smell, or make marks near caches that they use to guide them to hidden pine seeds. In the laboratory, smells can be removed, as can any marks made by the birds. Laboratory studies, in which cache recovery depends entirely on learning and remembering landmarks that identify cache sites, have shown repeatedly that both nutcrackers and scrub jays can use memories of landmarks to recover cached seeds. However, nutcrackers, the caching specialists, are significantly better than are scrub jays at recovering seed caches a week after creating them. Such findings, and there are a number of them, suggest a specialization of learning and memory for caches in birds that cache extensively in nature.

If there is indeed specialization in nutcrackers for learning and remembering landmarks associated with caches, you might expect to find areas of the brain involved in learning and remembering landmarks better developed in nutcrackers than in scrub jays. Further, one might predict that, in caching bird species in general, brain areas involved in landmark learning would be larger than the same brain areas in noncaching bird species.

The hippocampus, a part of the cortex of the brain, is extensively involved in memory for cache sites. We know that the hippocampus is involved in cache recovery because, although caching birds with lesions in this structure show normal feeding and caching behavior, they are unable to remember where they have cached seeds when they later look for them.

In comparison with noncaching birds, caching birds have large hippocampi for their body size. It is important to be sure that the different body size of caching and noncaching birds is taken into account, because otherwise if caching species were just generally larger than noncaching species and bigger birds tended to have bigger brains, it would look as if the hippocampus of food-storing birds was especially large, even though that was not true.

Homing Pigeons

Caching birds are not the only birds with especially large hippocampi. Lesions of the hippocampus disrupt the ability of homing pigeons to use local landmarks to return to their lofts, and the hippocampi of homing pigeons are larger than those of breeds of pigeon that do not home.

Meadow and Pine Voles

Meaningful relationships have also been found between the need for navigational skill and hippocampus size in mammals, although the best-studied relationship between spatial learning and brain size in a mammal involves differences between the sexes, as well as differences between species.

Various species of vole (small, plump, short-tailed rodents) are to be found in grasslands throughout North America, and different vole species differ markedly in their mating patterns. For example, male meadow voles mate with several different females, and during the breeding season each male meadow vole moves about an area that overlaps the territories of several female meadow voles. Male pine voles, on the other hand, are relatively faithful to a single female, and the territories of male and female pine voles are of roughly the same size throughout the year.

Because male meadow voles travel greater distances than do female meadow voles, whereas male and female pine voles travel equal distances, male meadow voles (but not male pine voles) would seem to need greater proficiency in navigation than would females of their respective species. Indeed, in the laboratory, male meadow voles (but not male pine voles) perform better than do females of their species on tests of spatial learning. As you might expect, male meadow voles (but not male pine voles) have larger hippocampi than do females of their species.

BIRDSONG LEARNING AND IMPRINTING

Learning

Males of many bird species produce a series of notes, trills and pauses (a song) that is used during the mating season both to attract females and to defend territory against intrusion by other males. Males of each species sing a different song, and in some species birds from different geographical areas sing local ‘dialects’, not unlike the different

dialects of native English speakers coming from different parts of the world.

It has long been known that birds learn to sing the song typical of their species. However, the special properties of birdsong learning were clearly demonstrated only in the 1960s by Peter Marler and his associates, who studied song learning in a common North American species, the white-crowned sparrow.

Marler took young sparrows from the nest and reared them by hand in the laboratory under conditions where they could not hear other sparrows sing. When hand-reared sparrows that had never heard a sparrow song grew to adulthood and began to sing, they sang abnormal, simplified songs. Marler reared other white-crowned sparrows in the laboratory and allowed them to listen to tape recordings of adult male white-crowned sparrows. When adult, these sparrows sang not just normal song but also the same dialect as the male whose song was recorded on the tape. Clearly, learning was important for development of song in this bird species.

Marler also found that, although hand-reared white-crowned sparrows would learn white-crowned sparrow song from tape recordings, they would not learn the songs of other species of birds from such tutor tapes. Indeed, white-crowned sparrows reared listening to the songs of other bird species sang simplified songs, just like white-crowned sparrows reared in total auditory isolation. Further, tapes of white-crowned sparrow song played to sparrows when they were between 10 days and 50 days old saved them from singing simplified song as adults, while the same tapes played to the sparrows later in life had little or no effect. So, song learning in white-crowned sparrows was restricted both to certain songs and to certain times of life. The fact that sparrows learn song when young, but do not use this information until they are adult, also differentiated song learning from other types of learning.

Song learning is obviously very different from learning to traverse a maze or to press a lever for food, and like landmark learning has its own special physical basis in the brain. Nottebohm and his colleagues removed various areas from the brains of canaries and recorded their songs both before and after these operations. As a result, the researchers were able to describe a series of clusters of nervous tissue and their connections that control both song learning and song production. The more songs a male sang, the larger were his brain areas concerned with song. Males (which sing) had larger structures than did females (which do not sing). The relevant brain areas, but not others, also grew in the spring and summer, when males sing, and shrank in the fall and winter, when singing ceases.

Imprinting

Imprinting is a term used to describe two kinds of effects of early social experience on later social behaviour. Filial imprinting refers to the learned tendency of young precocial birds to become attracted to and follow their parents (precocial birds are those that hatch in a relatively mature state, like ducks and chickens). Sexual imprinting refers to the effects of early social experience on adult mate preference.

Similar features distinguish imprinting and birdsong learning from the usual types of learning:

- there is restriction on the stimuli which a young bird will learn to follow or to respond to sexually
- there is a restricted period during life when imprinting will occur
- there is (in sexual imprinting) a long interval between the time of imprinting and expression of the imprinted behavior
- there are identifiable neural structures that support imprinting.

CONCLUSION

Immediately following discovery of the special properties of taste-aversion learning, there was a reasonable expectation that many similar cases of adaptively specialized or domain-specific learning and memory processes would soon be discovered, and that a new era would dawn in the study of animal learning and memory. It was an expectation that was to prove difficult to fulfill. Although a few apparently novel learning and memory systems have been discovered, particularly those concerned with landmark learning, progress has been slow.

Nevertheless, the search for adaptively specialized learning processes has led both biologists and psychologists to look to the behavior of animals in their natural environments to identify instances in which animals in nature appear to need to learn. Such instances are not hard to find. Animals have to learn to recognize predators and prey; they have to learn to recognize both kin and other members of their social groups; they have to learn their way around their home ranges; they often have to learn mate preferences or vocalizations appropriate to their species. As we have seen, members of some species have to remember where they have stored caches of food.

However, field data pointing to instances in which animals need to learn provide little information on how learning occurs. Is the learning of biologically important relationships similar to learning in artificial situations, or is such learning special? Such questions can be answered only under the controlled conditions of the laboratory.

Although the search for adapatively specialized learning mechanisms in the laboratory has been in progress since the 1970s, it is not yet clear just how common such domain-specific cognitive processes are. In some cases, such as those described above and a very few others, learning does seem to reflect information-processing systems evolved to respond to particular environmental demands. However, more frequently than was anticipated, general process learning seems to be all that is needed to get the job done.

Learning in Simple Organisms

Introductory article

Kenneth W Eng, University of British Columbia, Vancouver, British Columbia, Canada
Jacqueline K Rose, University of British Columbia, Vancouver, British Columbia, Canada
Catharine H Rankin, University of British Columbia, Vancouver, British Columbia, Canada

CONTENTS

Invertebrate animals with small nervous systems have been studied to investigate the cellular basis of learning and memory. Through behavioral, physiological, and genetic studies many of the mechanisms of habituation, sensitization, and classical conditioning have been discovered.

INTRODUCTION

The principal objectives of researchers using a simple systems approach to learning and memory are to establish the neural circuits involved in a specific form of learning and to identify the cellular changes that occur within those neurons as a result of experience. Simple systems approaches to learning have revealed that modifications in behavior are the result of alterations in precise synaptic connections.

The use of simple organisms offers researchers the opportunity to analyze the neuronal and cellular mechanisms responsible for learning and memory. Because the nervous systems of many invertebrates are composed of only several thousand or tens of thousands of neurons, an investigator can establish with some certainty that any biochemical or neurophysiological changes in the neural system subsequent to learning are the result of that learning. The majority of advances made in cellular and molecular research on learning and memory using simple systems has come from investigating forms of involuntary learning: habituation, dishabituation, sensitization, Pavlovian conditioning (otherwise known as classical conditioning) and instrumental (or operant) conditioning. These simple forms of learning show the same behavioral characteristics and rules in all organisms studied, from the simplest invertebrates to humans. Thus studying them in a simple system may lead to insights unavailable in larger, more complex vertebrates.

ASSOCIATIVE AND NONASSOCIATIVE LEARNING

Behavior is altered by experience through two processes: learning, which refers to a change in behavior that results from an animal's experience with the environment, and memory, which is the storage of information from previous experience that can be retrieved to affect later behavior. This behavioral modification must be reflected in an alteration at the cellular and molecular level of the organism's nervous system; it must remain separate from the animal's natural development and biological maturation, and must not simply reflect sensory adaptation or motor fatigue. Memory is the ability of an animal to retain information from previous experience and the nervous system's ability to store and make use of that information.

Traditional learning theorists have divided simple forms of learning into two types: nonassociative learning and associative learning. The three forms of nonassociative learning studied are habituation, dishabituation, and sensitization. Habituation is defined as a decrement in behavioral response resulting from repeated presentation of the same stimulus. However, this decrement in response is not due to fatigue or sensory adaptation. Habituation can be rapidly reversed by the introduction of a novel or noxious stimulus, causing a return of the habituated response to almost baseline levels, a process referred to as 'dishabituation'. Sensitization refers to an increase of a reflex response above baseline levels due to the presentation of a strong or noxious stimulus.

The two forms of associative learning studied in simple systems are classical conditioning and instrumental conditioning. Classical conditioning, also known as Pavlovian conditioning, is the method by which an animal learns about the predictive relationships between stimuli and events in the environment. Classical conditioning is best illustrated by Pavlov's experiments with dogs. In these experiments Pavlov paired a tone with the presence of food in a dog's mouth. The food is an unconditioned stimulus (US) because it elicits the reflexive response of salivation, an unconditioned response (UR). With repeated exposure to a previously neutral stimulus (the tone) and food together, the dog eventually learns to salivate to the tone, now a conditioned stimulus (CS), before the onset of the food. When the tone alone leads to salivation, a conditioned response (CR) is said to have occurred.

Instrumental conditioning (also known as operant conditioning) is a change in behavior due to the positive or negative consequences of that behavior. Animals are more likely to repeat behaviors that are rewarded and to discontinue behaviors that fail to elicit rewards or that result in punishment.

APLYSIA CALIFORNICA

Aplysia californica is a salt-water mollusk that is about the size of a large rat. Members of this species have been useful in studies of the cellular basis of learning and memory because their large neurons are relatively easy to record from. Learning and memory have been extensively studied using the gill and siphon withdrawal reflex in *Aplysia*. The neurons that control this reflex are found in a cluster of neurons called the abdominal ganglion. Using this model system, researchers have shown that short-term forms of learning are produced through modification of neurotransmitter release, while the persisting memory for that learning involves activation of molecular cascades that can result in gene transcription.

Studies of nonassociative learning in *Aplysia* have focused mainly on defensive withdrawal reflexes: the gill and siphon withdrawal reflexes induced by a tactile stimulus applied to the siphon or mantle shelf, and the tail withdrawal response, which is a contraction of the tail musculature due to tail stimulation. Sensitization is observed when a noxious stimulus administered to the tail of an animal leads to an increase in reflex withdrawal responses. Habituation occurs as a decrement in withdrawal responses as a result of repeated exposure to a tactile stimulus to the siphon. Dishabituation can be observed when a novel or noxious stimulus is applied to the tail and reestablishes a previously habituated withdrawal response to a normal level. Repeated stimulation of the gill and siphon withdrawal reflex results in the formation of long-term memory that can last several weeks.

The best-understood form of learning in *Aplysia* is sensitization: following tail shock, a tactile stimulus to the siphon evokes a greater gill withdrawal response than it would have done before the shock. The cellular correlate of behavioral sensitization is heterosynaptic facilitation. Tail shock causes facilitatory interneurons to release serotonin onto the axon terminals of the siphon sensory neuron. This serotonin activates a biochemical process in the sensory neuron leading to the closing of an ion channel called the S potassium channel. Closing potassium channels causes the action potential to last longer, which results in calcium channels remaining open longer and allowing more calcium into the sensory neuron terminal. A higher level of calcium in the terminal leads to the release of a greater amount of neurotransmitter in response to each stimulus. This increase in transmitter release produces the strengthened behavioral response seen in short-term sensitization. For long-term memory of sensitization, Kandel and colleagues have shown that the serotonin receptors on the sensory neuron also activate a second metabolic pathway that activates genes involved in long-term memory formation. One gene that has been shown to be important in memory formation in *Aplysia*, *Drosophila*, mice, and humans is *CREB*, which encodes cyclic AMP reaction element binding protein, a transcription component linked to long-term memory formation.

The mechanisms underlying long-term memory for both habituation and sensitization in *Aplysia* have been studied in some detail. Memory for both of these forms of learning is reflected in changes in the number and the morphology of the sensory neuron synapses (Figure 1). Long-term sensitization results in more synapses per neuron, larger synapses, and more neurotransmitter vesicles in the area of the synapse. Long-term habituation results in fewer synapses per neuron, smaller synapses, and fewer neurotransmitter vesicles in the area of the synapse. Thus, one role of gene activation in long-term memory is to alter the shape and size of the synapse. This means that memory is reflected in an actual change in anatomical structure of the neurons.

In addition to nonassociative forms of learning, *Aplysia* also shows classical conditioning of the gill

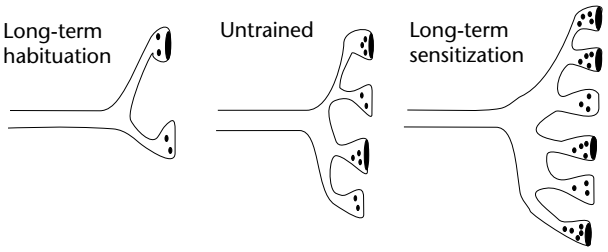

Figure 1. A physical change in the neurons reflects long-term memory. Morphological changes take place in the presynaptic terminals of sensory neurons following long-term nonassociative training in *Aplysia*. Dark ovals represent neurotransmitter vesicles, larger dark areas represent active zones. Long-term habituation training leads to a decrease in the number of synaptic terminals, transmitter vesicles, and active zones; long-term sensitization leads to an increase in their numbers when compared with untrained controls. Based on data from Bailey and Chen (1983).

and siphon withdrawal reflex: a pairing of weak siphon or mantle stimulation with tail shock leads to a pairing-specific enhanced response to the weak stimulus. During conditioning a cellular process known as long-term potentiation (LTP) takes place in the postsynaptic cell (the motor neuron) and involves activity of a special type of glutamate receptor, the *N*-methyl-D-aspartate (NMDA) receptor. When paired stimuli (siphon stimulation and tail shock) are received, increasing calcium influx through NMDA receptors activates a cellular cascade leading to changes in gene expression and memory for the classical conditioning. Interestingly, LTP is believed to underlie classical conditioning in mammals.

CAENORHABDITIS ELEGANS

Caenorhabditis elegans is a 1 mm long, free-living, nonparasitic nematode which has become a powerful model system for genetic studies of development and modern neurobiology. The *C. elegans* genome contains approximately 19 000 genes, more than 40% of which can also be found in humans. The deoxyribonucleic acid (DNA) of *C. elegans* has been completely sequenced and many mutations have been studied. With an understanding of the worm's general physiology, genetic composition, and neuroanatomical development, investigators are well equipped to study the underlying mechanisms of learning and memory. Of the 959 cells of the worm, some 302 are neurons. All 302 neurons and their synaptic connections have been anatomically mapped using electronmicroscopy to generate a complete wiring diagram of the worm's nervous system. This organism shows both nonassociative (habituation, dishabituation, sensitization) and associative (classical conditioning) forms of learning as well as short-term and long-term memory. Thus the learning ability of this well-understood model system allows researchers to isolate specific neuronal synapses where modulations due to learning may be occurring, in addition to identifying specific genes involved in that learning.

Studies using a mechanical stimulus produced by tapping the dish holding the worm have been used to investigate the behavioral, neural, and genetic aspects of habituation and dishabituation of the tap withdrawal response in *C. elegans*. Normally, a tap will elicit a reversal response in which the worm swims some distance backwards. With repeated mechanical taps, reversals become progressively smaller until the worm eventually stops responding, or habituates (Figure 2). Both habituation and spontaneous recovery from habituation are contingent upon the interstimulus interval (ISI) of the taps. Worms habituate more rapidly and more completely to stimuli delivered with short ISIs (10 s) than to long ISIs (60 s). Interestingly, spontaneous recovery is also more rapid at short ISIs than long ISIs. The worm also shows long-term

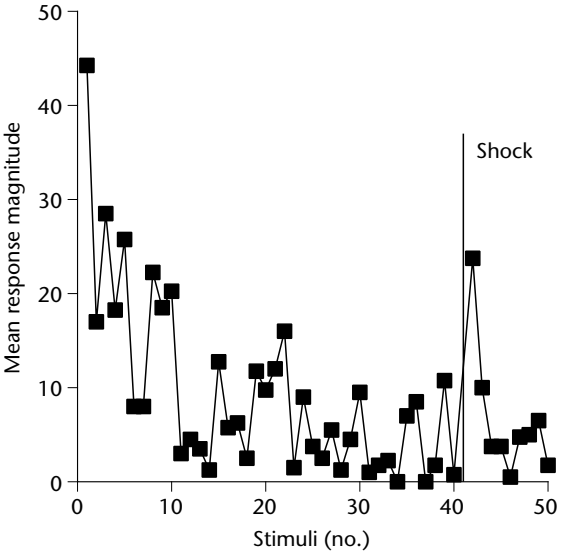

Figure 2. Habituation and dishabituation to tap in *Caenorhabditis elegans*. Mean response magnitude is shown for ten worms stimulated with 40 taps at 10 s intervals, followed by a 60 V shock, then nine more taps at 10 s intervals. The worms show habituation to the first 40 taps, and after the shock, show dishabituation and then rehabituation to tap.

habituation, which involves maintaining memory for habituation training for at least 24 h. Dishabituation (the immediate recovery of a habituated response) is seen in the worm by applying an electrical stimulus to the agar on either side of a habituated animal (Figure 2). *Caenorhabditis elegans* also shows context conditioning in habituation. In context conditioning the worm learns to associate specific environmental cues (e.g. a distinct chemical taste) with habituation to tap. In later tests the worm shows better memory for habituation if tested in the presence of the chemical cue that was present during training.

In order to study the neural circuit involved in the response to tap, a laser was used to kill candidate neurons and the resulting behavioral effects were recorded. The neural circuit for tap consists of five sensory neurons and 11 interneurons which activate a large number of motor neurons (Figure 3). The response to tap is produced by the activation of two competing circuits, one in the head of the worm producing backward movement, and one in the tail of the worm producing forward movement. The observed behavior is an integration of the two competing responses. Laser ablation studies have also shown that the two competing responses (backward movement following head stimulation, and forward movement following tail stimulation) habituate at different rates and with different properties.

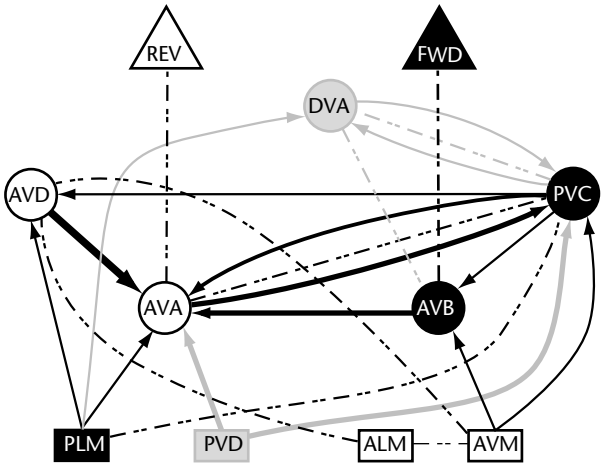

Figure 3. The neural circuit underlying response to tap. The squares represent sensory neurons, the circles represent interneurons, and the triangles represent large pools of motor neurons. Solid lines represent chemical connections with the width of the line corresponding to the number of synapses between the two cells connected. Dashed lines represent electrical connections. Cells shaded in black represent the tail touch circuit to produce forward movement (FWD), white cells represent the head touch circuit to provide backward movement (REV), and the gray cells appear to be involved in both forward and backward movement. Based on data from Wicks and Rankin (1995).

Since habituation to tap does not affect any other behavior in the worm, it is most likely that the learning is occurring in the sensory neurons or in the synapses from the sensory neurons onto the interneurons. These neurons are thought to use the neurotransmitter glutamate to activate the interneurons. A mutant, *eat-4*, thought to have decreased glutamate transmission, has been studied using the habituation to tap assay. At all ISIs *eat-4* worms habituate more quickly and recover more slowly than their wild-type counterparts. In addition, *eat-4* worms do not show dishabituation. Together, these findings suggest a possible role for glutamate transmission in normal habituation to tap in *C. elegans*.

HERMISSENDA CRASSICORNIS

The nudibranch *Hermissenda crassicornis* is a small marine mollusk with no shell which has been used to study memory for classically conditioned pairings of light and rotation. In nature these organisms receive strong vestibular stimulation in their intertidal environment; to avoid injury they respond to this stimulation by clinging to underwater rocks. To mimic this stimulation in the laboratory, researchers subject *Hermissenda* to rotation by placing individual animals in seawater-filled tubes clipped to a turntable. The animals are naturally attracted to light (positive phototaxis), as light directs the animal towards its surface plankton food source. In the classical conditioning paradigm researchers fix a light at the center of the rotating turntable to show that when rotation (US) is repeatedly paired with the light (CS), animals will eventually respond to light alone with increased latency of phototaxis and shortening of the foot. Using simultaneous CS–US presentations it has been demonstrated that the increased phototactic response latency persists during repeated training, lasts for more than 7 days, and is dependent upon the temporal CS–US association, since trials in which the CS and US occurred randomly showed no change in response latency.

The neuroanatomy of *Hermissenda* is well studied, giving researchers the opportunity to investigate specific locations along the sensory input pathways where neural changes take place during classical conditioning of paired light and rotation. Each eye comprises five photoreceptors (two type

A and three type B). In classical conditioning, the CS (light) is mediated specifically by the type B photoreceptors. When rotation (US) is coupled with light presentation, the sensory cells for rotation (statocyst hair cells) are thought to release serotonin which then acts on the type B (CS) photoreceptors. In response to serotonin the type B photoreceptors show a prolonged increase in excitability which produces a suppression of the phototactic response. This prolonged excitation in the photoreceptors is due to decreased potassium channel conductance. Photoreceptors also show increased calcium influx following activation that may also contribute to the reduction in potassium conductance. Long-term retention of type B photoreceptor excitability is blocked by protein synthesis inhibition, suggesting that protein synthesis is responsible for long-term memory for conditioning. Interestingly, application of serotonin followed by conditioning seems to facilitate suppression of phototaxis resulting from conditioning, lending support to the findings of the role of serotonin in learning in *Aplysia* described above.

Researchers have also demonstrated that *Hermissenda* shows inhibitory conditioning, in which the occurrence of one stimulus predicts the absence of another stimulus, and that *Hermissenda* is capable of context conditioning, where animals receive rotation stimulation in either a light or dark environment – animals who experience rotation in the dark prefer the light environment, while animals who experience rotation in the light prefer the dark environment. Changes in the activity of the type B photoreceptors were also reported following context conditioning.

DROSOPHILA MELANOGASTER

Drosophila melanogaster (fruit flies) are tiny flies that have been used for many years in genetic studies. The genome of *Drosophila* has an estimated 12 000 genes. Owing to its complex (many hundreds of thousands of very small neurons) and inaccessible nervous system, cellular examinations are difficult in this species. However, genetic investigation of learning and memory can be done with relative ease in these flies.

Although many different paradigms have been used to study learning in fruit flies, one of the most popular approaches uses a classical conditioning method that pairs an olfactory signal (CS) with an electric shock (US). Researchers measure the change in learned behavior by giving the flies a choice between the CS odor and a control odor not previously paired with shock; trained flies avoid the CS odor but not the control odor. This method has identified a number of mutations that alter flies' ability to learn or remember the training, leading to the hypothesis that *Drosophila* memory has four stages or components (Figure 4(a)). First, there is short-term memory (mutant flies missing this stage are called *dunce* and *rutabaga*), which lasts for about 2 h subsequent to training. Second, there is middle-term memory (mutant flies missing this stage are called *PKA* and *amnesiac*, which lasts approximately 1–7 h and is thought to be contingent upon short-term memory. Third, there is anesthesia-resistant memory (mutant flies missing this stage are called *radish*), which is dependent upon middle-term memory and lasts between 2 h and 7 days, is produced by massed training and is not disrupted by placing the flies in cold, which acts as an anesthetic. The last and final memory phase is termed long-term memory (mutant flies missing this stage are called *dCREB2*), which occurs about 24 h subsequent to spaced or distributed training and is maintained for more than 7 days. Long-term memory is dependent upon middle-term memory formation as well, but is reduced by low-temperature anesthesia and requires new protein synthesis to occur.

APIS MELLIFERA

Honeybees (*Apis mellifera*) are of interest to researchers owing to their well-developed yet compact brains (approximately 950 000 neurons within a cubic millimeter) and their complex behavioral repertoire which includes flying, nest building, defense and attack as well as communication. On the practical side, honeybees are easy to maintain in large numbers in a small space, since queen bees can lay up to 1500 eggs per day. In terms of developmental analysis, worker honeybees only take 21 days to develop from egg to adult, making the examination of several generations possible. Further, honeybees have been shown to be capable of several forms of learning and memory.

Since the early years of the twentieth century investigators have examined the prosboscis extension response (PER), whereby sucrose stimulation of the antennae or the proboscis of bees (analogous to the tongue) results in extension of the proboscis. When a novel odor stimulus (CS) is paired with sucrose stimulation (US) honeybees will show the PER when presented with the CS odor alone. Honeybees show retention of this olfactory conditioning following simultaneous CS–US presentation and forward conditioning; however, backward conditioning (where the US precedes the CS)

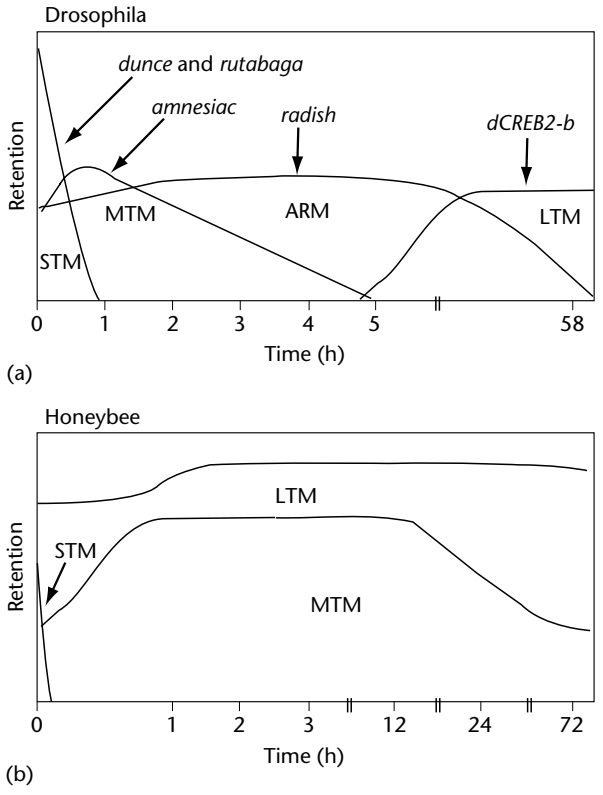

Figure 4. Time course of stages of memory for *Drosophila* and honeybees, with increasing values on the retention (x) axis representing better memory at certain time points following training. (a) *Drosophila* shows short-term memory (STM) which decays within 1 h of training. Single-gene mutants *dunce* and *rutabaga* are defective in this memory stage. Median-term memory (MTM) is present for approximately 5 h after training with *amnesiac* mutants showing a deficiency in this stage of memory. Anesthesia-resistant memory (ARM) and long-term memory (LTM) are longer-lasting forms of memory: ARM decays sooner than LTM (approximately 3–4 days) and is not interrupted by cold shock anesthesia. *Radish* mutants show deficiencies in ARM. Long-term memory lasts for more than 7 days and its formation can be blocked by cold shock anesthesia. The *dCREB2-b* mutants show LTM deficiencies (based on data from Dezazzo and Tully, 1995). (b) Short-term memory (STM) in the honeybee is primarily composed of a sensitization component and decays within 3 min of training. Median-term memory (MTM) forms by approximately 7 min after training, peaking at 30 min and decaying within 24 h, while long-term memory (LTM) shows high retention from immediately following training up to the lifetime of the bee (at least 3 days). Based on data from Hammer and Menzel (1995).

results in no retention of the CS–US association. Interestingly, if bees are presented with two different odors, one paired with sucrose (CS^+) and the other not (CS^-), honeybees will show depressed PER probability to the CS^- while demonstrating an increased PER probability to the CS^+ odor (differential classical conditioning). Honeybees have also shown second-order conditioning of PER in that a previously sucrose-associated odor can later be paired with another stimulus and honeybees will respond with a PER following presentation of the second conditioned stimulus. Acquisition of the PER is inhibited if the CS is repeatedly paired with the absence of sucrose prior to training (inhibitory conditioning). In addition, PER is suppressed if sucrose is made available in the presence of an odor formerly paired with electric shock, demonstrating the honeybee's capability of learning both reward and aversively paired contingencies.

Different phases of memory have been described using the PER paradigm: short-term memory, median-term memory and long-term memory. Short-term memory is brief in duration (0–3 min) with rapid decay and a nonassociative sensitizing component due to the sucrose itself (Figure 4(b)). Median-term memory (approximately 7 min to 12 h) is sensitive to cooling or electrical stimulation of the brain following training and is produced following single-trial conditioning. The discrepancy between the time course of short-term and median-term memory suggests that honeybee memory is biphasic in nature, degrading quickly within a few minutes only to reappear a few minutes after that. Long-term memory is thought to occur only following repeated trials; it lasts from 3 days to the lifetime of the bee and is insensitive to cooling or electric shock. Interestingly, it has been shown that protein synthesis inhibition with the chemical cycloheximide does not disrupt long-term memory, although it has also been reported that inhibition of upstream protein synthesis activators results in its attenuation. As has been described for *Drosophila*, long-term memory is thought to be induced in parallel to median-term memory, as single-trial conditioning does not elicit long-term memory, while cooling and/or electrical stimulation disrupt median-term but not long-term memory.

In addition to associative paradigms employing PER, researchers have also coupled color stimuli with a sucrose reward in an open-field training environment and measured preference for certain stimuli. This type of conditioning allows for more ethologically relevant training and testing of honeybees. Honeybees have also been shown to be capable of complex maze learning as long as it is divided into simpler steps, for instance, if colors cue direction within the maze.

CONCLUSION

Research using simple systems has allowed researchers to gain new insights into some of the mechanisms of learning and memory. Different organisms have been useful for obtaining different types of information. *Aplysia* and *Hermissenda* have allowed detailed studies of experience-related changes in individual neurons; *Drosophila* and *Caenorhabditis elegans* have allowed investigations into the genes involved in learning and memory; studies using honeybees have demonstrated the ethological importance of learning and memory. Since the behavioral rules characteristic of simple forms of learning have been shown to be the same in simple invertebrates and in more complex mammals including humans, it is not surprising that many of the mechanisms of learning and memory found in invertebrates also have a role in learning and memory in vertebrates. Research in these diverse species indicates that long-term memory formation requires training to be spaced out over time, with rests between blocks of training sessions, rather than given all at once. Through research on learning in invertebrates we have learned about biochemical reactions that play a part in learning, and about proteins and genes that are involved in both learning and memory. The simple systems approach to understanding the mechanisms underlying learning and memory has been successful in advancing our understanding of these important processes.

Learning, Psychology of

Introductory article

Geoffrey Hall, University of York, York, UK

CONTENTS

In its psychological usage, 'learning' refers to the process by which an animal (human or non-human) interacts with its environment and becomes changed by this experience so that its subsequent behavior is modified.

INTRODUCTION

Procedures for Demonstrating Learning

In order to demonstrate that learning has occurred, two observations of behavior must be made. There are two general procedures for doing this. In the first, a given individual is observed twice in the same situation, and if it behaves differently on the second occasion, we make the inference that there has been some change in the organism. In order to make this inference it is necessary that the test situation be identical to the initial training situation – otherwise any change in behavior could just as well derive from a change in the external conditions as from a change in the organism itself.

The change in the organism could occur as a consequence either of its initial experience of the training situation itself or of some experience that has occurred between the first observation of behavior and the second. An example of the former case is provided by the phenomenon of habituation in which, for example, the startle response evoked by a sudden loud noise is reduced in magnitude on the second presentation of the stimulus. We infer that the first presentation of the noise produced some change in the animal that caused it to respond differently to this stimulus on the second presentation. For an example of the latter case, consider the behavior of a student confronted with the question 'How is learning defined?' before and after reading this article. We may hope that the response to the question will be different on the two occasions and infer that the intervening activity (reading the article) has produced learning.

The second procedure is to compare the behavior of two individuals in a given test situation. Provided that these individuals are matched in other respects, differences in their behavior may be attributed to differences between them produced by their differing individual experiences. It seems likely that many of the individual differences exhibited by members of our own species are produced in this way, although, given that any two people (unless they are identical twins) will differ in their genetic make-up as well as in their experience, we cannot always be sure of this. Laboratory experiments allow more certainty. For example, if two laboratory rats of the same genetic stock differ in (say) their ability to perform a maze-running task when one has been raised in an enriched environment and the other has lived all its life in a standard cage, we may confidently attribute the difference in their behavior to learning.

An advantage of this procedure is that evidence for learning can be obtained even when the test situation is quite different from that used in training. A disadvantage is that it is not possible to know in which of the animals being compared the learning has occurred – does enrichment enhance the performance of the rat, or does an impoverished environment produce a change that retards performance? (Although learning will often make an organism better able to deal with the demands of its environment, there is nothing in our definition that requires that this be so.)

Qualifications

These basic definitions and procedures are subject to certain qualifications, of which the three most important are the following.

Firstly, although the demonstration of learning requires a change in behavior, it is possible that a given experience might produce a change in the animal (i.e. produce learning) that is behaviorally

silent under the conditions of the test. (A young child may learn from experience that the volume of a fluid is not changed when it is poured from one container to another, but may fail to show this when tested in the particular circumstances employed by the developmental psychologist.) The absence of a behavioral change cannot prove that no learning has occurred.

Secondly, some changes in behavior, although undoubtedly a consequence of interaction with the environment, are not usually regarded as instances of learning. For example, a rat will press a lever for the reward of a food pellet less readily on the second occasion than on the first if, in the meantime, it has been given free access to food. Such a change in behavior is attributed to a change in motivation rather than to learning. It is difficult to specify a set of rules for distinguishing between these two sources of behavioral change, but it is widely accepted that the changes that constitute learning are more permanent (or, at least, less easily reversed) than those classified as motivational. Similar considerations apply to the short-term behavioral changes produced by muscular fatigue or adaptation of the sensory system.

Thirdly, some of the changes in behavior shown by an individual over the course of its lifespan, although they satisfy the definition of learning offered above, are not usually regarded as such, but are attributed to a process of maturation. An example is the difference in behavior shown by a one-year-old when confronted with a flight of stairs and that shown by a two-year-old in the same situation. The input supplied by the environment over the intervening 12 months (even if it consists only of providing a good diet and the opportunity for exercise) is undoubtedly important in producing the change in the child that allows it to display enhanced stair-climbing ability. But whether this justifies our concluding that the ability has been 'learned' (in the sense in which we may say of an older child that he or she has learned to ride a bicycle) is a matter of debate.

EXAMPLES OF LEARNING

In spite of these qualifications, the psychologist's use of the notion of learning is much wider than that of the layperson. The latter is likely to restrict usage to cases in which new information is acquired (as in learning the properties of the elements in the periodic table) or in which a new skill is acquired (as in learning to drive a car). Both of these are certainly examples of learning under our definition, but so are the examples listed below. The list is not intended to be exhaustive; rather, its purpose is to give an indication of the variety of learning phenomena that have been studied by psychologists. Most of the cases cited below are from controlled laboratory studies (often from studies conducted on animal subjects rather than people), but their relevance to everyday instances of learning will be obvious. (*See* **Animal Learning**; **Comparative Psychology**)

Habituation

The magnitude of the response initially elicited by the presentation of a given stimulus will decline with repeated presentations of that stimulus. We have already cited the waning of the startle response to a loud noise, but the effect is found in many other response systems (e.g. a rat given a novel food will initially decline to eat it, but this neophobic response will decline with repeated presentations of the food). Habituation effects are not to be attributed to muscular fatigue or sensory adaptation: other tests reveal that an animal that has undergone habituation can still detect the stimulus and is still capable of performing the motor response, so that this behavior change should be categorized as learning.

Pavlovian Conditioning

A dog (the experimental subject used by the Russian physiologist Ivan Petrovich Pavlov in his early work on this phenomenon) given presentations of a neutral stimulus (such as the flashing of a light) immediately before the presentation of food will develop a tendency to salivate in response to the light. The light is then referred to as a conditioned stimulus (CS) and the response it evokes as a conditioned response. Food itself is an unconditioned stimulus (US), which, even without special training, is capable of evoking the unconditioned response (UR) of salivation. (*See* **Conditioning**; **Pavlov, Ivan Petrovich**)

The essential feature of this training procedure appears to be that the animal experiences paired presentations of two environmental events. Such pairings are effective in producing learning even when the detailed procedures used are very different from those used by Pavlov in his original studies. For example, a rat that experiences (experimentally induced) nausea after eating a novel food will develop a tendency to shun that food in the future (flavor aversion learning); a rat that experiences an electric shock while a tone is being sounded will develop a conditioned emotional

response (showing freezing and other signs of fear) when the tone is sounded again.

These effects are not confined to laboratory animals – the phobias (strong, seemingly irrational fears) exhibited by some people are plausibly interpreted as being the consequences of emotional conditioning that occurred early in life.

Instrumental (or Operant) Conditioning

If a hungry rat happens to perform some action, such as pressing a lever, that results in the delivery of a pellet of food, its behavior will change so that the rate at which it performs this action will increase. This form of learning is referred to as conditioning, but it differs from Pavlovian conditioning in that the paired events are an action performed by the animal and an environmental event, rather than two environmental events. It is called 'operant' because the animal operates upon its environment to produce an effect, or 'instrumental' because the animal's behavior is instrumental in producing that effect.

Other combinations of action and consequence will also produce learning. A response that removes the animal from a set of circumstances in which aversive events have previously occurred will tend to increase in frequency (a phenomenon known as avoidance learning); a response that is followed by an aversive consequence (as when a lever press produces an electric shock) will tend to decrease in frequency (a phenomenon known as punishment). The general principle underlying these forms of learning is that the likelihood of occurrence of a given form of behavior will be determined by the consequences that have followed that behavior in the past. Although the events that serve as rewards and punishments may be more subtle, it seems likely that much of our everyday behavior is governed by this principle – indeed, according to the American psychologist B. F. Skinner, operant conditioning is solely responsible for shaping all of the behavior that we conventionally refer to as 'voluntary'. (*See* **Reinforcement Learning: A Computational Perspective**)

Discrimination Learning

In discrimination learning, the subject learns to respond in different ways to different stimuli. A pigeon that receives food after pecking at a green disk but not after pecking at a red disk shows this form of learning as it comes to choose the green exclusively. Human subjects show the same sort of ability when they are required to sort a pack of cards, putting all those that bear a triangle (say) into one pile and all those that bear a circle into another.

The stimuli used in discrimination learning experiments may be much more complex than in these examples. In one study, pigeons were rewarded for pecking at each of 40 different pictures of oak leaves but not for pecking at pictures of other leaves. They not only solved the discrimination problem but also showed positive transfer when a new set of pictures of oak leaves replaced those used in initial training.

In this form of discrimination learning, the animal shows an ability to respond differentially according to the category to which the stimulus belongs. Category learning has been much investigated in our own species, for instance in studies of the way in which medical students become able to assign a particular disease name to the varying clusters of symptoms shown by individual patients. (*See* **Concept Learning and Categorization: Models**)

Perceptual Learning

Expert wine tasters are said to be able to make fine discriminations (e.g. distinguishing, by taste, between the top and bottom halves of a bottle) that are impossible for the rest of us. This ability is learned, depending on long experience of the relevant stimuli. The facilitation of discrimination by prior exposure to the stimuli has also been shown in laboratory studies. In one experiment, rats were exposed for many days in their home cages to cut-out geometrical shapes (triangles and circles). No explicit training was given at this stage; but when subsequently the animals were required to learn a discrimination in which one shape was associated with food and the other not, they were able to learn the task very readily. Thus, mere exposure to stimuli can modify the way in which they are perceived, making similar events more discriminable. This phenomenon is known as perceptual learning. (*See* **Perceptual Learning**)

Observational Learning

In one study, children were allowed to watch an adult behaving in an aggressive way towards a toy doll. Just watching was enough to produce learning, as was evidenced by the fact that the children subsequently repeated some of the actions of the adult and also behaved in a violent way to a range of other toys.

Learning by watching others may be a general phenomenon. An adult rhesus monkey confronted

by a snake (or a model of one) will show a characteristic set of fear responses; these responses are not normally shown by a laboratory-raised infant. But if the infant is allowed to watch its mother show the fear response, the infant will come to acquire the reaction.

Imitation constitutes a special case of observational learning in which an observer acquires some new skill from watching it being exhibited by a more competent demonstrator. Young primates who learn how to tackle some novel food may do so by imitating their elders. To some extent their performance may simply reflect the fact that the behavior of the demonstrator has drawn the attention of the observer to the relevant food object; but when the observer is seen to make use of the specific pattern of movement used by the demonstrator, true imitation may justifiably be inferred.

Verbal Learning

For the experimental investigation of learning in people, words (written or spoken) provide a convenient stimulus material. Verbal learning has been extensively studied. (*See* **Word Learning**)

A variety of procedures have been used. In the paired-associate procedure, the subject is exposed to a series of pairs of (usually unrelated) words. Learning is evidenced as the subject develops the ability to respond with the second word of the pair when presented just with the first.

In serial list learning, the subject is presented with a string of, say, 12 words, each being exposed for a few seconds before the next takes its place. With sufficient training the subject will acquire the ability not only to recall the items in the list but to put them in the correct serial order.

In one version of the procedure known as priming, subjects are presented in the training phase with a set of names of common objects. Later they are tested with questions for which the names of objects from the first list might be appropriate answers. Although the subjects may profess no memory of the original list, they are more likely to respond with an item from that list than are subjects not given the initial training (e.g. if 'ostrich' was in the first list they are likely to respond with this, rather than the more usual responses of 'canary' or 'sparrow', when asked to name a bird).

TYPES OF LEARNING

We have distinguished the examples of learning listed above largely in terms of their procedural or descriptive characteristics. Although these distinctions may be pragmatically useful, we may ask whether the various examples can be understood in terms of a smaller number of basic 'types' of learning that differ at a more fundamental level (in the mechanisms that produce them). This question has been vigorously debated since the early twentieth century, and has yet to be fully resolved.

Associative Learning

An extreme view, espoused by Pavlov himself, is that there is only one type of learning: that the process revealed by the Pavlovian conditioning procedure lies at the heart of all other examples of learning. This process was regarded by Pavlov as involving association formation, i.e. the formation of a newly functional link between the brain center that responded to the conditioned stimulus (CS) and the center sensitive to the unconditioned stimulus (US). This link was assumed to allow presentation of the CS to evoke activity in the US center – and thus to evoke behavior appropriate to the US (e.g. salivation to a light that had previously been paired with food) – even in the absence of the US itself.

Pavlov did not explain how such a process might result in, for example, the acquisition of a motor skill or the formation of a new concept; but in the absence of any well-specified alternative, it is difficult to rule out the possibility that the apparent complexity of these examples of learning might derive from the operation of a fundamentally simple associative mechanism.

The strongest arguments against Pavlov's unitary view came from those psychologists who studied another, seemingly simple, example of learning in laboratory animals, namely, instrumental learning. The essential feature of this procedure – that learning depends on the effect produced by the response – appears to have no parallel in Pavlovian conditioning. It was argued, therefore, that the two forms of learning depended on fundamentally different mechanisms: reward-produced strengthening of the response, in the instrumental case, and association formation produced by the contiguous occurrence of two stimuli in the Pavlovian case. It was further suggested that these two processes might operate selectively on different response systems: that Pavlovian conditioning works for simple reflex responses, whereas the modification of voluntary behavior depends on the instrumental learning process.

The distinction has, however, proved difficult to maintain given more recent demonstrations of the

instrumental conditioning of involuntary responses and of the fact that supposedly voluntary behavior (e.g. that shown by an animal in moving about its environment) can be modified by classical conditioning. The consensus now is that both are examples of associative learning, differing only in the nature of the events that become associated: two stimuli in the Pavlovian case; a response and its outcome in the instrumental case.

The notion that associations form between events that co-occur (be they neutral stimuli, motivationally significant events such as the delivery of food, or patterns of behavior emitted by the animal) provides a powerful explanatory tool that can be applied not only to classical and instrumental conditioning but to several others of the examples of learning given above. In discrimination learning, for instance, when the pigeon chooses one stimulus rather than another, this may simply reflect the fact that one has become associated with food and the other with the absence of food. The observational learning shown by an infant monkey may be interpreted as the formation of an association between the originally neutral stimulus and the aversive state engendered by the sight of its mother in distress.

In general, the fact that so many examples of learning involve presenting the animal with conjunctions of events makes the associative principle a plausible candidate for the explanation of all of them. But there remain examples in which learning occurs after exposure to just a single event (the most obvious cases are habituation and priming, but perceptual learning is also relevant here). It is difficult to see how associative mechanisms could be responsible for the behavior change seen in these procedures. We may therefore need to acknowledge the existence of at least two types of learning: associative learning (by which the animal learns what goes with what) and a nonassociative form of learning that allows the animal to learn something about the characteristics of an event to which it is exposed.

Implicit and Explicit Learning

Another distinction between different types of learning (which cuts across the distinction between associative and nonassociative learning) has recently been the subject of much attention. This is the distinction between explicit and implicit learning. When normal adult humans learn, they can often report the results of their learning verbally (they can tell you that, as a result of experience, they know that canaries are birds or that fire is hot). Sometimes they can report the details of a particular learning episode (they can tell you what they did on their twenty-first birthday). But not all learning is explicit in this way. Some people who have suffered damage to certain parts of the brain seem unable to acquire new facts or recall recent events from their everyday life. But although they may deny all knowledge of the episodes responsible, they are still capable of some forms of learning: they will show improvement when given practice at a new motor skill (e.g. learning to trace a pattern that is viewed only in a mirror); and they are sensitive to standard conditioning procedures (e.g. they will tend to blink to a neutral stimulus that has been paired with a puff of air to the eye). (*See* **Implicit Learning**)

Implicit learning phenomena are not confined to amnesic patients. The phenomenon of priming, described above, is a laboratory-based example. But anyone who practises a motor skill (as when learning to ride a bicycle) is likely to show an improvement from one session of training to the next while remaining largely unaware of the changed patterns of muscular coordination that produce the improvement (try explaining to a beginner exactly what he or she needs to do to ensure that the bicycle remains upright). And much of the learning that occurs as we acquire our native language remains implicit. Given a set of word strings we are usually able to distinguish those that are permitted by the rules of the language (those that are grammatical) from those that are not, even when we cannot specify the formal rules that justify the distinction. The learning of so-called artificial grammars may involve the same process. For example, people may be exposed to strings of letters that appear random but are in fact constrained by certain rules (e.g. when a J occurs it must always be followed by a V or an X, W can never be followed by itself). The subjects are not told these rules, and indeed are incapable of stating them, but nonetheless they prove able to make correct categorizations of new instances. (*See* **Motor Learning Models**; **Language Acquisition and Language Change**)

The importance of the distinction between implicit and explicit learning remains a matter of debate. One problem with the distinction is that it rests on the observation that the experimenter is unable to obtain from the subjects a verbal statement of what they have learned. Such a failure might be the fault of the experimenter rather than of the subject. Recent work has shown that in some cases more subtle interrogation will allow subjects to make explicit information that simpler questions (and the subject's own initial introspection) fail to reveal.

Secondly, even if it could be firmly established that some forms of learning produce changes that are truly implicit, this would not necessarily imply that the mechanisms involved are fundamentally different from those involved in explicit learning. We would still want to know why some of our memories are available to the conscious mind and some are not, but the difference between them might have no bearing on the nature of the physiological or psychological processes by which memories are formed.

MECHANISMS OF LEARNING

Neural Mechanisms

The changes that constitute learning almost certainly occur in the animal's nervous system; and one approach to investigating mechanisms of learning is to try to determine the nature of the neural processes involved. The dominant hypothesis (put forward by the eminent neuropsychologist D. O. Hebb in 1949 on the basis of very little evidence) has been that learning consists of a change in the properties of synapses (the structures by which one nerve cell makes contact with another). Hebb's proposal was that experience might render a nonfunctional synapse functional, so that activity in one nerve cell would become capable of inducing activity in another. (*See* **Hebb, Donald Olding**; **Hebb Synapses: Modeling of Neuronal Selectivity**; **Synaptic Plasticity, Mechanisms of**)

Recent work, principally on the simple forms of learning (e.g. Pavlovian conditioning) exhibited by invertebrates, has confirmed the validity of Hebb's conjecture, at least for the cases studied. In the mollusc *Aplysia*, the sensory neuron (nerve cell) that is sensitive to a touch on a structure known as the siphon makes a synapse with the motor neuron responsible for contraction of the gill. A light touch on the siphon is not usually enough in itself to excite the motor neuron and evoke the response. But pairing the touch with a more effective stimulus (a shock to the tail) produces a change in the synapse (a phenomenon known as presynaptic facilitation) so that a light touch now produces more neurotransmitter and gill contraction occurs. (*See* **Learning in Simple Organisms**)

An effect known as long-term potentiation provides evidence of synaptic plasticity in the mammalian brain. This phenomenon concerns the case in which two neurons (*A* and *B*) both have synapses with a third (*C*). Strong activation of one input (say *A*) will produce a near-permanent increase in the sensitivity of *C* to this input; and if *B* is activated (even if only weakly) at the same time as *A* is being strongly activated, the potentiation effect will spread to *B* so that it to will become more able to evoke activity in *C*. Direct links between this neural process and overt behavior have yet to be established; but there is a clear parallel with Pavlovian conditioning, which also depends on pairings of two stimuli, only one of which is initially capable of evoking the target response. (*See* **Long-term Potentiation, Discovery of**; **Long-term Potentiation and Long-term Depression**)

A Conceptual Nervous System

Although our knowledge of the neural mechanisms responsible for learning is still very incomplete, the psychological analysis of the phenomenon is relatively advanced. Such analysis proceeds by studying, usually in contrived laboratory preparations, how the nature of what an animal learns, and how readily this learning occurs, can vary according to conditions manipulated by the experimenter. It is possible to make deductions about the mechanisms that must be operating in order to produce the behavioral data obtained. The aim is to provide a specification of what has sometimes been called a 'conceptual nervous system'. The properties of this system will, it is hoped, be consistent with what we know about the functioning of the real nervous system; but the specification is usually given in rather general terms, as a high-level design for a machine that could just as readily be made of silicon and copper wire as of nervous tissue.

In fact, there is a widely accepted picture of the conceptual nervous system that fits very well with what we know of the functioning of the real nervous system. Many psychologists, who have approached the study of learning from a variety of different perspectives, have converged on the view that the mechanism responsible for learning should be viewed as consisting of a large set (a network) of interconnected units. Units may be inactive, or they may be activated to varying degrees, and activity in one unit will engender activity in another unit with which it has a functional connection. Learning is held to consist of changes in the strengths of connections, and thus of changes in the ease with which one unit can modulate activity in its neighbor. Within this scheme, the psychological analysis of learning consists in determining the nature of the units, their pattern of connections, and, most importantly, specifying the factors that determine how connection strengths will change.

These general principles (often referred to as connectionism) have been applied with some

success to a wide range of cognitive phenomena that involve complex information processing. But an appreciation of how they work may best be obtained by considering a simple form of learning such as Pavlovian conditioning. Pavlovian conditioning involves pairings of a CS with a US that evokes a UR. We begin by postulating sensory units, which are activated by presentation of the appropriate stimuli, and an output unit, whose activity generates the response. The US unit must be assumed to be unconditionally connected to the UR unit. The acquired ability of the CS to evoke a response is taken to indicate the formation of a new functional connection. The obvious hypothesis that a connection is formed between the CS unit and the UR unit has not been supported by experiments: conditioning has been demonstrated when the training conditions are such as to preclude the occurrence of the UR. This and other observations have led to the conclusion that Pavlovian conditioning reflects the formation of a connection that allows activity in the CS unit to engender activity in the US unit. (*See* **Connectionism**)

Other cases of conditioning require an associative structure more complex than the 'two units, one link' structure that serves for simple acquisition. For example, animals given training in which the US is paired with a compound stimulus (*A* and *B* presented together) along with separate presentations of *A* and *B* that are not accompanied by the US, will learn to respond just to the compound and not to the individual stimuli. One possible explanation of this accomplishment assumes a structure in which the units sensitive to presentations of *A* and *B* have connections with a third unit, which is activated when it receives inputs from both *A* and *B* (i.e. when the compound is presented). The strengthening of a connection between this third unit and the unit representing the US allows the animal to learn the discrimination and show a response to the compound stimulus. The presence of such hidden units (which are not directly activated by environmental events, but serve a purely computational function) greatly increases the explanatory power of the associative network. Networks employing such units have been applied to complex learning phenomena, such as category learning, with some success. (*See* **Bayesian and Computational Learning Theory**)

Laws of Association

The proposal that experience can produce changes in the strengths of the connections between units is central to the idea of this conceptual nervous system. Therefore, for a proper account of the mechanisms of learning we need to be able to state the conditions under which such changes will occur. A version of this question has engaged the minds of philosophers for several centuries; and they have proposed a variety of possible laws of association (principles determining the readiness with which one idea is able to 'call up' another). Examples include the law of contiguity (the principle that events that occur together in time and space will become associated) and the law of similarity (the principle that similar events are more likely to become associated than dissimilar events). Experimental study of these proposals has made use of simple learning preparations (particularly of Pavlovian conditioning) in which the nature and timing of the events to be associated can be easily manipulated. The magnitude of the response evoked by the CS is used as an index of the strength of the association that is formed under various conditions.

Conditioning experiments have largely confirmed the importance of contiguity. The conditioned response develops most readily when the CS and the US are presented close together. This supports the assumption that an excitatory connection will be strengthened when the units representing these stimuli are active concurrently. But contiguity may be neither necessary nor sufficient for learning to occur.

That contiguity may not be necessary for association formation is illustrated by the fact that in flavor aversion learning, nausea induced several hours after an animal has tasted a novel food will be effective in establishing some measure of aversion to that food. But whether this observation constitutes a fundamental challenge to the contiguity principle is not clear. Conditioning is readily established in more orthodox procedures when there is a short delay (of a second or two) between the CS and the US; and this observation is readily explained by supposing that the activity induced in the CS unit will persist for some time after the CS itself has ended. There is no reason why the same analysis should not be applied to the case of flavor aversion learning. Admittedly, the residual activity in the unit representing the taste of food is likely to be at a rather low level after an hour or so; but if there is any activity at all (and it is difficult to see how an association could be formed if there were not), then the principle of contiguity can be maintained.

It should be noted, however, that such long-delay learning is readily obtained only with certain combinations of events (such as taste and

nausea – indeed, it is difficult to establish any association at all with nausea as the US when the CS is an exteroceptive cue such as the sounding of a tone). The special ability of taste and nausea to become associated even over a long delay may indicate that another principle, in addition to the contiguity principle, is operating in this case. One hypothesis is that events concerned with maintaining the internal state of an animal have special propensity to become associated, thus allowing a taste unit that is only weakly activated to form a strong association with the nausea unit. No mechanism that might be responsible for this propensity has been specified. It may be an example of the more general principle that associations form with particular ease when the events to be associated are similar.

That contiguity is not sufficient to produce association formation is well supported by experimental evidence from a variety of procedures. Two examples will be given here. In one experiment, rats were given presentations of a CS that was followed with a certain probability by the US; pairings occurred often enough that a conditioned response was established, indicating that the association had been formed. Other rats received the same treatment except that, for them, further presentations of the US occurred in the interval between CS presentations. The probability of occurrence of the US was the same in the absence of the CS as in its presence. Rats in the latter condition (who received the same number of CS–US pairings as those in the former condition) did not acquire the conditioned response.

The second example comes from a procedure, much studied in recent years, known as blocking. In this, the subject is initially given training in which one CS (*A*) is paired with the US. The subject then receives a further phase of training in which a second CS (*B*) is added, and the compound (*A* and *B*) continues to be paired with the same US. A final test, in which *B* is presented alone, reveals that this stimulus will not evoke the conditioned response: apparently no *B*–US association is formed in these circumstances, in spite of the fact that the subject has been exposed to contiguous presentations of the two events a number of times during the second phase of training.

These two examples seem to show that contiguity is not enough: that conditioning will occur only when the CS supplies information about the likelihood of occurrence of the US. In the first example, learning fails to occur in the condition in which the US is as likely to occur when the CS is absent as when it is present; in the second, the subject fails to learn about a stimulus that supplies no new information about the likelihood that the US will occur (this being fully predicted by the presence of the pretrained stimulus, *A*).

One possible specification of the mechanisms responsible for these effects was proposed by the psychologists R. A. Rescorla and A. R. Wagner in the early 1970s. They accepted that an associative link between CS and US units will be formed when contiguous presentation of these events evokes activity of some sort in the relevant units. They went on to point out that the formation of the link means that presentation of the CS will be able to evoke activity in the US unit in advance of the occurrence of the US itself. Further strengthening of the link, they suggested, will be a function of the discrepancy between the level of activity evoked in the US node by the associative connection and that engendered by the application of the US itself.

This simple discrepancy principle (sometimes called the 'delta rule') proves to have wide explanatory powers. Its application to the phenomenon of blocking runs as follows. In the initial phase of training a strong connection is formed between the unit representing CS *A* and the US unit. This connection continues to be effective during the compound (*A* and *B*) trials, and thus fully activates the US unit during these trials. When *B* is presented, therefore, there is no discrepancy between the level of associatively produced activity and the level of activity produced by the US itself, and no connection involving CS *B* is established.

The essence of associative learning is that initially the organism does not know what the outcome of a given event will be but that with training it comes to do so. Once the relationship is well established there is no need for further learning. The Rescorla–Wagner principle provides a very simple mechanism by which associative learning may be achieved. It has been very widely accepted. This principle (or some version of it) has been a fundamental feature of all subsequent connectionist theories, and has allowed the successful application of these theories to a wide range of learning phenomena. It remains to be established whether these associative mechanisms can be extended to apply (as some psychologists have argued) to all instances of learning.

CONTENTS

Lexical development refers to the rules that children use to understand, produce, and create the meaning of individual words and their combined relationship to one another.

INTRODUCTION

The rapid growth of lexical development during the preschool years is indicated by the addition of at least five words daily to the child's meanings. Acquiring new meanings is a complex developmental stage for young children. For instance, a particular word has many characteristics that establish its meaning, and a child's task is to learn which factors are critical in acquiring the appropriate use of a word. As children learn words and their meanings, they are taking the first steps towards a complex sequence in the development of language. Thus, early lexicon development is a foundation for later language development. As children increase in age, the complexity, variety, and total number of words in their vocabulary increase, as do the individual relationships among words.

LEXICAL DEVELOPMENTAL KNOWLEDGE

Knowledge of lexical development refers to a young child's information concerning objects, people, and events with regard to function and attribute, as well as to the relationships between and among these factors (Bloom and Lahey, 1978; McLean and Snyder-McLean, 1978; Owens, 1996; Rice, 1984; Wells, 1985). For example, the frequency and variety of lexical categories that are present in a child's utterances as they progress from single to multiple word utterances represents important information about the emergence of language form, lexicon content, and the interaction between form and content. Early semantic meanings involve all aspects of language development, that is, syntax, pragmatics, and morphology that children apply to agents, actions, and objects within their vocabulary. One of the most important concepts to realize is that there appears to be semantic, syntactic, and pragmatic overlap in lexical development.

Critically, the semantic content of children's utterances is influenced by both pragmatic and cognitive constraints (Bloom and Lahey, 1978; Owens, 1996; Wells, 1985). Children's earliest words are pure performatives such as 'hi' or 'bye bye' (i.e. the word itself performs the action named) (Menyuk, 1974). Operation of reference follow (Leonard, 1976) includes nomination of substantive words, existence, non-existence, disappearance, recurrence, and negation. However, children are highly individualized and do not all follow the same developmental pattern.

At approximately 18–22 months of age, children have developed the cognitive capacity to separate entities from dynamic states and relationships. This developmental advance is reflected in the content and form of their productive language (Bloom and Lahey, 1978; Owens, 1996). For example, children now begin to combine words and increasingly follow simple word-order patterns in the production of their multiple word utterances that are based on semantic distinctions or 'semantic-syntactic rules' (Bloom and Lahey, 1978). At this level, the utterance 'dere truck' denotes the static location of the truck (i.e. 'the truck is there') – a 'locative state' utterance, whereas the utterance 'my truck' indicates possession or ownership of the truck (i.e. 'the truck belongs to me'), a 'possession' utterance.

Such two-word utterances also may include verbs, as in 'push truck', that designate the semantic category 'action', soon to be expanded into a full subject–verb–complement structure ('me push truck').

One of the first tactics in lexical development is a child's limited and faltering definition of words. That is, the child understands the concept that words have referents in the real world and that words stand for persons, places, objects, events, or things. When acquiring meaning, children tend to match up a set of semantic markers. For example, the semantic markers for the word 'dog' might include 'furry', 'four legs', 'bark', 'wagging tail'. The acquisition of a set of semantic markers for a given word may be described as a process of concept development.

CONCEPT DEVELOPMENT

One of the early developmental concepts that may assist children in acquiring meanings of words is object permanence. Object permanence refers to the understanding that things exist even when we are not currently experiencing them. Children are able have a mental picture of objects, persons, places or things even though these things are not in their immediate presence. If a child understands this basic concept, he or she will come to realize that mom leaving the room does not mean that she has disappeared entirely, but merely that she has disappeared from view.

This process of development can also be observed in the child who uses the word 'car' to refer only to the family's vehicle which is a 'station wagon', indicating a narrow sense of the word 'car'. Over a period of time the child will begin to apply the word to all cars, trucks, and tractors, and soon will label anything with four wheels a 'car'. Now the child's concept of car has become too broad and must be refined. The child will soon learn that there are different names for different types of vehicle.

Nelson (1974) writes that a young child carries around a set of concepts, or organized categories, referring to aspects of the environment. These basic terms consist of nouns, such as the child's own names for pets and family members, names of objects the child relates to directly (e.g. shoe/spoon), names of body parts (e.g. nose, ear), and foods that are liked by the child. As one can see from these samples the concepts are derived from the child's own environmental experiences. These concepts are further developed over time by the influence of the child's caregivers when they respond to the child's use of words; i.e. regarding them as right or wrong.

Eve Clark (1973) reviewed several diary studies, in which parents recorded their children's early communication attempts. The diaries showed that the children's first utterances seem heavily perceptual, i.e. based on sensory characteristics of objects. These organizations of sensory input, or precepts, might be responsible for the kind of overgeneralization of 'car' described above. Clark found that the most frequently used basis for perceptual categories is shape; other relevant attributes of reality include sound, size, movement, texture, and taste. She found no early categories based on color. Clark argued that these perceptual categories are universal: that is regardless of the language being acquired, there is something about children's nonlingusitic experience with the environment, and perhaps about the human sensory system itself, that causes children to organize reality around these characteristics.

SUMMARY

There appears to be disagreement about exactly what kinds of early, nonlinguistic experience lead to the meanings children express in their earliest words. Children's language is not meaningless. In young children, lexical development in context will progress from two-, three- and four-word utterances to more complex adultlike form and content. As the adult/child interactions continue, the child's contribution increases in meaningfulness. Increased vocabulary and relational terms enable the child to sustain and relate conversational-limited topics. Semantic meaning reflects the relations between words and concepts of reality. These aspects of language will change greatly throughout the school years and continue to be challenging to the study of lexical acquisition.

Lexical Ambiguity Resolution

Intermediate article

Cyma Van Petten, University of Arizona, Tucson, Arizona, USA

CONTENTS

Most words have several meanings, yet readers and listeners are able to determine a writer's or speaker's intent from the word's context. Research on the resolution of lexical ambiguity has developed not only theories on how comprehenders settle on a single meaning, but also experimental paradigms for examining this process.

INTRODUCTION

A small number of words in English are lexically ambiguous in that one spelling and/or one pronunciation is associated with two unrelated meanings – for example, 'spoke'. This small set of words has been the topic of hundreds of journal articles and book chapters since 1970. One reason for this great research interest is that almost all other words are 'polysemous' – they have multiple but related senses. Consider 'clear' as in 'passes light' versus 'easy to understand'; 'running' in 'running a marathon' versus 'running for election'; and 'paper' in 'wrapping paper' (substance) versus 'liberal paper' (institution). Britton (1978) reported that 44 percent of a random sample of English words had more than one dictionary definition. The more commonly a word is used, and the longer it has been part of the language, the more meanings it possesses (Zipf, 1945; Lee, 1990). Linguists and psycholinguists have wrestled with the proper treatment of the one-to-many mapping between word forms and word senses (Klein and Murphy, 2001), and many consider ambiguity to be the extreme end of a continuum of polysemy. Studies of ambiguity resolution thus concern a fundamental aspect of comprehension – how readers and listeners identify the contextually appropriate senses of words. Most lexical ambiguity research has been conducted in English, but ambiguity and polysemy also occur in the world's other languages. For example, one-to-many mappings between pronunciations and meanings are prevalent in spoken Chinese (Li, 1998), so that by one count the syllable '*yi*' (with dipping tone) has 90 different meanings in Mandarin (Yip, 2001). (*See* **Lexicon**; **Lexical Semantics**; **Word Meaning, Psychology of**)

MODELS OF AMBIGUITY RESOLUTION

In everyday language use, the meaning of words is clarified by their context. Laboratory studies have focused on how comprehenders use context to arrive at the relevant word sense, and have suggested three different models. The exhaustive access model proposes that comprehenders first activate all possible senses of a word, then use context to select one meaning. The ordered access model suggests that comprehenders initially activate the most common sense of a word, and proceed to less common senses only when the initial meaning does not fit the context. The selective access model suggests that appropriate prior context can direct comprehenders to the relevant meaning of a word immediately. Hybrid models are also possible, for instance that access is selective when the context is strong, but that the most frequent meaning is initially accessed with less constraining context. The following text provides a snapshot of different and often conflicting empirical findings. For a discussion of computational models of lexical ambiguity resolution, the reader is directed to articles by Kawamoto (1993) and Dixon and Twilley (1999).

THE CONTEXT–AMBIGUITY–PROBE PARADIGM

A commonly used paradigm for investigating ambiguity resolution consists of three stimuli: a semantic context biasing one sense of the ambiguity, the ambiguous word, and a probe word. The context may be a single word ('iron bar' versus 'gay bar'), a sentence frame providing semantic context ('She covered the floor of the stable with clean straw') or a sentence frame providing syntactic

context alone ('He needed to change' versus 'He needed some change'). Probe words are related to the contextually relevant sense of the ambiguity, to the irrelevant sense, or to neither (in the last example, 'clothes', 'coins' or 'water'). Responses to the probe word are the critical measure, in particular whether responses to irrelevant probes more closely resemble the relevant or the unrelated condition. Important factors include:

- the amount of time between the ambiguity and the probe
- the nature and strength of the context
- the dependent measure, or how the processing of the probe word is evaluated
- whether the sentence biases the more common (dominant) or less common (subordinate) meaning of the ambiguity (Simpson, 1994).

Two reaction time (RT) tasks are sensitive to semantic relationships: deciding whether a letter string is a word or a nonword (lexical decision time), and reading a written word aloud (naming latency). Table 1 shows a typical pattern of results in the context–ambiguity–probe (CAP) paradigm: when a short time elapses between the ambiguity and probe (around 200 ms), responses to the contextually irrelevant probes are faster than to unrelated words. When a slightly longer time elapses (around 700 ms), responses to the irrelevant probes are equivalent to those elicited by unrelated words (Swinney, 1979). These results have been taken as support for the exhaustive access model. The interpretation is that, when presented quickly enough, contextually irrelevant probes are processed as related because both meanings of the ambiguity are still active. A short time later, the second stage of semantic processing selects the contextually relevant sense of the ambiguity, and the contextually irrelevant probe is now processed as unrelated. (*See* **Language Comprehension, Methodologies for Studying**; **Lexical Access**; **Word Recognition**)

Table 1. Typical reaction time (RT) results from the probe word paradigm. With a short period between onset of the ambiguous word and onset of the probe word, each of the three RTs was significantly different from the other two. This pattern of a three-way difference between conditions is often observed in the probe word paradigm, although the difference between contextually relevant and irrelevant conditions has not been statistically significant in all studies. With the longer period between the stimuli, the RT in the contextually relevant condition was faster than the other two conditions, which were not significantly different. Data from Van Petten and Kutas (1987)

	Mean naming latency time (ms)	
Probe type	*200 ms SOA*	*700 ms SOA*
Contextually relevant	591 (73)	547 (71)
Contextually irrelevant	617 (77)	562 (69)
Unrelated	635 (85)	571 (71)

Values are in ms, standard deviation in parentheses. SOA, stimulus onset asynchrony, the time between the onset of the ambiguous word and the onset of the probe word.

Nature and Strength of the Context in the CAP Paradigm

The finding of faster RTs for contextually irrelevant probe words than for unrelated probe words has been replicated many times and serves as the central support for the exhaustive access model. However, two other experimental findings are problematic for this model. The first is that the majority of experiments showing faster RTs in the contextually irrelevant condition compared with the unrelated condition also show that RTs in the contextually irrelevant condition are slower than those in the contextually relevant condition. A gradient of RTs across conditions is incompatible with all three of the major models in their purest forms. One possibility is that one of the major models is true, and that the pattern of contextually relevant < contextually irrelevant < unrelated RTs is due to imperfect stimulus construction. For instance, a proponent of the exhaustive access model might suggest that contextually relevant probes receive additional contextual support directly from the sentence context, as well as from the ambiguity itself, and that the former contribution is of no interest. A proponent of the selective access model might suggest that some portion of the contexts used in a given experiment were, in fact, too weak to count as good contexts for the desired meaning of the ambiguity.

The second experimental finding that precludes accepting the pure version of the exhaustive access model is that some studies have found equivalent RTs for contextually irrelevant and relevant words – results supportive of the selective access model (Tabossi and Zardon, 1993; Simpson, 1994). Many arguments in this research area revolve around defining both the nature and the strength of context which can (sometimes) lead to such results. For instance, Seidenberg *et al*. (1982) suggested a three-way distinction between (1) syntactic context ('a rose' and 'he rose'), (2) single-word associative context (as in 'ship–deck' and 'card–deck'), and (3) more global semantic context which is

neither syntactic nor associative, but created by the overall meaning of a sentence. In this view, contexts of type 2 can indeed yield selective access because they work via direct word-to-word links within the mental lexicon, but contexts of types 1 and 3 are ineffective in blocking exhaustive access. A different view is that it is unnecessary to postulate different forms of context and that overall strength of context is the critical factor: strongly predictive contexts yield selective access, whereas weakly predictive contexts (such as 'a' or 'to') are much the same as no context at all (Paul *et al*., 1992).

The CAP Paradigm and Retroactive Context

Another important issue concerns the logic of the CAP paradigm itself. The standard interpretation of the paradigm is that reaction times to the probe reveal how the ambiguous word was initially interpreted, and that the probe itself has no additional impact. This interpretation assumes that the processing of sequential words is both serial and linear, so that each word can benefit only from what was presented earlier. However, several experiments with unambiguous words have shown that reaction times can be speeded, and error rates reduced, by the presentation of a related word shortly after the target word (Kiger and Glass, 1983; Dark, 1988; Van Petten and Kutas, 1991; Logan and Schulkind, 2000). These retroactive semantic context effects (sometimes called 'backward priming') are best understood in terms of temporal overlap in the processing of two words: if a second item is presented while the first is still being processed, both will benefit from their semantic relationship, much as a simultaneous pair of words are processed more rapidly if related than unrelated. A retroactive-context interpretation of the CAP paradigm suggests that access to a contextually irrelevant meaning is not a spontaneous response to reading an ambiguity, but is instead caused by presentation of the contextually irrelevant probe itself. Although retroactive context effects can clearly occur, the impact of this phenomenon in the CAP paradigm has been contentious (Burgess *et al*., 1989).

Event-related Brain Potential Measures in the CAP Paradigm

An undisputed finding of the CAP paradigm is that the results are sensitive to small differences in the timing of stimulus presentation, so that one appeal of the paradigm is the possibility of tracking the time course of language processing. A dependent measure that is particularly well suited to examining time course is the event-related potential (ERP), a measure of brain electrical activity that can be recorded as participants read or listen for comprehension. The ERP provides a continuous record of brain activity, so that one can describe the temporal onset and offset of experimental effects with some precision. One component of the ERP is sensitive to semantic context. The N400 (a negative voltage peaking 400 ms after stimulus onset) is elicited by all words, but is smaller in amplitude when a word fits with an established semantic context than when it does not (Van Petten and Kutas, 1994). (*See* **Event-related Potentials and Mental Chronometry**)

When a long period between the onset of one stimulus and the next (stimulus onset asynchrony, SOA) is used in the CAP paradigm, both contextually irrelevant and unrelated probe words elicit larger N400s than do contextually related probes (Figure 1a). These long SOA results are a perfect match with the typical pattern of reaction times. With a short SOA, the exhaustive access model predicts a large N400 only for unrelated probes, and equally small N400s for contextually relevant and irrelevant probes. The results in Figure 1b are somewhat different from this prediction. The semantic relationship between ambiguity and probe word influences the ERP beginning at 300 ms after the onset of the probe word. During the initial phase of the context effect, from 300 ms to 500 ms, the ERP to contextually irrelevant probes is similar to the response to completely unrelated words, indicating early access to only the contextually relevant meaning. Only some time later, from 500 ms to 1100 ms, does the contextually irrelevant response grow to resemble the contextually relevant response. This pattern of results is consistent with selective access, combined with a retroactive context effect. The contextually relevant sense of the ambiguity has a head start in influencing probe word processing, but temporal overlap in the processing of the contextually irrelevant sense and its related probe word is visible later.

EYE MOVEMENT MEASURES OF LEXICAL AMBIGUITY RESOLUTION

Gaze durations during reading have also been applied to the problem of ambiguity resolution. Readers generally spend longer fixating words that are contextually unpredictable or low in frequency of use. Gaze duration measures thus offer a naturalistic way of examining a reader's processing difficulty, without the need for an extra reaction

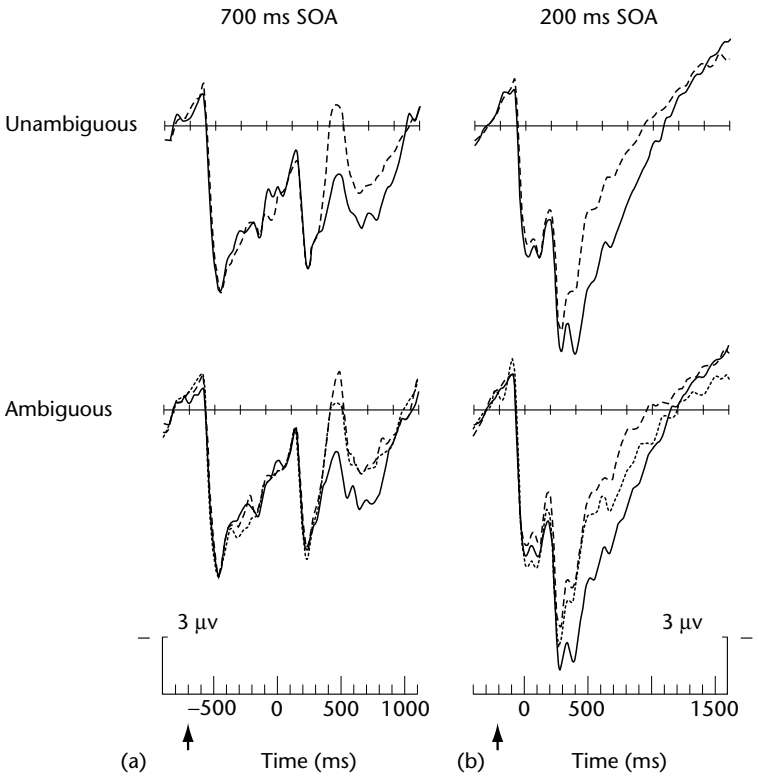

Figure 1. Grand average event-related brain potentials (ERPs) to ambiguous and unambiguous sentence terminal words and subsequent probe words which were unrelated (dashed line), contextually irrelevant (dotted line) or contextually relevant (solid line). Onset of the sentence terminal words is indicated by an arrow; onset of the probe words is at 0 ms. The ERPs were recorded at a midline central scalp site. Stimulus onset asynchrony (SOA) is 700 ms in (a), 200 ms in (b). Data from Van Petten and Kutas (1987); see also Van Petten (1995) for replication.

time task. Because they do not include probe words, these measures thus avoid the possibility of retroactive semantic context effects.

In the absence of prior semantic context, gazes are longer on ambiguous words with two equally strong meanings (balanced homographs) than on unambiguous words, or on homographs with one dominant meaning. If subsequent portions of a sentence favor the subordinate meaning of an unbalanced homograph, readers spend a particularly long time on disambiguating regions. These findings suggest that readers favor the more common sense of an ambiguity on first reading, and must do some extra work if the two meanings are in close competition, or if their initial choice of meaning turns out to be incorrect.

When prior context biases one meaning, gaze durations for balanced homographs are like unambiguous words, indicating that readers no longer suffer a conflict between two equally likely interpretations (an apparent case of selective access). However, when the prior context biases the subordinate sense of an unbalanced homograph, gaze durations are longer on the homograph than on unambiguous words (Pacht and Rayner, 1993). The latter finding suggests that readers may access the dominant meaning despite the context, supporting the ordered access model. However, others have argued that this result depends on relatively weak contexts, and that strong contexts can produce selective access for even subordinate meanings (Kellas and Vu, 1999). Overall, the gaze duration research has lent little support to the exhaustive access model, but has instead indicated that meaning frequency and strength of semantic context are critical factors in determining which (and how many) meanings of ambiguous words are considered by readers.

CONCLUSION

Disagreements in the domain of lexical ambiguity resolution reflect our imperfect understanding of the sequence of events that yields the comprehension of any word. Future language research that sheds light on the nature of semantic relationships

(thus allowing a better quantification of 'context'), and a detailed understanding of the time course of processing from sensory analysis to semantic integration are also likely to clarify how readers and listeners know when 'spoke' means 'part of a wheel' and when it means 'talked'. Linguistic Relativity

Intermediate article

Lera Boroditsky, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA

CONTENTS

Languages differ dramatically from one another in terms of how they describe the world. Does having different ways of describing the world lead speakers of different languages also to have different ways of thinking about the world?

DOES LANGUAGE SHAPE THOUGHT?

Humans communicate with one another using an amazing array of languages, and each language differs from the next in innumerable ways (from obvious differences in pronunciation and vocabulary to more subtle differences in grammar). For example, to say that 'the elephant ate the peanuts' in English, we must include tense – the fact that the event happened in the past. In Mandarin and Indonesian, indicating when the event occurred would be optional and couldn't be included in the verb. In Russian, the verb would need to include tense and also whether the peanut-eater was male or female (though only in the past tense), and whether said peanut-eater ate all of the peanuts or just a portion of them. In Turkish, on the other hand, one would specify (as a suffix on the verb) whether the eating of the peanuts was witnessed or if it was hearsay. It appears that speakers of different languages have to attend to and encode strikingly different aspects of the world in order to use their language properly (Sapir, 1921; Slobin, 1996). Do these quirks of languages affect the way their speakers think about the world? Do English, Mandarin, Russian, and Turkish speakers end up attending to, partitioning, and remembering their experiences differently simply because they speak different languages?

The idea that thought is shaped by language is most commonly associated with the writings of Benjamin Lee Whorf (Whorf, 1956). Whorf, impressed by linguistic diversity, proposed that the categories and distinctions of each language enshrine a way of perceiving, analyzing, and acting in the world. In so far as languages differ, their speakers too should differ in how they perceive and act in objectively similar situations. This strong Whorfian view – that thought and action are entirely determined by language – has long been abandoned in the field. However, definitively answering less deterministic versions of the 'does language shape thought' question has proven to be a very difficult task. Some studies have claimed evidence to the affirmative (e.g. Boroditsky, 2001; Bowerman, 1996; Davidoff *et al*., 1999; Gentner and Imai, 1997; Levinson, 1996; Lucy, 1992; Dehaene *et al*., 1999), while others report evidence to the contrary (e.g. Heider, 1972; Malt *et al*., 1999; Li and Gleitman, 2002).

In recent years, research on linguistic relativity has enjoyed a considerable resurgence, and much new evidence regarding the effects of language on thought has become available. This chapter reviews several lines of evidence regarding the effects of language on people's representations of space, time, substances, and objects.

SPACE

Languages differ considerably in how they describe spatial relations. Many such differences have been noted among English, Dutch, Finnish, Korean, and Spanish, among others (Bowerman, 1996). For example, English distinguishes between putting things into containers ('the apple *in* the bowl', 'the letter *in* the envelope') and putting things onto surfaces ('the apple *on* the table', 'the magnet *on* the refrigerator door'). Cross-cutting this containment/support distinction, Korean distinguishes between tight and loose fit or attachment. For example, putting an apple *in* a bowl requires a different relational term (*nehta*) from putting a letter *in* an envelope (*kitta*), because the first is an example of loose containment and the second an example of tight fit. Further, putting a letter

in an envelope and putting a magnet *on* the refrigerator are both described by *kitta* because both involve close fit.

To test whether these cross-linguistic differences are reflected in the way English and Korean speakers represent spatial relations, McDonough *et al*. (2000) showed scenes involving tight or loose fit to Korean- and English-speaking adults. After they had seen a few examples of either tight fit or loose fit, the subjects were shown an example of tight fit on one screen, and an example of loose fit on another. While Korean-speaking adults looked longer at the kind of spatial relation they had just been familiarized with, English speakers did not distinguish between the tight- and loose-fit scenes, looking equally long at the familiar and novel scenes. Further, when given several examples of tight fit and one example of loose fit (or vice versa), Korean adults could easily pick out the odd picture, but English speakers could not. Finally, McDonough *et al*. found that unlike adult English speakers, prelinguistic infants (being raised in both English-speaking and Korean-speaking households) distinguished between tight and loose fit in the looking-time test described above. This pattern of findings suggests that infants may come ready to attend to any number of spatial distinctions. However, as people learn and use language, the spatial distinctions reinforced by their particular language are the ones that remain salient in their representational repertoire.

Dramatic cross-linguistic differences have also been noted in the way languages describe spatial locations (Levinson, 1996). Whereas most languages (e.g. English, Dutch) rely heavily on relative spatial terms to describe the relative locations of objects (e.g. left/right, front/back), Tzeltal (a Mayan language) relies primarily on absolute reference (a system similar to the English north/south direction system). Spatial locations that are north are said to be downhill, and those south are said to be uphill. This absolute uphill/downhill system is the dominant way to describe spatial relations between objects in Tzeltal; no relational equivalents to the English terms front/back or left/right are available (Levinson, 1996).

To test whether this difference between the two languages has cognitive consequences, Levinson (1996) tested Dutch and Tzeltal speakers in a number of spatial tasks. In one study, participants were seated at a table and an arrow lay in front of them pointing either to the right (north) or to the left (south). They were then rotated 180 degrees to a second table which had two arrows (one pointing to the left (north) and one to the right (south)), and were asked to identify the arrow 'like the one they saw before'. Dutch speakers overwhelmingly chose the 'relative' solution. If the stimulus arrow pointed to the right (and north), Dutch speakers chose the arrow that still pointed to the right (though it now pointed south instead of the original north). Tzeltal speakers did exactly the opposite, overwhelmingly choosing the 'absolute' solution. If the stimulus arrow pointed to the right (and north), Tzeltal speakers chose the arrow that still pointed north (though it now pointed left instead of right). Thus, Tzeltal speakers' heavy reliance on absolute reference in spatial description appears to have affected their interpretation of (and performance on) a nonlinguistic orientation task.

Further studies of this task showed that English speakers (English is the same as Dutch in this respect) do not always favor relative responses; certain contextual factors can be used to induce English speakers to produce both absolute and relative responses on these tasks (Li and Gleitman, 2002). This is not surprising since English speakers use both absolute and relative forms in their language. It remains to be seen whether the same contextual factors can induce Tzeltal speakers to produce relative responses despite an apparent lack of relative terms in Tzeltal.

In summary, the evidence available so far suggests that reference frames and distinctions made available by one's language may indeed impose important constraints on one's spatial thinking.

TIME

Languages also differ from one another on their descriptions of time. While all languages use spatial terms to talk about time ('looking *forward* to a brighter tomorrow', 'proposing theories *ahead* of our time', 'falling *behind* schedule'), different languages use different spatial terms. For example, in English, we predominantly use front/back terms to talk about time. We can talk about the good times *ahead* of us, or the hardships *behind* us. We can move meetings *forward*, push deadlines *back*, and eat dessert *before* we're finished with our vegetables. On the whole, the terms used to order events are the same as those used to describe asymmetric horizontal spatial relations (e.g. 'he took three steps *forward*' or 'the path is *behind* the store'). In Mandarin, front/back spatial metaphors for time are also common (Scott, 1989). Mandarin speakers use the spatial morphemes *qián* (front) and *hòu* (back) to talk about time. What makes Mandarin interesting for present purposes is that Mandarin speakers also systematically use vertical metaphors

to talk about time (Scott, 1989). The spatial morphemes *shàng* (up) and *xià* (down) are frequently used to talk about the order of events, roughly translated into English as *last* and *next*. Earlier events are said to be *shàng* or 'up', and later events are said to be *xià* or 'down'. In summary, both Mandarin and English speakers use horizontal terms to talk about time. In addition, Mandarin speakers commonly use the vertical terms *shàng* and *xià*.

So, do the English and Mandarin ways of talking about time lead to differences in how people think about time? Specifically, are Mandarin speakers more likely to construct vertical timelines to think about time, while English speakers are more likely to construct horizontal timelines? A collection of studies showed that Mandarin speakers tend to think about time vertically even when thinking for English (Boroditsky, 2001). For example, Mandarin speakers were faster to confirm that March comes earlier than April if they had just seen a vertical array of objects than if they had just seen a horizontal array. The reverse was true for English speakers. Another study showed that the extent to which Mandarin–English bilinguals think about time vertically is related to how old they were when they first began to learn English. In another experiment native English speakers were taught to talk about time using vertical spatial terms in a way similar to Mandarin. On a subsequent test, this group of English speakers showed the same bias to think about time vertically as was observed with Mandarin speakers.

This last result suggests two things: (1) language is a powerful tool in shaping thought, and (2) one's native language plays a role in shaping habitual thought (how we tend to think about time, for example) but does not completely determine thought in the strong Whorfian sense (since one can always learn a new way of talking, and with it, a new way of thinking).

SHAPES AND SUBSTANCES

Languages also differ in the extent to which they make a grammatical distinction between objects and substances. For example, in English, objects like candles and chairs have distinct singular and plural forms (e.g. one candle versus two candles), but substances like mud and wax do not. Further, objects and substances are distinguished in English in counting. While one can say 'one candle, two candles, three candles' and so on, counting substances is a bit trickier. Instead of saying 'one mud, two muds', English speakers must specify the unit of measurement such as 'one mound of mud' or 'one cup of mud' (words like 'mound' and 'cup' here are called 'unitizers' because they specify the unit of measurement).

Unlike English, some languages do not have a grammatical boundary between objects and substances. In Yucatec Mayan, for example, all nouns act almost as if they refer to substances. All nouns require a unitizer when counting (usually specifying shape or form, for example 'one long thin unit'), and don't necessarily need to take distinct plural and singular forms (Lucy and Gaskins, 2001). This means that 'two candles' in English is more like 'two long thin units of wax' in Yucatec. Does talking about objects as if they were substances in their language lead Yucatec Mayans to attend more to the materials and substances that comprise the objects? Several studies suggest that this is indeed the case (e.g. Lucy and Gaskins, 2001). English speakers and Yucatec Mayans were shown an example object (e.g. a plastic comb with a handle) and asked to choose which of two other objects was more similar to this example. The two choices varied from the example either in shape (a plastic comb with no handle), or in material (a wooden comb with a handle). English speakers preferred the shape match, saying that the two combs with a handle were more similar (even though they were made of different materials). Yucatec Mayans, on the other hand, preferred the material match, saying that the two plastic combs were more similar (even though they differed in shape). These findings suggest that aspects of grammar can in fact shape the way speakers of a language conceptualize the shapes and materials of objects.

OBJECTS

Finally, languages also differ in how names of objects are grouped into grammatical categories. One such common feature of languages is grammatical gender. Unlike English, many languages have a grammatical gender system whereby all nouns (e.g. penguins, pockets, and toasters) are assigned a gender. Many languages only have masculine and feminine genders, but some also assign neuter, vegetative, and other more obscure genders. When speaking a language with grammatical gender, speakers are required to mark objects as gendered through definite articles and gendered pronouns, and often need to modify adjectives or even verbs to agree in gender with the nouns. Does talking about inanimate objects as if they were masculine or

feminine actually lead people to think of inanimate objects as having a gender?

A recent set of studies suggests that the grammatical genders assigned to objects by a language do indeed influence people's mental representations of objects (Boroditsky *et al*., in press). For example, Spanish and German speakers were asked to rate similarities between pictures of people (males or females) and pictures of objects (the names of which had opposite genders in Spanish and German). Both groups rated grammatically feminine objects to be more similar to females and grammatically masculine objects more similar to males. This was true even though all objects had opposite genders in Spanish and German, the test was completely nonlinguistic (conducted entirely in pictures with instructions given in English), and even when subjects performed the task during a verbal suppression manipulation (which would interfere with their ability to subvocally name the objects in any language). Other studies demonstrated that Spanish and German speakers also ascribe more feminine or more masculine properties to objects depending on their grammatical gender. For example, asked to describe a 'key' (a word masculine in German and feminine in Spanish), German speakers were more likely to use words like 'hard, heavy, jagged, metal, serrated, and useful', while Spanish speakers were more likely to say 'golden, intricate, little, lovely, shiny, and tiny'. To describe a 'bridge', on the other hand, (a word feminine in German and masculine in Spanish), German speakers said 'beautiful, elegant, fragile, peaceful, pretty, and slender', while Spanish speakers said 'big, dangerous, long, strong, sturdy, and towering'. These findings once again indicate that people's thinking about objects is influenced by the grammatical genders their native language assigns to the objects' names. It appears that even a small fluke of grammar (the seemingly arbitrary assignment of a noun to be masculine or feminine) can have an effect on how people think about things in the world.

CONCLUSION

Languages appear to influence many aspects of human cognition: evidence regarding space, time, objects, and substances has been reviewed in this article, but further studies have also found effects of language on people's understanding of numbers, colors, shapes, events, and other minds. Considering the many ways in which languages differ, the findings reviewed here suggest that the private mental lives of people who speak different languages may differ much more than previously thought.

Beyond showing that speakers of different languages think differently, these results suggest that linguistic processes are pervasive in most fundamental domains of thought. That is, it appears that what we normally call 'thinking' is in fact a complex set of collaborations between linguistic and nonlinguistic representations and processes. Further research into linguistic relativity may help uncover the exact nature of the interactions between these many processes in the service of complex cognitive function, as well as help us to establish what might be core or universal in human cognition.

Masking

Intermediate article

Gregory Francis, Purdue University, West Lafayette, Indiana, USA

CONTENTS

Masking refers to a class of phenomena where presentation of one stimulus (the mask) can impair performance on some task that requires judgment about another stimulus (the target).

INTRODUCTION

Visual masking plays two roles in cognitive science. First, masking is used to investigate properties of the visual system. By identifying the way in which the target and mask stimuli influence each other, vision scientists are able to deduce details about the underlying mechanisms involved in visual perception. Second, visual masking is used to indirectly restrict systems involved in information processing of visual stimuli. The logic of this type of approach is that the mask can halt further processing of the target, and one can thereby explore the order and time course of many information-processing systems. A special subset of this approach is based on evidence that persons with various types of cognitive disorders may respond differently from normal subjects under some masking conditions. Thus, masking has been proposed as a simple method for detecting some disorders, and as a means of specifying the underlying mechanisms for those disorders.

FORWARD AND BACKWARD VISUAL MASKING

The distinction between forward and backward masking refers to the presentation order of the target and mask stimuli. In forward masking the mask stimulus onset precedes the target stimulus onset. In backward masking the mask stimulus onset follows the target stimulus onset. Of course, for some combinations of stimulus durations, the mask presentation may both precede the onset of the target and continue after offset of the target. Thus, it is not always appropriate to consider forward and backward masking as entirely distinct; they may contain many similar components. Forward masking is usually weaker than backward masking, and backward masking has more interesting properties and is more useful as a tool for investigating cognitive systems.

Both the target and mask stimuli are usually very brief (often less than 200 milliseconds). Despite its short duration, if the target stimulus is presented by itself, it is clearly visible and it is easy for observers to perform whatever judgment is required of them. What is interesting is that the subsequent presentation of a mask stimulus, even a hundred milliseconds after the target has turned off, can make the observer's task of judging something about the target exceedingly difficult. When this effect was first noted by Stigler (1910), it forced the field of perceptual psychology to realize that processing of visual information took time and could be interrupted. Backward masking has been used to identify details of the perceptual and cognitive processes involved in building percepts and judgments.

Types of Masks

Historically, masking has often been distinguished by the physical characteristics of the mask. For example, with fixed target stimuli and a fixed task (say, identification of a letter as D or O), the mask could be any of a number of stimuli. When the mask consists of a stimulus whose contours surround the target contours, but which does not overlap the target stimulus (e.g. an annulus around the target letter), the mask is called a metacontrast mask. (The term 'metacontrast masking' is more restrictive as it refers only to backward masking and not to a situation where the mask precedes the target, which is called paracontrast.) When the mask contours substantially overlap the contours of the target (e.g. a jumble of oriented lines), the mask is called a pattern mask. A noise mask is similar, but the mask is made of random noise (e.g. black and white dots). Finally, when the mask is a homogeneous field, the masking process is referred to as masking by light.

Pattern masking and metacontrast masking are the most commonly investigated types of masking. The former is often used as a means of curtailing information processing. The latter is often used to explore various properties of the visual system, particularly interactions among systems sensitive to image contours.

Masking Functions

Often the properties of the target and mask stimuli are held fixed, but the stimulus onset asynchrony (SOA) or the interstimulus interval (ISI) between the target and mask is varied. Performance of the observer for a given target-based task is then compared for different SOAs (or ISIs). The resulting set of data is often called a 'masking function'.

The masking function is interesting for two reasons. First, for those studies that use masking as a tool for exploring another cognitive process, it can partially reveal the time course of that process. For example, suppose that the observer's task is to distinguish between target letters D and Q. Suppose that when the mask appears right after offset of the target letter (ISI = 0), observers are simply guessing on the letter identity. Presumably, there is some perceptual or cognitive process that is computing information from the target stimulus. That process takes time, and if the mask interferes with that processing before it is completed, the observer will have to guess the identity of the letter. Thus, larger ISIs between the target and mask should eventually allow the observer to identify the target letter above a chance level. The ISI for which this happens can then, tentatively, be identified as a lower bound for the duration of information processing that limits the observer in this task. A masking function that corresponds to this idea would be monotonic increasing from ISI = 0, and is sometimes called a Type A function.

The second interesting characteristic of the masking function is somewhat problematic for the first. Namely, for some targets, masks, and tasks, the masking function is U-shaped. That is, for short ISIs (or SOAs) the target is clearly seen, and the task fairly easy to perform. For middle-duration ISIs (around 80 milliseconds, but it varies substantially), the target is harder to see and the task difficult to perform. For long-duration ISIs the target is seen and interpreted before the mask arrives, and task performance is again quite good. That going from a short-duration ISI to a medium-duration ISI should cause a larger detrimental effect on the observer's task is interesting because it implies that the effect of the mask is not just to interrupt the processing of the target. If the mask simply interrupted target processing, then increases in ISI would be expected to allow for more processing and so better performance on the task (or at least, not worse performance). But worse performance is what is found experimentally.

The U-shaped masking function is most commonly reported for metacontrast masking. However, U-shaped masking functions have also been reported for masking by light and pattern masking (Stewart and Purcell, 1974). For all types of masks, increasing the intensity, duration, and size of the mask tends to produce a monotonic masking function rather than a U-shaped masking function. It is for this reason that anyone intending to use masking as a means of investigating cognitive processes is advised to use strong masks. However, it remains unclear whether the existence of a monotonic-shaped masking function truly indicates that increases in ISI free various cognitive processes for longer durations.

VISUAL CHANNELS

Classically, there have been two theories of backward masking: interruption and integration. An interruption-based theory supposes that the mask stimulus interrupts the cognitive or perceptual processing of the target stimulus. Since that processing takes time, the appearance of the mask can hinder or weaken the observer's task of judging something about the target. An integration-based theory supposes that the mask and target stimuli are treated as a single combination stimulus, and this makes the observer's judgments about the target alone more difficult. These theories are not generally considered to be competing as a given masking situation may contain both interruption and integration effects. One difficulty in working with these theories is that they are described verbally rather than quantitatively. Without a quantitative specification of some underlying mechanisms, it is difficult to identify which theory is relevant for a given situation.

A more specific dual channel theory has developed out of the recognition that psychological theories of transient and sustained visual channels may be related to the magnocellular and parvocellular visual channels identified in animal neurophysiology (Breitmeyer and Ganz, 1976). This theory posits that the percept of a stimulus is largely related to representation of information in the sustained pathway. This representation tends to develop more slowly and last longer than the

corresponding representation in the transient pathway. Inhibition from the transient pathway to the sustained pathway is hypothesized to be an important mechanism for masking. In a backward masking situation, mask-generated transient signals inhibit target-generated sustained signals. In particular, because of the difference in onset times, the transient inhibition will often most strongly overlap the sustained representation when the target and mask are separated by a positive ISI. This is the basis of the U-shaped masking function. To account for other masking effects, this theory has been elaborated to include sustained–sustained inhibition and sustained–transient inhibition. Breitmeyer and Ögmen (2000) discuss some recent developments in this dual channel theory.

Although many parts of the transient–sustained theory correspond to neurophysiological findings, a full neurophysiological basis for masking remains elusive. This is primarily because neurophysiological studies of masking often find that the mask has no effect, or that the effect of the mask does not correspond to behavioral measures (e.g. Rolls *et al*., 1999).

Masking has been used to explore relationships between conscious and unconscious processing of visual information. Fehrer and Raab (1962) first reported that reaction time for responding to a target stimulus was unaffected by the presence or absence of a mask stimulus, even when the mask was so strong as to cause the observer to claim the target was invisible. This result led to an investigation of unconscious processing, which was hotly debated for many years. Recent work by Klotz and Neumann (1999) now seems to show convincingly that unconscious processing of the target does proceed, even when the mask renders it consciously absent. They demonstrated that a stimulus that was so completely masked that observers could not identify it could still have a priming effect on a subsequently presented stimulus by modifying the observer's reaction time. These results seem to be tantalizingly consistent with a theory of separate visual channels for perception and action (Goodale and Milner, 1992). In this theory, it would be possible for the visual channel related to action to process the target, even though the channel related to perception had its representations masked out. However, priming of masked stimuli seems to exist even when the priming information should be, in the theory, only in the perceptual visual channel (Klotz and Neumann, 1999).

BACKWARD MASKING PSYCHOPATHOLOGY

Some research suggests that backward visual masking may be a trait marker of various pathologies. For example, Merritt *et al*. (1986) showed that schizotypic observers (defined by other tests that suggest a person has a tendency to develop schizophrenic traits) tend to be more susceptible to backward masking than normal subjects or observers with other psychiatric conditions. Similar results are found in schizophrenia patients (e.g., Suslow and Arolt, 1998).

Masking differences between individuals with some disorder or tendency to a disorder and normal subjects have also been noted in studies of reading impairment (e.g., Boden and Brodeur, 1999), bipolar disorder (e.g., Tam *et al*., 1998), Type I diabetes (Muise *et al*., 1997), Alzheimer disease (Cronin-Golomb, 1995), and mania (Green *et al*., 1994).

The general application of masking to a range of disorders reflects the ability of masking to influence a wide variety of different cognitive functions. Thus, when those disorders influence different cognitive abilities, some type of masking study will be likely to reveal those differences.

Mathematical Psychology

Introductory article

Richard A Chechile, Tufts University, Medford, Massachusetts, USA

CONTENTS

Mathematical psychology is broadly defined as the utilization of mathematical and computational modeling methods to measure, describe, and explain psychological processes.

EARLY PROGRESS TOWARDS A MATHEMATICAL PSYCHOLOGY

Gustav Fechner's 1860 psychological treatise was a pioneering demonstration of both mathematical psychology and experimental psychology. However, in the succeeding six decades after Fechner's work, the field of experimental psychology continued to develop, but there was relatively little utilization of mathematical models in psychology. In the 1920s, the field of psychometrics emerged under the leadership of Louis Thurstone, but these models were primarily designed to understand the latent structure of multi-item psychological tests and questionnaires and are different from the type of models that are associated with mathematical psychology. The formal field of mathematical psychology did not develop until after the Second World War.

During the Second World War, a number of psychologists interacted with engineers, physicists, and mathematicians, and this interaction helped foster a desire to create a more rigorous theoretical psychology that employed mathematical methods similar to those used in the physical sciences and in engineering. Moreover, the post-war period saw the development of new branches of applied mathematics such as control theory, cybernetics, information theory, system theory, game theory, and automata theory. These mathematical advances contained great promise for utilization within psychology.

By 1950 a number of psychologists were openly dissatisfied with the prevailing state of scientific psychology, in that it stressed behavioral and empirical fact-gathering within restricted domains of inquiry and did not emphasize the formulation of precise theories to account for experimental findings. There was also a desire to create a theoretical psychology that was different from the test theory emphasis in psychometrics. The pioneers of mathematical psychology in the 1950s sought to develop mathematical and computational models for the psychological processes studied in experimental psychology (e.g. learning, memory, and signal detection).

MATHEMATICAL PSYCHOLOGY AS A DISCIPLINE WITHIN PSYCHOLOGY

In the 1950s, 10 percent of the papers published in the *Psychological Review*, the primary theoretical journal in psychology, represented mathematical psychology research. Also, books appeared that were detailed monographs about mathematical psychology. Starting in the mid-1950s, there were regular summer workshops on the mathematical behavioral sciences held at Stanford University in California, and these meetings helped foster the exchange of information and the development of research collaborations in mathematical psychology. Early in the 1960s, there was an explosion of edited books with high-quality mathematical psychology papers. In 1964, the *Journal of Mathematical Psychology* was initiated with an editorial board of Richard Atkinson, Robert Bush, Clyde Coombs, William Estes, Duncan Luce, William McGill, George Miller, and Patrick Suppes. They selected Richard Atkinson as the first editor. In 1968, the first formal conference on mathematical psychology was held; this annual conference series has continued to the present. After the ninth meeting, an official society was created (the Society for Mathematical Psychology). Consequently, in North America the intellectual infrastructure was in place in the 1960s to support the field of mathematical psychology.

Outside North America, a parallel development in mathematical psychology occurred. In 1965, the *British Journal of Statistical Psychology* changed its name to the *British Journal of Mathematical and Statistical Psychology* in order to reflect the inclusion of mathematical psychology papers along with the more traditional psychometric papers. In 1967, the journal *Mathematical Social Sciences* was founded, with an editorial board including both North American and European social scientists. Furthermore, in 1971 a group of European mathematical psychologists held a conference in Paris. The annual European mathematical psychology meetings have continued to the present, and a number of edited books have ensued from the papers presented at this conference series. Moreover, in 1989 a group of Australian and Asian mathematical psychologists created their own series of research meetings (the Australasian Mathematical Psychology Conference).

RESEARCH IN MATHEMATICAL PSYCHOLOGY

During the 1990s, 39 percent of the papers in *Psychological Review* contained mathematical models. This statistic reflects the salience of mathematical psychology in the primary theoretical journal for psychology. It also reflects a wide range of research within psychology. Because of this breadth, it has not been possible to capture the content of mathematical psychology with any single volume. Researchers have come to specialize within mathematical psychology. Consequently, the research in mathematical psychology is perhaps best described through a series of selected examples of mathematical psychology models. The examples have been chosen to reflect a range of modeling techniques and research topics.

Signal Detection Theory

Signal detection theory (SDT) is perhaps the best known mathematical psychology model, and it is routinely used in experimental psychology. Although there are many variants of SDT, the model that is most widely used is from a seminal book in 1966 by Green and Swets. SDT emerged from the psychophysical framework of detecting a faint stimulus within a noisy background. On each trial of a typical experiment, the observer is presented either with a stimulus embedded in a noisy background or with just the noisy background without the stimulus. On trials where the observer responds positively, the response is either correct (a hit) if the stimulus was actually present or incorrect (a false alarm) if the stimulus is absent. Similarly, if the observer responds negatively, then the person is either correct (a correct rejection) if the stimulus is absent or incorrect (a miss) if the stimulus is present. For faint signals the discrimination is difficult and the responses will depend on the criterion used by the observer. For example, if a person adopts a strict criterion for responding positively, then the observer will commit few false alarms at the cost of missing many stimuli. In general, the data are affected both by the signal strength and by the decision criterion. The goal of SDT is to measure perceived signal strength.

The key concepts involved in SDT are illustrated in Figure 1. It is assumed that there is an underlying strength axis. It is also assumed that even on stimulus-absent trials, there is an activation on the psychological strength axis. The distribution of those responses across all the noise-alone trials is assumed to be characterized by a probability distribution. In the standard model, the probability distribution for the noise-alone condition is assumed to be a normal or Gaussian distribution (i.e. the distribution labeled N in Figure 1 which has mean μ_N and standard deviation σ_N). The noise is due to either random environmental sources or internal neural sources. The second distribution (the one labeled S + N) represents the probability distribution for the stimulus-present trials. It is assumed that the stimulus causes a shift in the underlying response distribution, and it can also cause a change in the standard deviation. The S + N distribution is also assumed to be Gaussian with the mean μ_S and the standard deviation σ_S. The total area under each distribution is 1.0. Areas under portions of a probability distribution correspond to probabilities. The signal sensitivity parameter d'_s is defined as the difference between the two means divided by the average of the standard deviation of the noise distribution and the signal-plus-noise distribution.

Also shown in Figure 1 is a point labeled A on the strength axis. This point represents a decision criterion (i.e. the observer responds positively only if the evoked strength is greater than the strength at point A). The proportion of hits are illustrated by the slanted-dashed section of the S + N distribution that is to the right of A. The proportion of false alarms are illustrated by the horizonal-shaded section of the N distribution (the section to the right of A). As the observer adopts different decision criteria, the hit and false alarm proportions will change accordingly, but the measure of the strength of the stimulus (d'_s) remains constant. It

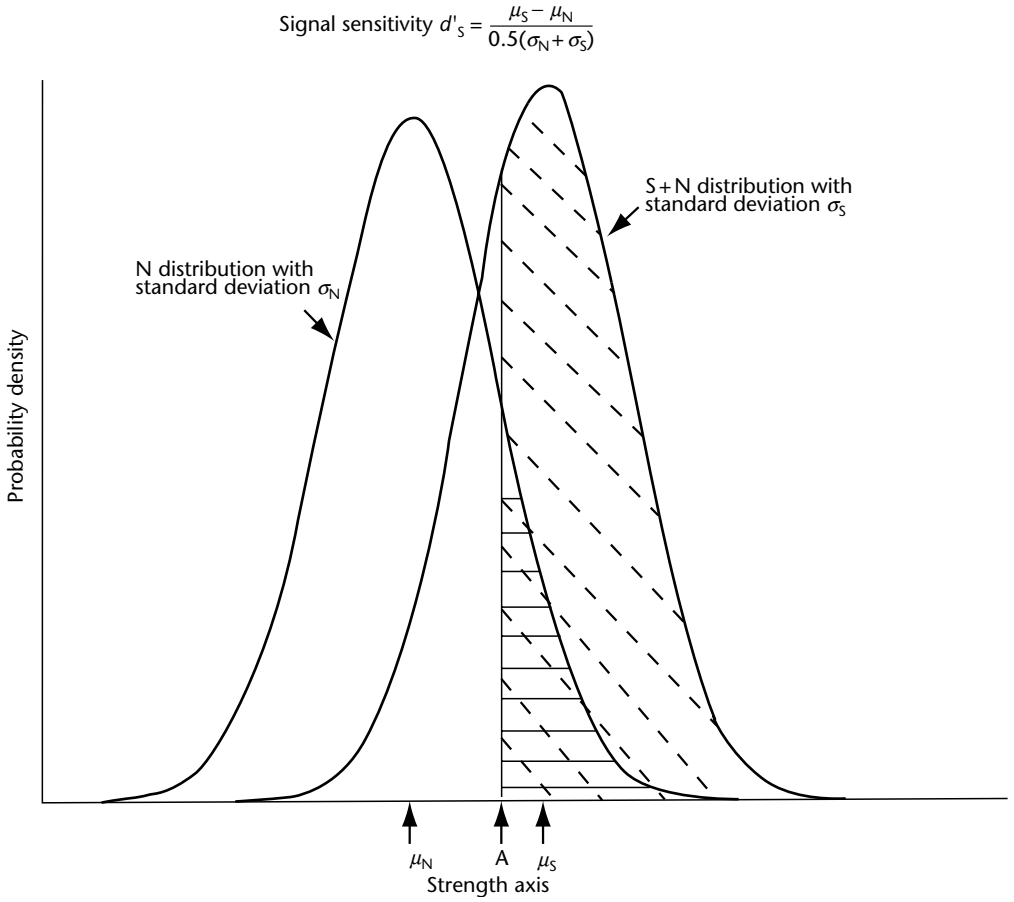

Figure 1. The assumed representation of response distribution according to signal detection theory. N = noise alone, S = stimulus present; μ = mean, σ = standard deviation. Slanted shading represents correct positive responses; horizontal shading represents 'false alarms'.

is possible to estimate both d'_s and the ratio σ_S/σ_N if the experimenter has hit and false-alarm data for more than one decision criterion.

Multinomial Process Tree Models

Multinomial process tree (MPT) models share with signal detection theory the measurement of underlying psychological processes that are not directly measurable. The model parameters are related to psychological processes that determine a set of categorical responses (i.e. the multinomial data structure). The psychological model is a detailed probability tree description as to how the latent processes result in the various proportions for the observed multinomial data. The mathematical psychologist must establish methods for statistically estimating the latent model parameters. William Batchelder and David Riefer have done considerable research on this class of psychological model.

An illustration of a multinomial process tree model is provided in Figure 2. This model is a form of the 1998 model developed by Chechile to obtain separate measures for the probability of sufficient storage, θ_S, and the probability of retrieving a sufficiently stored item from memory, θ_r. Sufficient storage is defined as the state of information representation that would enable the correct recall of the target event, provided that the person could gain access to that information. The probability of sufficient storage is the proportion of times that the memory representation is in this state of sufficient storage. However, even if a memory is sufficiently stored, it may not be recalled because of a problem of memory retrieval.

The model for the estimation of the storage and retrieval probabilities is designed for a very specific task. The participants in a memory experiment are previously shown a series of 'target' items to learn, and at a later time the people are asked to 'free recall' as many of the target items as they can

(a)
Multinomial cells

1	2	3	4	5
correct free recall	correct 4-afc	correct 3-afc	correct 2-afc	incorrect 2-afc

(b)
Tree model in terms of psychological parameters

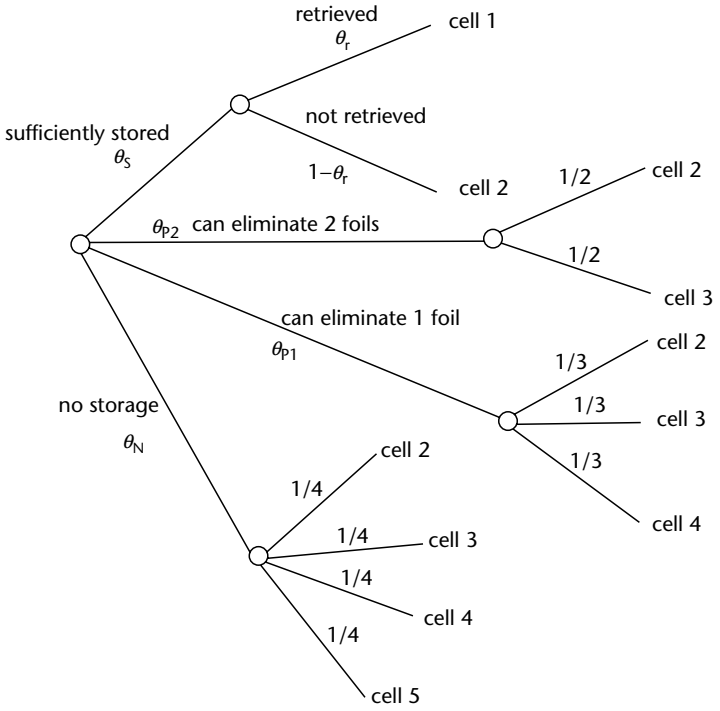

Figure 2. A multinomial process tree. The data representation is illustrated in (a) for the task of recall testing followed by forced choice recognition; (b) shows the latent process tree model for the task in terms of psychological parameters. Parameters are probabilities and are shown on branches of the tree.

remember. If a memory target is correctly recalled, then that is a response in cell 1 of Figure 2(a). After the recall test, the targets that were not recalled are further tested on a four-alternative forced-choice (4-afc) recognition test in which a single target is embedded in a string with three novel items. If a person is correct on the 4-afc task, that would be a response in cell 2 of Figure 2(a). If the person is incorrect, then the wrongly selected item is removed and the person must make a three-alternative forced-choice (3-afc) response. If the person is correct on the 3-afc task, then that is a response in cell 3. However, if the person is incorrect, then there is two-alternative forced-choice test for the last two items.

In Figure 2(b), the process tree for this task is shown. According to the model, the probability of correct free recall (cell 1) can occur only if the target is sufficiently stored with probability θ_S, and successfully retrieved with probability θ_r; hence the proportion of correct free recall is equal to $\theta_S\theta_r$. If the person has no representation of the target whatsoever, an outcome that occurs with probability θ_N, then the person will not be able to recall the target and will have a probability of 1/4 for responding in cells 2 through 5. In this case, where there is absolutely no target knowledge remaining in the memory system, the responses on the recognition tasks are at a pure guessing level. The other two states of insufficient storage shown in Figure 2(b) are related to two levels of partial storage of the target (i.e. being able to have enough knowledge of the target to eliminate two of the three novel items on the 4-afc task with probability θ_{P2} or being able

to eliminate only one of the novel items with probability θ_{P1}). The probability of partial target storage is $\theta_{P2} + \theta_{P1}$. If the target is sufficiently stored but not retrieved, then the person would have incorrect recall but would be correct on the 4-afc task (cell 2). Given data for the number of responses in the various cells of the multinomial, the underlying probabilities for storage, retrieval, partial storage, and no storage probabilities can be estimated, thus providing measures of the underlying psychological processes of interest.

With multinomial process tree models, the model is tightly linked to a specific experimental task. The mathematical psychologist usually must invent a task that provides a means to measure the psychological processes of interest. In the above model, the experimental task was novel and was created by the mathematical psychologist in order to obtain measures of complete as well as partial storage.

Information Processing and Reaction Time Models

Mathematical models have played a central role in the research in psychophysics, information processing, and cognition. Here the investigator is typically interested in explaining features of the dependent measures that are directly observable, such as the person's response time, percentage correct, or the tradeoff of time to complete a task with task accuracy. As with SDT and MPT models, these psychological models arise from a probabilistic framework.

One problem of particular interest is the differentiation between various information-processing architectures, for example, serial models versus parallel models. The differentiation between serial processing (processing one piece of information at a time in stages) and parallel processing (the concurrent processing of information) was a topic of particular interest in the experimental, memory search work by Saul Sternberg in the early 1960s. In experimental psychology, the signature for parallel processing was considered to be a flat reaction time function as task complexity was increased, whereas serial processing was expected to have an increasing time requirement for more complex tasks. The consistent experimental finding of a linearly increasing mean completion time for longer memory searches seemed to settle the matter that memory search was processed in a serial fashion. However, mathematical psychologists pointed out that this conclusion, based on mean response times, was premature. The problem was examined mathematically first in 1973 by James Townsend in a journal article and later in the 1983 book by James Townsend and Gregory Ashby. These analyses pointed out that a flat response time function would occur for parallel systems if the information-processing capacity (computations per unit of time) is unlimited. However, the more realistic assumption is that information-processing capacity is finite, and in this case the discrimination between serial and parallel architectures is more difficult because parallel processing models also require more time for tasks of greater complexity. Townsend and Ashby also showed that it is possible to differentiate between information-processing architectures with sufficiently rich response time data (i.e. examine many features of the response time distribution in addition to the mean task completion time).

Many psychological experiments require the subject to make a choice response; that is, the individual must decide if a stimulus is the same as or different from some reference standard. The statistical properties for the time to give a 'same' response is not equivalent to the time for a 'different' response. Mathematical psychologists have been interested in accounting for the entire response time distribution for each type of response. One successful model for response time was developed in 1975 by Steven Link and Richard Heath, and is called the relative-judgment, random-walk model. In general, random-walk models are characterized by a state variable (a real-value number that reflects the current state of evidence accumulation). The state variable is contained between two barriers. The state variable for the next time increment is the same as the old value plus or minus a random step value. Eventually the 'random walk' of the state variable terminates when the variable reaches either the upper or the lower barrier. The Link and Heath model specifies model parameters for the random walk, such as the location of the two barriers and the probability distribution for the incremental step size. The model results in a host of predictions for the same–different times.

Axiomatic Measurement Theories and Functional Equations

In contrast to the highly specific models that arise from a statistical framework (e.g. SDT and MPT), a great deal of research has also been conducted in mathematical psychology that deals with measurement at a very general level. This research focuses on the necessary and sufficient conditions for a

general type of measurement scale or a form of a functional relationship among variables. In this area of research, a set of general principles or axioms is considered, and the consequences of the assumed axioms are derived. If the theory is not supported, then at least one of the axioms is in error. One way to evaluate a theory is by testing the validity of the essential axioms.

An example of the axiomatic approach is the 1959 choice axiom formulated by Duncan Luce. To further clarify the axiom, let us consider a finite set of alternatives (e.g. potential candidates for a job). If there is a candidate who is never preferred over some another candidate, then that dominated candidate is removed from the set of alternatives because the remaining set of candidates includes the stronger alternative. This process is repeated until all dominated alternatives are removed. The remaining alternatives have pairwise choice probabilities P_{ij} which are neither 0 nor 1 (where P_{ij} denotes the probability that candidate i is preferred over candidate j). The key component of the choice axiom states that the probability that any candidate is preferred is statistically independent of the removal of one of the candidates. Luce shows that this axiom implies that there must exist nonnegative numbers v_i associated with each alternative, and that the choice probability is $v_i/(v_i + v_j)$. Other consequences of the choice axiom were developed by Luce.

Functional equation theory is another formal analysis method that is similar to the axiomatic measure approach. Functional equation theory is a branch of mathematics that dates back to d'Alembert, an eighteenth-century mathematician. In mathematical psychology, functional equation analysis has been utilized to determine, in a principled manner, the form of a mathematical relationship between critical variables. With this approach, theorems are developed that demonstrate that only one mathematical function satisfies a given set of requirements. One classic example of a functional equation analysis in mathematics is referred to as the Cauchy equation, and it is the proof that the only continuous function solution for the stipulation that $\mathrm{f}(x+y) = \mathrm{f}(x) + \mathrm{f}(y)$, where x and y are nonnegative, is $\mathrm{f}(x) = cx$, where c is a constant.

An excellent example in mathematical psychology of a functional equation analysis was provided by Luce. For this example, consider two different stimuli of intensities I and I', respectively, and let $\mathrm{f}(I)$ and $\mathrm{f}(I')$ be the corresponding psychological perception of the stimuli. From a functional equation analysis, if $I/I' = c$, where c is a constant, and if $\mathrm{f}(I)/\mathrm{f}(I') = g(c)$, then $\mathrm{f}(I)$ must be of the form of a power function, i.e. $\mathrm{f}(I) = AI^{\beta}$, where A and β are positive constants that are independent of I. With a functional equation analysis, the results are rationally established without the necessity of curve-fitting and statistical analysis.

Judgment and Decision-making Models

The topics of judgment and decision-making have been the focus of considerable research in mathematical psychology. Much of this work centered on the differences between normative models (i.e. rational models from a mathematical perspective) and descriptive models that characterize more accurately the behavior of individual decision-makers. For example, the perception of the psychological worth (or utility) of gambles is an area where there is a marked discrepancy between normative theory and experimental findings. Utility theory was formulated by the mathematician Daniel Bernoulli in 1738 as a solution to a gambling paradox. Prior to that time, the worth of a gamble was the expected value for the gamble; for example, given a gamble that has a 0.8 probability for a gain of \$10 and a probability of 0.2 for a loss of \$5, the expected value is $0.8(\$10) + (0.2)(-\$5) = \$7$. However, Bernoulli considered a complex gamble that was related to a bet-doubling system and demonstrated that the gamble had infinite expected value. Individuals did not perceive that gamble as having infinite value, and hence the paradox. To resolve this problem, Bernoulli replaced the monetary values with subjective worth numbers for the monetary outcomes – these numbers were called utility values.

In 1944, von Neuman and Morgenstern generated general axioms for an expected utility theory that became a theoretical cornerstone for economics. However, psychologists have provided numerous experimental demonstrations that this theory is not an accurate descriptive theory. In an effort to achieve more realistic theories for the perception of probability and the utility of gambles, mathematical psychologists and theoretical economists have formulated alternative models.

Models of Memory

The modeling of memory has been a vigorous area of research in mathematical psychology. These models typically have a number of parameters, often more parameters than are identifiable in a single condition of an experiment (i.e. given the data for a single condition, it might not be possible to estimate all the model parameters). However,

given values for the model parameters, it would be possible to account for the data obtained in that one condition as well as many other experimental conditions. In fact, a successful model is usually applied across a wide range of experiments and conditions without major changes in parameter values. In 1968, Richard Atkinson and Richard Shiffrin developed a model that explored the short-term retention of information by means of a multiple-store framework (a very short-term sensory register, a short-term store, and a permanent memory store). The model differentiated between hardware features of the memory system, such as the properties of the memory stores, and the strategies or control processes that a person could use with respect to the memory system. This model stimulated considerable research and is one of the best-known models in psychology.

Subsequent memory models have explored more fully the processes associated with recognition memory. One class of recognition memory models has come to be called 'global matching models'. Within this class of models, there are rather different conceptualizations as to the format of information in memory. Array models are a type of global matching model that treat the memory targets as separate *N*-dimensional vectors of attributes. A recognition memory probe activates each existing item in the memory system by an amount that is dependent on the similarity between the two items. For example, in Estes' 1994 array model for classification and recognition, there is a similarity function between any two *N*-dimensional memory vectors. The recognition decision is a function of the total similarity produced by the probe item with all the items in the memory system. In contradistinction to the array models, there are also distributed memory theories that utilize global matching. With distributed memory models, memory is composed of either a single matrix or a single vector. Consequently for the distributed models, there are no separate vectors for various items in memory. For example, in the TODAM (theory of distributed associative memory) model by Bennett Murdock, the totality of memory is contained in a single vector. Recognition is based on a vector function that depends only on the recognition probe and current state of the memory vector. As more items are added to distributed memory, previous item information may be lost.

Neural Network Models

Neural networks research is vast in scope and interest. Mathematical psychologists, such Stephen Grossberg, James McClelland, and David Rumelhart, have played a prominent role in this research area. Neural networks also have wide appeal outside psychology, and important contributions have been made by statisticians, engineers, and physicists.

In general, there is a distinction between real and artificial neural networks. By 'real' neural network is meant a model of brain structures such as the hippocampus, or the visual cortex. Real neural networks have a close linkage with research in neurology and physiological psychology.

Artificial neural networks are distributed computing systems that pass information and change the properties of links and nodes in the network. Artificial neural networks have proven to be valuable as models for learning and pattern recognition. There are many possible arrangements for artificial neural networks (e.g. the number of layers between the input of information and the output level, and the properties for revising linkage weights). A common feature of artificial neural networks is that the memory system is characterized by a large number of separate nodes that process information strictly in terms of information available to the node. These nodes are activated in parallel, but there can be multiple layers of nodes and inhibitory as well as excitatory activation.

Memory Distortions and Forgetting

Intermediate article

Asher Koriat, University of Haifa, Haifa, Israel
Morris Goldsmith, University of Haifa, Haifa, Israel
Ainat Pansky, University of Haifa, Haifa, Israel

CONTENTS

Forgetting refers to the failure to remember specific facts or events that took place in the past. In contrast, memory distortion includes many ways in which what a person does remember can deviate from what actually happened.

INTRODUCTION

Forgetting is perhaps the single most intrinsic aspect of the concept of memory; were there no forgetting, there would be little need for the concept of memory at all. For better or worse, however, forgetting is a ubiquitous phenomenon for all of us.

An influential memory metaphor that was proposed by the philosopher John Locke conceives memory as a storehouse: a place in which thoughts and experiences are initially stored and later retrieved. Such a conception implies a *quantity-oriented* approach to memory, in which the focus is on how much information is retained (remembered) and how much is lost (forgotten). This approach underlies much of the traditional experimental research on memory. More recently, however, a different conception has been gaining prominence, motivated primarily by real-life memory phenomena. In this *correspondence* conception, memory is treated as a representation or description of past events, and interest focuses on the extent to which that description faithfully portrays those events (see Koriat and Goldsmith, 1996a).

The contrast between the storehouse and correspondence conceptions of memory is useful for distinguishing two different notions of forgetting. The quantity-oriented storehouse view leads to a definition of forgetting in terms of omission, that is, the failure to remember specific facts or events. In contrast, the accuracy-oriented, correspondence conception leads to a focus on the many ways in which what a person does remember can deviate from what actually happened. For instance, we might 'remember' events that never occurred or distort those that did occur. In real-life situations, memory distortions are often more serious than omissions. For example, we would not expect an eyewitness to a crime to remember everything that happened at the time. We do, however, want to be able to depend on what he or she *does* report to be correct.

This article outlines and reviews some of what is known about the causes of omission errors, and about several different types of memory distortions.

FORGETTING

The first experimental investigation of forgetting was performed by Hermann Ebbinghaus in the late nineteenth century. Ebbinghaus studied lists of nonsense syllables until he achieved perfect recall, and then tested himself after different retention intervals. The resulting forgetting curves showed a great deal of forgetting within the first few hours after learning, quickly levelling off such that relatively little forgetting occurred thereafter. This basic pattern of decelerated forgetting over time has since been replicated repeatedly for various types of memory materials.

Ebbinghaus's approach implies a storehouse conception in which forgetting is defined as the loss of information over time. Such forgetting can derive from the spontaneous decay or weakening of memory traces, but it can also reflect the temporary inaccessibility of information that is otherwise available in memory. For example, experiments show that items that cannot be recalled at one point in time may be recalled (or recognized) on

subsequent memory tests, indicating that the memory traces of these items were not lost (this is often experienced by students who recall the 'forgotten' answers to exam questions just after leaving the exam room). Similarly, the 'tip-of-the-tongue' phenomenon, in which one feels that one knows the answer to a question (and really does) but is unable to retrieve it, is familiar to all of us. In fact, it is commonly held that the primary cause of forgetting is loss of access to stored information rather than loss of the information itself.

A major factor that can impair memory retrieval is interference. *Retroactive interference* occurs when newly acquired information interferes with the retrieval of previously learned information, whereas *proactive interference* occurs when previously learned information interferes with the acquisition and retrieval of new information. For example, remembering where I parked my car yesterday may impair my memory for where I parked it today (proactive interference) and vice versa (retroactive interference). Interference is especially likely to occur when the new and old pieces of information are similar.

People may also fail to retrieve a piece of information simply because the available retrieval cues are insufficient or ineffective. For example, we might fail to recollect the name of an acquaintance we are about to meet, but then her name may suddenly pop to mind when we see her face. Retrieval is especially likely to fail when retrieval cues do not match the way in which the information was initially encoded into memory, a principle known as 'encoding specificity' (Tulving and Thomson, 1973). For example, we may not recall who 'Debra Johnson' is, but then immediately remember her when a friend prompts us with: 'You know – Debbie!' Similarly, retrieval may also be impaired when the retrieval context differs from the encoding context. Thus, one's memory of an event may be enhanced by returning to the same place (external context) in which it occurred, or by re-experiencing the same mood or state of mind (internal context) that one was in at the time. State-dependent learning implies, for example, that if one were to study for an exam while drunk, it might actually be best to show up drunk to the exam as well!

In addition to the cognitive factors mentioned above, Sigmund Freud emphasized the importance of motivational factors that cause people to actively repress the memory of painful or traumatic personal events. Such repressed memories are held to remain active in the unconscious while being sealed off from consciousness. According to psychoanalytic theory, repressed memories cannot be wilfully retrieved, but they may emerge in the course of psychotherapeutic treatment (see below).

Finally, pathological memory disorders involving brain damage caused by injury or disease can obliterate the ability to recall portions of the person's autobiographical experience or to acquire new information. In *retrograde amnesia* a patient fails to recall past events, whereas in *anterograde amnesia* the patient has difficulty forming new memories.

MEMORY DISTORTION

Although a great deal of what we learn or experience is forgotten, it is perhaps more intriguing that what we do remember is not always veridical. Research on memory distortion and 'false memory' has important implications for real-life issues: for example, to what extent can we trust the memory of a courtroom witness? How reliable is the memory of a childhood traumatic event that is recovered years later in the course of psychotherapy? These questions concern the *accuracy* of what one remembers, rather than the amount.

Two basic principles can be used to explain many memory distortions and false memory phenomena:

1. What people remember depends not only on what actually happened, but also on constructive and reconstructive memory processes that people use to infer what might or should have happened.
2. What people remember depends on their ability to attribute remembered pieces of information to their proper source.

We now present phenomena and findings that illustrate these principles.

Memory Construction/Reconstruction Errors

Bartlett (1932) promoted the view of remembering as a dynamic, goal-directed 'effort after meaning'. Following his lead, a vast amount of research has shown that what is remembered is not simply a reproduction of the original input, but is an active construction or reconstruction based on inference and interpretation processes that are applied to that input – first when the information is initially encoded, and then again when the stored information is later retrieved.

These inference and interpretation processes are guided by one's general knowledge and expectations about the world. For example, one's cognitive

schema or *script* about what typically occurs in a restaurant may lead one to fill in and remember details that did not actually occur: that the host paid the bill, for instance, when in fact he walked out without paying. Such schema-based intrusions reflect a confusion between what one expects and what actually happened.

Reconstructive memory processes can also distort remembered details. Such distortions have been examined extensively in eyewitness research focusing on the effects of *leading questions* (Loftus, 1979). For example, the question 'how fast were the cars going when they *smashed into* each other?' was found to yield significantly higher speed estimates than more neutrally phrased questions, such as 'how fast were the cars going when they *hit* each other?' Apparently, people's memories can be contaminated by implications conveyed in a question's wording. Moreover, when questioned again a week later, witnesses who had previously been asked the leading question were more likely to falsely remember the presence of broken glass than witnesses who had received the more neutral question. In fact, simply using a definite article (e.g. 'Did you see *the* broken headlight?') rather than an indefinite article ('Did you see *a* broken headlight?') can bias witnesses into falsely remembering the specified object or event.

Reconstructive bias need not be externally induced, however. For example, one's current knowledge and beliefs about oneself (self-schemas) can distort one's memory for past beliefs, attitudes, and behaviors, often causing one to remember them as being more compatible with one's current self than they really are.

Finally, another type of reconstructive error derives from people's tendency to remember the general meaning or gist of experienced events rather than their exact details. Consequently, people often report information that is consistent with the gist of an event, though it may be inconsistent with its details. Even when relatively sterile word-list study materials are used, gist-based errors can appear, such as remembering 'canary' or 'bird' when 'sparrow' was actually studied.

Source/Reality Monitoring Errors

Many memory errors stem from a failure to identify correctly the source of retrieved information. For example, we may remember having called the doctor to cancel an appointment, but in fact we only thought about doing so. *Reality monitoring* – the ability to distinguish actual events from fantasy – is a special case of *source monitoring*: the ability to attribute experiences to their proper source (Johnson *et al*., 1993). Source-monitoring errors can result in confusions between details of events that were experienced in one situation and those that took place in another. A dramatic example is an incident that ironically involved a well-known memory researcher, Donald Thomson, who was wrongly identified by a rape victim as the rapist. Thomson's alibi both exonerated him immediately and helped explain the false accusation. He was giving a live television interview at the time of the rape: apparently, the victim had been watching the interview just before she was raped, and confused the memory of his image with that of the rapist. Thus, source-monitoring failures can often be more harmful than retrieval failures: fragments of real experience are accurately and vividly recalled, but are attributed to the wrong person, location, or time, resulting in false memory.

Source-monitoring errors may explain many false-memory phenomena. A prominent example again comes from eyewitness research. Studies indicate that wrong information presented to witnesses after the witnessed event (e.g. a statement or question that erroneously refers to an actual stop sign as a yield sign) can distort their subsequent memory for that event (e.g. remembering having *seen* a yield sign). This phenomenon may derive from deficient source monitoring: the post-event misinformation is more accessible than the original information and is wrongly attributed to the original event.

A second example comes from an experimental paradigm that has attracted much interest recently (Roediger and McDermott, 1995). In this paradigm, subjects study a list of related words (e.g. BED, REST, TIRED, DREAM), all converging on a particular 'lure' word (e.g. SLEEP) that is *not* presented for study. When tested later, the subjects tend to falsely recall or recognize the lure word. Interestingly, subjects are generally quite confident about these false memories, sometimes even claiming to remember the tone of voice in which the (nonpresented) word was spoken! Such errors may result from an incorrect inference regarding why the critical lure feels 'activated' or familiar – with the person misattributing the feeling to memory.

There has been a heated debate over the authenticity of memories of childhood sexual abuse that are recovered in adulthood (often through psychotherapy). The question is whether such recovered memories are accurate recollections that were repressed for years due to their traumatic nature, or were false memories induced during the process of therapy (by repeated imagination or compliance

with the therapist's suggestions). Can people 'remember' entire events that did not occur? Studies indicate that indeed memory for false events can be implanted: subjects who are urged to repeatedly imagine fictional childhood events subsequently tend to remember those events as real, and even provide additional details about them. Thus, people sometimes attribute to reality an episode that was only suggested to them, or only imagined by them, demonstrating extreme cases of faulty reality monitoring.

METACOGNITIVE PROCESSES AND THE PREVENTION OF MEMORY ERRORS

The preceding sections have indicated a variety of ways in which memory can go wrong. When a person has remembered and reported incorrect information, this implies not only a failure of memory, but also of *metamemory* processes; that is, a failure to realize that the remembered information is faulty. Conversely, sometimes information is omitted or 'forgotten' not because the information fails to come to mind, but because the person does not realize that the retrieved information is in fact correct. In this context, metamemory refers to what one knows about one's own memories, and how that knowledge is used to regulate what one reports.

To illustrate, consider a courtroom witness who is sworn to tell 'the whole truth and nothing but the truth'. To fulfill that goal, the witness must try to distinguish between correct and incorrect information that comes to mind, and report only (and all of) the correct information. The attempt to regulate one's memory reporting in order to provide as much information as possible but to avoid reporting wrong information seems to be an intrinsic aspect of remembering in real-life situations. Two types of strategic control over memory reporting have been examined (see Goldsmith *et al*., 2002; Koriat and Goldsmith, 1996b). The first, *report option*, involves the decision whether to report a remembered piece of information or to withhold it (e.g. to reply 'I don't know'). People tend to avoid reporting information that they feel unsure about, which generally enhances the accuracy of what they report, but may reduce the amount of correct information (i.e. increase omission errors) if people mistakenly screen out correct answers. Importantly, both the accuracy benefits and the quantity costs that ensue from the option of free report depend on two metacognitive factors: (a) monitoring effectiveness – people's ability to monitor the correctness of the information that comes to mind, and (b) control policy – the strictness or liberality of the confidence criterion that is set for volunteering answers.

Many of the cues that people use to monitor their memories have to do with source and reality monitoring (Johnson *et al*., 1993). Memories of witnessed events tend to be more vivid and include more perceptual detail than imagined events. Thus, people may utilize a *distinctiveness heuristic* to screen out false memories (Schacter *et al*., 1999), based on the awareness that the memory of true events should include recollection of distinctive details. Also, when the demands for accuracy are strong, the person may deliberately recruit additional corroborative information that helps verify the source of the retrieved events, or adopt a relatively strict criterion for reporting the information.

A second way in which rememberers regulate the amount and accuracy of the information that they report is by controlling the *grain size* of their answers, choosing a level of precision or coarseness at which they are unlikely to be wrong. Instead of reporting that the accident occurred precisely at 5:21 p.m. (which is likely to be wrong), one may choose to report that it occurred between 5:00 and 5:30, or even 'sometime in the late afternoon' (both of which are more likely to be correct). Of course, coarsely grained answers, though more likely to be correct, generally provide less information than more precise answers. Here too, rememberers tend to utilize their monitoring and control processes in a strategic manner, choosing a grain size that represents an expedient compromise between accuracy and informativeness (Goldsmith *et al*., 2002).

CONCLUDING REMARKS: HOW FAULTY IS MEMORY?

The focus on forgetting and memory distortion in this article could leave a pessimistic impression about the general faithfulness of human memory. But is human memory really as flawed as it seems? We think not. First, although some types of memory errors may appear to reflect flaws in the 'system design', they are in fact by-products of otherwise adaptive features of memory. Thus, for example, remembering the gist but forgetting the details of stories and events, or inferring information not actually present in the input, is often what is required in real-life situations. Second, when detrimental memory errors do occur, they appear to derive from the same memory processes that normally lead to accurate remembering. Thus,

although schema-based inferences are sometimes wrong, they are probably more often right – assuming that events that take place in the world ordinarily do agree with our general knowledge and expectations. Although perhaps it is natural for memory researchers to focus on the 'dark' side of memory in attempting to understand the causes of forgetting and distortion, it is amazing how much information people actually do remember, the vast majority of which is correct – or at least useful. Which brings us to one final point. Some of the functions of memory are expressed neither in its quantity nor in its accuracy, but rather, in its personal and social *utility* (Neisser and Winograd, 1988). Thus, for instance, our memories are important vehicles for preserving a sense of self, and in facilitating our interactions with others (e.g. storytelling and reminiscing). Such goals may be achieved despite (and perhaps because of) a certain amount of forgetting and distortion. Current work has begun to address these broader functions of memory, and how they are realized.

Memory: Implicit versus Explicit

Intermediate article

Neil W Mulligan, Southern Methodist University, Dallas, Texas, USA

CONTENTS

Human memory is expressed via conscious recollection (explicit memory) as well as through unconscious changes in behavior (implicit memory). Numerous dissociations indicate that these are distinct forms of memory mediated by different parts of the brain.

INTRODUCTION

We typically use the term 'memory' to refer to our ability to consciously and intentionally recollect past experience. We speak of remembering what we did last weekend or of trying to recall where we left our keys. In his landmark book, *The Principles of Psychology*, William James's definition of memory similarly emphasized conscious recollection:

> Memory… is the knowledge of a former state of mind after it has already once dropped from consciousness; or rather *it is the knowledge of an event*, or fact, of which meantime we have not been thinking, *with the additional consciousness that we have thought or experienced it before*. [italics in original] (James, 1890, p. 648)

However, researchers have also long supposed that memory for prior events can affect behavior even when people are not trying to remember and, indeed, when people are not aware that memory for prior events is operative (James, in his chapter on habit, was not insensitive to this point). Just such a consideration led Ebbinghaus (1885/1964) to develop the savings measure of memory. Ebbinghaus taught himself lists of nonsense syllables (e.g. ZUD) and later attempted to re-learn the same lists, measuring how much more quickly these lists could be learned the second time. This savings measure was designed to measure all memorial influences, not just those that give rise to conscious recollection. In modern psychology, a confluence of results from cognitive psychology, neuropsychology, and cognitive neuroscience has focused attention onto these divergent manifestations of memory, embodied in the distinction between *explicit* and *implicit* memory. Explicit memory refers to intentional or conscious recollection of prior experiences. Implicit memory, in contrast, refers to changes in behavior that are produced by prior experience and are unaccompanied by intentional or conscious recollection. Consequently, implicit memory is frequently described as unintentional or unconscious memory.

Research on anterograde amnesia provided a major impetus for modern interest in implicit memory. Anterograde amnesia was traditionally defined as an inability to retain new experiences coupled with preserved perceptual and intellectual abilities. Having been presented with a new piece of information, amnesics quickly lose the ability to recall it; that is, amnesics have a deficit in explicit memory. However, research in the 1970s and 1980s showed that amnesics are influenced byprior experience when memory is tested implicitly.

An early and very influential demonstration was provided by Warrington and Weiskrantz (1970). In this study, amnesics and normal control subjects were presented with a list of words. Their memory for the words was then tested explicitly, by asking them to recall the words, or implicitly, by asking them to identify fragmented words or to complete word stems (e.g. MET ___) (in which case some of the fragments or stems corresponded to studied words, such as METAL). In the latter tests, subjects were not asked to remember the words, yet the influence of the studied list can be observed by the increased likelihood of responding with studied words. The amnesics recalled many fewer words than the normal control subjects (consistent with the defining definition of the disorder). However, on the fragment and stem completion tests, amnesics demonstrated the same amount of improvement in performance as the normal control subjects. Thus, although deficient in conscious recollection of the past, the amnesics demonstrated an equivalent unconscious influence of past experience.

THE EXPERIMENTAL STUDY OF EXPLICIT AND IMPLICIT MEMORY

The Warrington and Weiskrantz (1970) experiment illustrates the standard approach for studying explicit and implicit memory. The typical memory experiment consists of two parts, a study episode followed by a memory test. In the study episode, the experimental subject is presented with some type of controlled experience, such as a series of words or pictures presented on a computer screen. The subsequent memory test measures how much of the studied information is retained. The memory test is either an explicit test, in which the subject is asked to think back and try to retrieve information about the study episode, or an implicit test, in which the subject is asked to perform a task that is nominally unrelated to the study episode. The operative distinction between explicit and implicit memory tests lies in the task instructions.

Examples of explicit memory tests include free recall, in which the subject is simply asked to report as much as possible about prior events ('Try to recall as many words from the study episode as possible'); cued recall, in which the subject is presented with cues to aid in recall ('Try to recall the name of fruits that were presented during the study episode' after having seen the word 'orange' during the study session); and recognition memory tests, in which the subject is asked to discriminate between previously experienced information and new information ('Which of these words were presented earlier?').

Examples of implicit memory tests include word-stem and word-fragment completion. In these tasks, the subject is presented with a series of word stems (e.g. ora___) or fragments (e.g. '_r_ng_') and asked to complete each with the first appropriate word that comes to mind (e.g. 'orange'). Some of the word stems/fragments correspond to words presented during the study episode and some do not, although the subject is not informed of this relationship. Memory for the study episode is inferred from enhanced performance for the studied words relative to a control set of unstudied words, a measure called *priming*.

DISSOCIATIONS OF EXPLICIT AND IMPLICIT MEMORY

Population Dissociations

The principles that govern performance on explicit and implicit memory tests differ in many ways. Warrington and Weiskrantz (1970) provided a striking example: compared to normal healthy adults, patients with anterograde amnesia are profoundly impaired on tests of explicit memory but show normal or near-normal levels of retention on implicit tests. In this example, the variable of neurological population has different effects on explicit and implicit memory tests, a pattern of results known as a *dissociation*. This dissociation has been observed many times for a number of different explicit and implicit memory tests, implying that conscious, recollective aspects of memory are impaired in organic amnesia, whereas unintentional, unconscious aspects of memory are unaffected by this disorder.

A number of other population dissociations have been reported. When healthy older and younger adults are compared, older adults generally produce worse memory on explicit tests such as recall and recognition. However, older adults often produce the same amount of priming on implicit tests such as word-stem and word-fragment completion. Likewise, patients with depression or schizophrenia have memory deficits in explicit remembering (as compared to healthy control subjects) but produce intact priming. In all of these cases, a population with deficient explicit memory produces normal or near-normal implicit memory.

Functional Dissociations

Experimental manipulations also produce dissociations of explicit and implicit memory tests, providing converging evidence for the separability of these forms of memory and providing insight into functional differences between explicit and implicit memory.

For example, manipulations of attention can produce divergent effects on explicit and implicit tests. In studies of attention and memory, some subjects are presented with a study list under full attention conditions, in which their sole task is to encode the stimuli. Other subjects are presented with the same study list but at the same time must carry out a secondary task, such as listening to a sequence of tones, and categorizing each as high, middle, or low. The secondary task is designed to distract subjects from the study list, reducing their attention to the study stimuli. Subjects in the divided attention condition typically recall or recognize fewer of the study items than subjects in the full attention condition. However, if memory is tested with implicit tests, such as word-fragment completion or perceptual identification, the two groups produce comparable levels of priming (Mulligan, 1998). Thus, dividing attention at encoding dissociates

performance on explicit and implicit tests, impacting performance on the former but not the latter. A similar dissociation is produced by varying the amount of semantic processing during the study episode, which has a marked effect on explicit memory tests (the levels-of-processing effect) but has little or no effect on such implicit memory tests as word-stem completion and perceptual identification.

Conversely, the similarity between the physical (or perceptual) features of the stimuli as presented at the time of study and test has a strong effect on many implicit memory tests but little or no effect on many explicit tests. An example is the effect of study modality. If some of the words on a study list are presented visually and some are presented aurally, later explicit memory for the words is typically unaffected. However, when memory is tested with the implicit tests of word-stem and word-fragment completion, study modality has a large impact; visually presented words lead to more priming than the aurally presented words.

Thus, some variables (divided attention, levels of processing) produce effects on explicit but not implicit tests, whereas other variables (e.g. study modality) produce the opposite pattern, affecting implicit but not explicit tests. Joining these is the read/generate manipulation which can produce directly opposite effects on explicit and implicit memory. This was initially demonstrated by Jacoby (1983) who had subjects either read individual words (e.g. 'cold') out of context ('xxx – cold'), or read words in a meaningful context ('hot – cold'), or generate words from context ('hot – ????'). Subjects' memory for the words was then tested with either an explicit (recognition memory) test or an implicit test (perceptual identification). For recognition, the generated words produced the greatest accuracy followed by words read in context and then words read out of context; this is the traditional finding that generating words leads to superior explicit memory (the generation effect). On the perceptual identification task, the opposite results obtained: reading words out of context produced the most priming, followed by reading words in context. The generate condition produced the least priming.

Pharmacological Dissociations

The benzodiazepines (including alprazolam, triazolam, diazepam, and midazolam) are a class of drugs used in anesthesia and to treat insomnia and anxiety disorders. These drugs also produce a powerful, but temporary and reversible, form of anterograde amnesia, in which information encountered after administration of the drug is poorly remembered. As the drug dosage wears off, so do its amnesic effects. Recent research indicates that these effects are restricted to explicit memory.

In a typical study, one group of subjects was administered a dose of a benzodiazepine (sufficient to affect memory but insufficient to induce stupor or sleep) and a second group was given a placebo. After an absorption period (allowing the drug to take effect in the drug group), both groups were presented with study materials. Following a retention interval sufficient to allow the effects of the drug to wash out, a memory test was administered. Compared to the placebo group, the group given benzodiazepine produced poor explicit memory for the study materials on tests such as free recall (thus evincing amnesia for information encountered while under the effects of the drug). However, if the subjects were presented with an implicit test, such as word-stem or word-fragment completion, then the drug and placebo group produced equivalent levels of priming.

Thus, pharmacological amnesia produces the same type of dissociation as produced by organic amnesia: it affects conscious recollection but appears to have no effect on unconscious influences of memory (see Curran, 2000, for a review).

THEORETICAL FRAMEWORKS

Activation View

An early account attributed implicit memory phenomena to the temporary activation of pre-existing knowledge representations. This view proposed that the initial processing of a stimulus automatically activated representations in long-term memory. Residual activation of these representations increased the probability and decreased the amount of time necessary for these representations to reach a threshold level of activation, at which time the information in the representations would be available in working memory (such as to support responses, decision-making, etc.). Thus, the speed and accuracy of processing would be enhanced for items that had recently been perceived compared with those that had not.

Although initially a viable account, several lines of evidence are contrary to this view. First, the activation view has difficulty accounting for the longevity of priming effects, which can last over periods of days, weeks, or even months. Such a time frame is inconsistent with standard notions of activation which assume that activation returns

to baseline within a period of minutes or hours, not days. Second, priming effects have been obtained for novel stimuli, such as nonsense words and line-drawings of nonsense objects. This is also contrary to the activation view, which predicts that only those stimuli with pre-existing representations (familiar, well-integrated stimuli) should exhibit priming. Third, the perceptual specificity of many priming phenomena (e.g. effects of study modality) appears incompatible with the activation view because this attributes priming to abstract, amodal representations of words and concepts.

Multiple Memory Systems

Neuropsychological and neuroscientific analyses of memory have often emphasized neurally distinct and functionally dissociable memory systems. A familiar distinction is that between short-term (or working) memory and long-term memory, supported by findings that patients with anterograde amnesia exhibit their deficit on delayed (explicit) memory tests but not on immediate memory tests such as digit span. The finding that amnesia dissociates performance on explicit and implicit memory has likewise been interpreted as reflecting the operation of distinct memory systems, in this case extending the fractionation of memory to long-term memory systems. Because anterograde amnesia is typically associated with damage to the hippocampus and medial temporal lobes, it is believed that this part of the brain is necessary for acquiring new experiences in ways that later produce conscious recollection.

Initially, multiple-memory system theories proposed dichotomous memory systems (e.g. declarative versus procedural, episodic versus semantic) to account for explicit and implicit memory, respectively. However, as evidence for dissociable forms of implicit memory mounted, the number of proposed long-term memory systems has increased. The dominant theoretical framework proposes four: episodic memory, semantic memory, the perceptual representation system (PRS), and procedural memory (Schacter *et al*., 2000). Episodic memory stores information about episodes in our personal past, enabling the experience of recollection. Semantic memory stores general knowledge about the world, including facts, conceptual information, and vocabulary. These two systems are sometimes jointly referred to as declarative memory, referring to knowledge that can be verbalized ('knowing that'). The PRS is a perceptual memory system that processes information about the form and structure of words and objects prior to the analysis of their semantic content. Finally, procedural memory represents knowledge of cognitive and motor skills ('knowing how'). Within this framework, explicit memory is assumed to be a product of the episodic memory system, whereas various forms of implicit memory are produced by the other systems.

Under this view, dissociations of implicit and explicit memory tests reflect the operation of distinct memory systems. Population and pharmacological dissociations provide critical support for the existence of multiple memory systems in the brain. For example, anterograde amnesia produces deficits on explicit memory, implying disruption to the episodic memory system, but typically not on verbal implicit memory tests (such as word-stem and word-fragment completion) or on tests of skill-learning, implying that the other systems are not disrupted. Perhaps the strongest support for the multiple-memory systems view is garnered by reports of double dissociations, dissociations in which two different patient groups (with damage to different parts of the brain) exhibit complementary dissociative patterns on implicit and explicit memory tests. For example, amnesic patients (with damage to medial temporal regions of the brain) have disrupted memory on explicit tests but not on implicit tests, as noted. The opposite dissociation occurs in patients with occipital-lobe lesions, who exhibit preserved explicit memory coupled with deficits in implicit memory for visual–perceptual information (Gabrieli *et al*., 1995). This provides strong support for the view that brain systems mediating performance on these two types of tests differ. Similar dissociative patterns support distinctions among the other imputed memory systems (Schacter *et al*., 2000).

Transfer-appropriate Processing

Although population and pharmacological dissociations strongly argue for the operation of multiple memory systems, patterns of functional dissociations have often been interpreted in terms of disparate processing requirements of different memory tests within a single memory system.

The dominant such account is the transfer-appropriate processing (TAP) framework (Jacoby, 1983; Roediger and McDermott, 1993). The TAP framework assumes that performance on a memory test benefits to the extent that cognitive processes carried out during initial learning are re-engaged at test. The TAP framework distinguishes between cognitive processes that are involved in the analysis of meaning (conceptual

processing) and processes that are involved in the analysis of perceptual or surface-level features (perceptual processing). The TAP view assumes that explicit and implicit memory tests often rely differentially on conceptual and perceptual processing, and consequently benefit from different types of initial learning. Many implicit memory tests require identification of degraded or ambiguous perceptual stimuli, such as word fragments, briefly presented words, or fragmented pictures. Under the TAP view, such tests rely heavily on perceptual processing and reflect the similarity between perceptual processes engaged at study and test. On the other hand, explicit memory instructions encourage the re-engagement of conceptual memory processes.

As an illustration, consider the results of Jacoby's (1983) read/generate experiment, reviewed earlier. One can characterize the encoding conditions as varying in the amount of perceptual or conceptual analysis required. Generating a word from a meaningful context requires conceptual processing, but provides no visual information for perceptual processing. Reading a word out of context requires perceptual processing of the word but presumably little conceptual processing. Reading a word in context occupies a middle ground in which both perceptual and conceptual processing contribute. According to the TAP view, encoding conditions that require more perceptual analysis should transfer well to implicit memory tests focusing on perceptual analysis, whereas encoding conditions encouraging conceptual processing should transfer well to explicit tests owing to their reliance on conceptual retrieval processes. The observed results are consistent with these expectations.

The distinction between perceptual and conceptual processing is not coextensive with the distinction between explicit and implicit test instructions. According to the TAP framework, dissociations of explicit and implicit tests are only indirectly attributable to test instructions; it is the memory cues and response requirements in conjunction with the test instructions which determine whether a test primarily re-engages perceptual or conceptual processing. Specifically, if the memory cues are conceptually related to the to-be-retrieved information, then conceptual processes are evoked. If the relationship between cues and responses is perceptual, perceptual processes are evoked. This theoretical view suggests that, with the appropriate choice of memory cues and response requirements, one can develop implicit memory tests which re-engage conceptual processes as well as explicit memory tests which re-engage perceptual processes. For example, consider the category production task. In this task, subjects are presented with the names of taxonomic categories and are asked to produce examples from each category. Examples from some of the categories are presented during the study episode and are consequently produced more often than examples which had not been presented previously, despite the fact that the subject is not informed of the relationship between the test and the study episode. Because the memory cues (the category names) bear a conceptual rather than a perceptual relationship to the target items (the category examples), this task would be an example of a conceptual implicit memory test.

The TAP framework predicts that dissociations are likely to occur between two implicit tests if one is perceptual and the other conceptual, and a number of such dissociations have been reported. For example, study modality affects perceptual implicit tests such as word-stem and word-fragment completion (as noted earlier) but not the conceptual implicit test of category production. Alternatively, levels of processing and divided attention have minimal impact on perceptual tasks such as word-fragment completion and perceptual identification, but produce substantial effects on conceptual priming tasks. Finally, the read/generate manipulation likewise dissociates perceptual and conceptual priming tasks; reading produces more perceptual priming but generating produces more conceptual priming.

The TAP framework enjoys great success accounting for functional dissociations between explicit and implicit tests, and among implicit tests of different types (perceptual and conceptual). Thus, the perceptual–conceptual processing dimension is an important element in accounting for implicit memory phenomena. However, it is unlikely to provide a complete explanation because, as noted by the progenitors of the TAP account, this view does not readily account for the population and pharmacological dissociations so important to the multiple-systems view. In particular, it has been generally found that explicit tests, whether relying on conceptual or perceptual retrieval cues, are affected by anterograde amnesia and drug treatments like the benzodiazepines. In addition, both organic amnesia and drug (benzodiazepine)-induced amnesia produce normal levels of priming on conceptual as well as perceptual implicit tests. Likewise, older compared to younger adults produce generally worse performance on explicit tests coupled with equivalent levels of conceptual and perceptual priming. These dissociations resist explanation in terms of perceptual versus conceptual

processing because, in these cases, perceptual and conceptual tests produce similar rather than different outcomes.

Component-processes Approach and Evidence from Neuroimaging

The complementary successes of multiple memory systems in accounting for population and pharmacological dissociations, and the TAP approach in accounting for functional dissociations, has produced the current view, which emphasizes multiple forms of priming and attempts to articulate the component processes that mediate performance on various memory tasks.

Recent neuroimaging research, using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), has supplemented traditional approaches in pursuing this goal. Neuroimaging techniques are used to elucidate the neural regions involved in explicit and implicit memory tests in normal control subjects. One interesting result is that there is substantial overlap in the active brain regions during explicit and implicit retrieval tasks. Despite this overlap, there are certain hallmarks of explicit and implicit memory.

Studies of explicit retrieval have consistently shown increased activity in anterior frontal (especially right prefrontal) lobe as well as activity in the medial–temporal regions, including the hippocampus. A common interpretation is that activity in the frontal lobe reflects a retrieval mode in which the individual is oriented towards the past and is intentionally trying to retrieve information. The medial–temporal activity is interpreted as reflecting the recollective experience itself, when the memory is successfully retrieved (Nyberg and Cabeza, 2000).

Priming on implicit tests is associated with decreased activity in various brain areas. This is believed to reflect a reduction in processing demands when a stimulus is processed a second time, which in turn produces increased speed and accuracy on the priming task. The brain regions involved depend on whether the implicit test is perceptual or conceptual, consistent with the TAP view. For perceptual tests such as word-stem or word-fragment completion, the decreased processing is found in visual cortex (in the posterior occipital lobe). In contrast, when items are reprocessed on conceptual implicit tests, decreased activity is found in the inferior frontal lobe and mid-temporal lobe. In general, these results imply that the same neural substrates responsible for the initial (perceptual or conceptual) processing are re-engaged at the time of test and exhibit the effects of the initial processing by their subsequent reduced activity.

Memory Mnemonics

Intermediate article

John Best, Eastern Illinois University, Charleston, Illinois, USA

CONTENTS

Mnemonics are techniques that are used to improve both the amount of information that a person might retrieve from memory, and its accuracy. These techniques typically use highly overlearned organizational schemes and visual imagery.

INTRODUCTION

The term 'mnemonics' refers to a class of strategies for organizing material that a person believes he or she will want to retrieve. Thus, they have features in common with strategies used in other domains: their use is always conscious, deliberate, and effortful. The proponents of mnemonics believe, however, that the effort involved in using a mnemonic technique is amply rewarded by ease and accuracy at retrieval time.

Generally speaking, the effectiveness of most mnemonic techniques results from their exploitation of some other characteristic of the human cognitive system. For example, humans have long known they might improve their retrieval by incorporating some type of sensory information into the memory they wish to retrieve. Thus, when we use jingles and nursery rhymes to help us retrieve otherwise abstract things, we are exploiting the fact that the acoustic or phonetic properties of a stimulus can be used to help organize it. Similarly, the power of human imagination, with its ability to create unusual and hard-to-forget visual images, is even more likely to play a role in many formal mnemonic techniques.

Despite some impressive findings, the overall utility of mnemonic techniques has not yet been conclusively demonstrated. Similarly, it is not currently clear whether or not the astonishing feats of memory produced by modern mnemonists have any real implications for existing theories of 'normal' memory.

COMMON MNEMONIC METHODS

Loci

Loci is a Latin term pronounced 'low-sigh' and meaning 'locations' (singular: locus). The 'method of loci' thus refers to the notion of using a sequence of highly overlearned and easily visualized locations as a system for organizing memory stimuli. It is a technique whose origins lie in antiquity: the Greek bards of the fifth century BC used it to organize recitations of many hours' length.

To use this technique, you must know, and be able to visualize, a set of places in the exact order in which you might encounter them. For example, you might visualize the buildings you would encounter on your campus if you were to take a walk from your residence hall to the academic building where your lectures are held. Or, you might visualize the sequence of shops you would encounter at a nearby mall as you walked along one particular corridor. The important elements are that there is only one sequence of events, and that you are positive in your knowledge of that sequence.

To begin the method of loci, you construct a composite image consisting of the first stimulus you want to remember mentally placed in the first location of the sequence. Then you continue in the same fashion until all the elements on the list of stimuli to be learned have been imagined at their respective locations. To retrieve the elements, you 'take a mental walk' through the set of landmarks, mentally scanning the image you created for each landmark, and, if all goes well, retrieving the stimulus that you mentally placed there.

There are some principles that seem to enhance the technique's success. First, the likelihood of retrieval seems to be improved if the to-be-remembered element interacts in some way with the location. For example, if the memory task consisted of retrieving a list of words beginning with 'goat', a composite image of a goat simply standing passively on the doorstep of your residence hall might be less likely to be retrieved than would an image of a goat impatiently butting its head against the door. Some researchers have focused on the novelty, vividness, or 'bizarreness' of the composite image. So an image of a goat dressed up in the

uniform of doorperson, and opening the door for you as you leave your residence hall, might lead to still better retrieval. Neither the interaction nor the bizarreness is crucial for the technique to work, however. Some people experience an apparent loss of content addressability when using the method of loci. If you are like them, you may find that you cannot readily contact the seventh item on the list without mentally going through the first six. If then asked for the fifth item on the list, you may find that you cannot simply 'back up' two places from the seventh item, but rather must restart your mental walk.

Peg Mnemonics

'Peg' mnemonics exploit both the phonetic and imaginal properties of words. The peg is a concrete word that is readily imagined, and the peg word is constant. Each peg word in the system is used because it rhymes with the word for a particular ordinal position.

For example, the readily imagined word 'shoe' rhymes with the ordinal position word 'two', and so the peg word for two is 'shoe'. To learn an arbitrary list of objects that can be placed in an ordinal arrangement, the learner creates an image that incorporates both the object he or she is trying to recall with its associated ordinal position term. In our example, if you had a list of chores to do on Saturday morning, and the second chore involved getting the oil changed in your car, you might create an image of a shoe full of oil.

As with the method of loci, the learner must first master the rhyming list of peg words (Higbee, 1988). For example, the user first encodes the following list of associations:

One is a bun
Two is a shoe
Three is a tree
Four is a door
Five is a hive
Six is sticks
Seven is heaven
Eight is a gate
Nine is a line
Ten is a hen

To remember a set of objects, let's say a grocery list, each item on the list is associated in a visual image with the appropriate peg word. Thus, if the fourth item that you wanted to remember to get was a carton of milk, you might create an image of a door with a milk carton for a doorknocker. It's interesting to note that apparently several lists can be stored 'on' the same set of pegs, similar to hanging up more than one coat on a single peg. In other words, you might be able to remember the list of chores to be done, and the list of grocery items to be purchased, using the same list of peg words as shown above. Currently, it is not clear how our memory system avoids mixing the two lists up, despite the fact that it would seem very likely that such interference would occur.

Imagery

Interactive imagery is a technique that exploits the imaginal properties of words to create a single image in which unrelated elements are pictured together. For example, a person who wanted to remember a short list consisting of three unrelated words, 'farmer', 'cowboy', and 'Arkansas', might create an image of a farmer wearing a cowboy hat and being chased by a pig (that is, a razorback, the nickname of the University of Arkansas athletic teams). Apparently, rather lengthy lists of unrelated words can be retrieved using this technique, and it has an advantage over some other techniques in that much less prior work needs to be done to use it, compared to memorizing a list of peg words.

The creation of images is a common theme in most mnemonic techniques. However, the functional role of imagery in mnemonics continues to be debated. For example, Canellopoulou and Richardson (1998) tested the efficacy of image-based mnemonics in neurologically impaired patients. They found that those individuals who had intact central executive processing systems in working memory were able to profit from using the method of loci in a free recall task, whereas individuals who were impaired in this way were not able to use the method of loci, even when they were given imagery instructions. This finding suggests that it is not the image itself that is really 'doing the work' at retrieval time, but rather the ability of the working memory executive to simultaneously manage all the information that is needed to create the image in the first place.

SITUATIONS WHERE MNEMONIC METHODS ARE APPROPRIATE

Current thinking is that the number of retrieval situations that can be aided by mnemonics is actually rather limited (Searleman and Herrmann, 1994, p. 356). It is the case that the method of loci or a peg-word system can definitely enhance the retrieval of a list of unrelated words, but that is not a task we are often called upon to perform. Further, mnemonic techniques have not been shown to produce

dramatic improvements on the types of tasks we actually do. For example, mnemonic techniques do not generally lead to improvements in retrieving poems, stories, or lines in a play (the performances of the bards notwithstanding), nor do they lead to improved retrieval or execution of a series of physical actions such as in dance, gymnastics, or the playing of a musical instrument.

A finding reported by van Hell and Mahn (1997) is typical. College students who were familiar with the general principles of language learning were given concrete and abstract words to learn either by rote or by an imaginal-based keyword system. Experienced learners learned more of the novel words by rote than they did with the keyword system. This pattern was also observed among novice foreign language learners, with the added disadvantage that more time was required by the mnemonic users to retrieve the words compared to the rote learners.

Even in cases when mnemonic techniques could be used, such as going to the grocery store and retrieving all the items needed to make Thanksgiving dinner, most people find it much easier just to write the items down beforehand rather than burden themselves with learning a mnemonic.

THEORETICAL IMPORT OF MNEMONICS
