CONTENTS

Inducing preferences is a method of creating a laboratory commodity that enables tests of expected utility in both single-person and multi-person economic environments.

TESTING THE PREDICTIVE ABILITY OF ECONOMIC THEORIES

Economic theory attempts to explain the behavior of agents in an economy. There is no stipulation in the theory that these agents are economists, that these agents have been trained in mathematics, or that they have any conscious awareness of the forces that guide their behavior. Rather, agents are assumed to behave 'as if' the tenets of the theory guided their behavior, even though they may be unaware that such forces are at work. (For example, agents may not know their own utility functions.)

Since the 1950s, economics has moved towards being a formal science. Notable advances include the first laboratory demonstrations that the theory of competitive equilibrium, the theory of games, and theories of choice have predictive content (Smith, 1962; Roth and Malouf, 1979; Siegel and Goldstein, 1959). Since expected-utility theory remains a cornerstone of much theorizing, there is a continuing interest in how to test its exact predictions, specifically its predictions of individual choices and prices. The results, while contributing to our understanding of a theory when it performs well, also appear to bear on a related body of research on attention, according to which slight environmental changes (in this case levels of incentives) can alter subjects' attention and thus their decision-making performance.

EXPECTED-UTILITY THEORY

According to expected-utility theory, each economic agent is in a world of uncertainty. Any setting, no matter how simple or complex, can be viewed as consisting of lotteries from which the agent is choosing. The theory is especially useful for describing choices between lotteries with monetary pay-offs. In such cases, it is possible to make two important assessments. Firstly, it is possible to determine, for any two lotteries A and B, whether lottery A is preferred to lottery B; and secondly, it is possible to determine the maximum (or minimum) price at which the individual would buy (or sell) any lottery.

In theorizing about behavior, economists assume that the system of preferences over lotteries can be summarized by a function (the 'utility function') that describes an individual's attitudes towards pay-offs, and that the individual in effect maximizes the expectation of this function. Applying this assumption to knowledge about specific lotteries enables the economist in principle to assess choices and prices.

For example, suppose lottery A represents a 0.5 chance of winning \$5 and a 0.5 chance of winning \$15; and lottery B represents a 0.5 chance of winning \$1 and a 0.5 chance of winning \$20. Suppose that the subject's attitudes toward dollar pay-offs x can be summarized by the utility function $u(x) = \sqrt{x}$. For each gamble, the expected utility will be the sum of the probability-weighted utilities of the pay-offs. Specifically, the expected utility of A is $0.5 \times u(5) + 0.5 \times u(15) = 3.05$, and the expected utility of B is $0.5 \times u(1) + 0.5 \times u(20) = 2.74$. Given that the decision maker maximizes expected utility, lottery A would be chosen over lottery B.

The maximum (minimum) price at which the decision maker would buy (sell) the lottery would be the amount that yields the same utility as the lottery. For lottery A, this amount would be determined by solving the equation $u(x) = \sqrt{x} = 3.05$, i.e., \$9.33. Since the certainty equivalent to the decision maker of the lottery (\$9.33) is less than its expected pay-off ($\$10 = 0.5 \times \$5 + 0.5 \times \$15$), the individual is said to be 'risk-averse'. A certainty

equivalent greater than \$10 would indicate a risk-preferring individual.

HOW TO INDUCE PREFERENCES

The method of inducing preferences (Berg *et al*., 1986; Roth and Malouf, 1979) enables researchers to test in a laboratory virtually any individual choice or equilibrium prediction that derives from expected-utility theory. (In general, an economy is in equilibrium when no agent has an incentive to alter his or her action.) The particular advantage of the inducing technique is that, to predict any subject's choices and prices, the experimenter does not need to learn the subject's utility function.

We will show how, by constructing examples, inducing preferences solves the problem of predicting bids and prices of a subject. The technique requires no assumptions about the subject's utility function except that the subject prefers more money to less.

To predict subjects' choices and prices, we introduce a binary lottery to be played for cash (for definiteness, assume it pays \$0 or \$10), along with a new currency called the 'econo', and a function G, that converts econos to probabilities of winning the binary lottery.

Suppose the subject has to choose between a lottery with a 50 per cent chance of 5 econos and a 50 per cent chance of 15 econos, and a lottery with a 50 per cent chance of 1 econo and a 50 per cent chance of 20 econos. Also assume that the subject's conversion function is given by $G(x) = \sqrt{(x/50)}$, where x represents the number of econos that the subject has after the lottery is played. Figure 1 illustrates one way in which lotteries are presented to subjects using this technique.

Each lottery is presented as a wheel divided into two parts. The proportion of the wheel shaded in a given color is the probability of receiving the number of econos associated with that color.

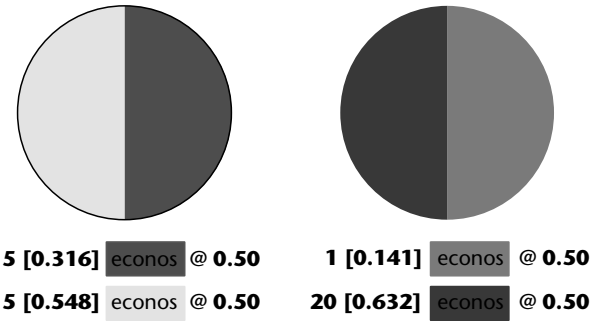

Figure 1. [*Figure is also reproduced in color section.*] A pair of lotteries as presented to subjects in the relative risk-averse condition.

Suppose the subject, with utility function u, considers lottery A. He or she would behave 'as if' going through the following computation. If red came up on the disk, the subject would have a G (5)probability of receiving \$10 and a $(1-G(5))$ probability of winning \$0. The expected utility would then be $G(5)u(\$10) + (1 - G(5))u(\$0)$. Similarly, the expected utility if yellow came up would be $G(15)u(\$10) + (1 - G(\$15))u(\$0)$. Therefore the expected utility of lottery A is $(0.5 \times G(5) + 0.5 \times G(15))u(\$10) + (1 - (0.5 \times G(5) + 0.5 \times G(15)))u(\$0) = 0.432 \times u(\$10) + 0.568 \times u(\$0)$.

A similar computation for lottery B yields $0.387 \times u(\$10) + 0.613 \times u(\$0)$.

Since more dollars are preferred to less, and since under lottery A there is a 0.432 chance of \$10 while in lottery B there is only a 0.387 chance, any individual who obeys expected-utility theory will prefer lottery A to lottery B. Note that this observation holds without the experimenter, or even the subject, knowing what u is.

PREDICTING BOUNDS ON ACCEPTABLE PRICES

Now consider the more difficult problem of predicting maximum (minimum) buying (selling) prices for a subject. (Again, for definiteness, assume that the binary lottery pays \$0 or \$10.) To price lottery A, the decision maker behaves 'as if' determining the price in econos (not dollars) of a lottery that pays off 5 econos with a 50 per cent chance and 15 econos with a 50 per cent chance.

Again, suppose the conversion function is $G(x) = \sqrt{(x/50)}$. The subject's expected utility is $0.432 \times u(\$10) + 0.568 \times u(\$0)$. The value x^* to the subject in econos of lottery A will be the number of econos that yields exactly the same probability of winning \$10 as when lottery A is played. Thus, $\sqrt{(x^*/50)} = 0.432$, or $x^* = 9.33$.

Without knowing the utility function of the subject, we are able to predict the price the subject will pay. Admittedly, the price is in econos; however, if our interest in studying behavior is the pricing process and not the price in dollars then it does not matter whether we are talking about dollars or econos. Since 9.33 is less than 10 (the expected number of econos), we can say that the subject is 'induced' to be risk-averse in econos.

EQUILIBRIUM BEHAVIOR

Much of economics is concerned with equilibrium behavior. By inducing preferences it becomes possible to unambiguously state what the equilibrium

predictions are in a laboratory experiment. By rewarding subjects with the probability of winning a binary lottery, Roth and Malouf (1979) and Cooper *et al*. (1990, 1993) have been able to test the predictive ability of the Nash equilibrium. A Nash equilibrium is one in which no individual agent has an incentive to alter behavior given the actions of the other agents. By mapping outcome–action pairs to probabilities of winning a binary lottery, Berg *et al*. (1992) study how well incentives (getting agents to take desirable actions) are traded off for risk sharing (getting agents to bear risk). By inducing concave functions on econos, Srivastava and O'Brien (1991) are able to ask if laboratory security markets lead to optimal risk sharing. The inducing technique has found application in accounting (Sprinkle, 2000) and marketing (John, 2001).

PERFORMANCE OF THE INDUCING TECHNIQUE

Since its inception, the inducing technique (and slight modifications of it) have been subjected to numerous examinations. One series of studies focused on its applicability in first-price auctions. (In a first-price auction, the highest bidder for an object gets the object at the price he or she bid.) Based on subjects' bids, Cox *et al*. (1984) estimated subjects' utility functions. Usually, subjects are estimated to have convex utility functions (i.e., they are risk-averse) when being paid in dollars. Cox *et al*. found that if subjects were induced to be risk-neutral, the corresponding estimated utility functions were not risk-neutral, but rather risk-averse in econos. These findings have been vigorously debated by Rietz (1993) and by Cox and Oaxaca (1995). Rietz argues that with proper modifications there is some support for inducing, while Cox and Oaxaca contest the ability of the technique to induce risk-neutrality in a majority of subjects.

Several points emerge from these two papers. First, it appears that in assessing predicted auction prices, the induction technique does reasonably well. Second, since to fit many subjects' data Rietz needs to incorporate a constant term, the inducing technique appears not to work for all values that come up in the auction.

It appears that both sets of results are consistent with the idea that the inducing technique works best when subjects are likely to win the auction, or alternatively when the potential gains are higher.

When lotteries are presented as in Figure 1, choices, on average, reflect risk-aversion (risk-preferring) when risk-aversion (risk-preferring) is induced. In pricing tasks, the effect of the induction technique is more variable than in the choice task. In a review paper, Berg *et al*. (2003) show that the variance in the bidding task is highest when penalties from erroneously bidding are lowest.

Selten *et al*. (1999) tried to induce risk neutrality in a nonstrategic setting. Their design involves four experimental treatments that vary in two dimensions: pay-offs are made in econos or in money, and subjects are allowed to request statistical summaries (expected value and mean absolute deviation from expected value). The tasks test the ability of the inducing procedure to mitigate traditional choice biases (the common-ratio effect, the reference-point effect, the preference-reversal effect, and violations of stochastic dominance). Selten *et al*. found that the inducing technique does not mitigate traditional choice biases.

Selten *et al*. do not assess differences in the performance of the lottery technique associated with the differences in expected rewards. Their raw data reveal that there were only three lotteries with high reward conditions. In only three lottery choices was the difference in winning the preferred prize greater than 14 per cent. For these choices, on average only 9 per cent of subjects' choices deviated from the predicted choice. In 70 per cent of all choices in the Selten *et al*. experiment, the expected difference in the probability of winning between the predicted and alternative choice was less than 6 per cent. Thus their data appears consistent with the notion that the level of incentive affects the performance of the technique.

Loomes (1998) further explores the Selten *et al*. result that individuals process probabilistic pay-offs in the same way that they process monetary pay-offs. In the Loomes task, a subject sees a lottery that has a 13/20 chance of outcome A and a 7/20 chance of outcome B. In the monetary task, the subject picks the pay-offs in pounds that he wishes to assign to each outcome (A and B), with the proviso that the sum of the pay-offs be 20 pounds. In the probability task, the subject assigns the probability of winning 20 pounds to outcome A and the probability of winning 20 pounds to outcome B, with the proviso that the probabilities sum to one. In the probability task, the subject will maximize expected utility by assigning probability 1 to the A outcome. However, in the money task, the subject will assign 20 pounds only if he or she is risk-neutral. Given a reasonable distribution of risk types, the distribution should be different in the two tasks. Loomes finds that he cannot identify any difference between performances in the

distribution of outcomes under this task. Like Selten *et al.*, Loomes did not attempt to measure whether the performance of the inducing procedure improved with the level of pay-offs.

THE PRASNIKAR STUDY

Induced Utility Functions

Prasnikar's (2001) study examines what produces variations in performance of the inducing procedure, and shows, as do Berg *et al.*, that conclusions about the inducing technique (paying off in probabilities) should be tempered by a consideration of the reward structure. Prasnikar attempted to induce one of three utility functions. One function reflected constant absolute risk-aversion, another reflected constant absolute risk-preferring, and the third, risk-neutrality. These functions were, respectively:

$$G(x) = \left(1 - e^{-0.07365x}\right)/\left(1 - e^{-0.35}\right) \quad (1)$$

$$G(x) = \left(-1 + e^{0.07365x}\right)/\left(-1 + e^{0.35}\right) \quad (2)$$

$$G(x) = x/50 \quad (3)$$

Estimation

For each induced utility function, Prasnikar asked if the observed responses deviated significantly from the coefficient of risk aversion she attempted to induce (the target). To assess the deviation, each subject's coefficient of risk aversion was estimated using probit analysis, assuming that the subject's utility function for econos was in the constant absolute risk-averse (preferring, relative risk) class. Then Prasnikar asked if the estimated coefficient was within a 95 per cent confidence interval around the target. The results are shown in Table 1. A total of 20 subjects were examined for each of the three utility functions. Estimated coefficients are stated, and the tests to determine if they are significantly different from prediction are presented, for each of the induced coefficients.

The Effect of Different Probabilities of Winning

Much of Prasnikar's study is concerned with determining the circumstances in which the induction technique does not predict. In the design, pairs of lotteries are selected so that the number of pairs of lotteries is evenly distributed from smaller to higher differences in expected rewards (i.e., absolute differences in expected probability between lottery A and lottery B). (In our example, the probability difference was $0.432 - 0.387 = 0.045$.) In Prasnikar's study, the differences in expected probabilities of winning for each choice pair are divided in increments of 5 per cent from 0 per cent to 35 per cent.

The data show a lower chance of making the predicted choice when the difference in expected probabilities between the choices is small. Even when the difference in expected probabilities is high, some subjects do make unpredicted choices. Figure 2 shows the percentage of correct predictions for each level of difference in expected probability of winning. The pattern, whereby predicted lotteries are selected more frequently at higher differences in expected probability than at lower differences, is observed in risk-neutral, risk-averse, and risk-preferring induction categories. For example, at 5 per cent difference in expected probability, subjects selected the predicted lottery in the risk-preferring sample only 37 per cent of the time, and 53 per cent of the time in the risk-averse and risk-neutral samples. The percentages did not change when Prasnikar compared the results of the lottery pair at 10 per cent minus 5 per cent and the lottery pair at 62 per cent minus 57 per cent. When the difference in expected probabilities is greater than or equal to 15 per cent, the chance of selecting the predicted lottery is always above 80 per cent for the risk-averse induced preferences; and it increases to 88 per cent at 30 per cent difference. For the risk-preferring induced behavior, at 15 per cent difference in expected probabilities subjects select the predicted lottery 71 per cent of the time, and if the difference is greater than 25 per cent, the predicted lottery is chosen 86 per cent of the time. Four subjects from the sample of 20 were making unpredicted choices when the difference was greater than or equal to 15 per cent, and when the difference was greater than or equal to 30 per cent there were two subjects who were making unpredicted choices for the risk-averse induced preferences. For the risk-preferring preferences, three subjects were making unpredicted choices for differences greater than 20 per cent.

The Effect of Different Knowledge Levels of Subjects

After completing all choices, each subject was tested to see whether they understood how to calculate the probability of winning the $10 prize in Prasnikar's experiment. (No instructions on computation of compound lotteries are given to subjects in the

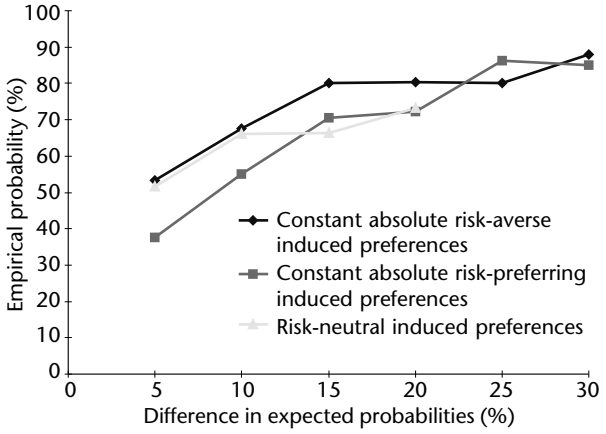

Figure 2. Empirical probability of making the predicted choice, as a function of the difference in expected probabilities (Prasnikar, 2001).

instructions before they finish the experiment.) This test question allows Prasnikar to distinguish subjects with good understanding of compound lotteries.

To identify whether unpredicted choices are related to the knowledge of how to compute the expected probability of winning, empirical frequencies were plotted separately for a sample of subjects who knew and for a sample who did not know how to calculate the expected probability. Figure 3 shows the empirical frequencies for each difference in expected probabilities.

Subjects who knew how to calculate the expected probability were making the predicted choices approximately 10 per cent more often than subjects who did not know how to calculate the expected probability, for risk-averse and risk-neutral induced preferences. At 30 per cent difference in expected probabilities, subjects who knew how to calculate the expected probability made the predicted choice 94 per cent of the time for the risk-averse induced preferences and 86 per cent of the time for risk-preferring induced preferences. Figures 2 and 3 show that the pattern of tendencies to make the predicted choice is similar for the induction of risk-aversion, risk-preference, and risk-neutrality.

The Effect of Natural Preferences

The design of the experiment also permits a test of the relationship of individuals' (natural) risk-aversion for money and the subjects' estimated risk coefficients (shown in Table 1). In theory, the natural risk-aversion for money should not affect the performance of the inducing technique. Prasnikar examines this hypothesis first by plotting the relationship between natural risk-aversion and the estimated coefficients of risk-aversion. Natural risk-aversion is assessed by asking a subject to answer a series of 19 questions in Table 2. Each question asks a subject to assess receiving \$5 for sure versus a p chance of \$10 and $1-p$ chance of \$0, where p varies between 5 per cent and 95 per cent. The minimum p for which the lottery is chosen is an indication of risk-aversion. Higher p is assumed to reflect higher risk-aversion.

Figure 4 shows this relationship for the three induced conditions (risk-averse, risk-preferring, and risk-neutral) with subjects divided into four categories, according to whether they knew how to calculate expected probability and whether their estimated coefficient of risk-aversion is significantly different from the induced coefficient. The horizontal axis represents the values of natural risk-aversion, measured by minimum selected probability p, and the vertical axis represents the estimated coefficients of risk-aversion obtained from Table 1.

In the risk-neutral sample, we find that a subset of players (i.e., subjects whose estimated coefficient is significantly different from the induced coefficient) with lower values of natural risk-aversion have lower values of the estimated coefficient of risk-aversion, while players with higher values of natural risk-aversion have higher values of the estimated coefficient of risk-aversion. A positive relationship between natural risk-aversion and estimated coefficient is also observed for the risk-averse sample.

To test formally for such a relationship, Prasnikar estimated a probit function with the coefficient of risk-aversion β replaced by $\beta_0 + \beta_1 p$, where β_0 measures the effect of induced preferences, β_1 measures the effect of natural risk-aversion, and p is the minimum probability selected by subjects. See Table 3.

Columns 6 and 9 suggest that subjects' decisions were influenced by their natural risk-aversion, and not only by their induced preferences. The estimates of natural risk-aversion – $\beta_1 = -0.078$ for risk-preferring induced preferences, and $\beta_1 = -1.012$ for risk-neutral induced preferences – are statistically significant. The effect of natural risk-aversion ($\beta_1 = 0.081$) for the risk-averse induced preferences

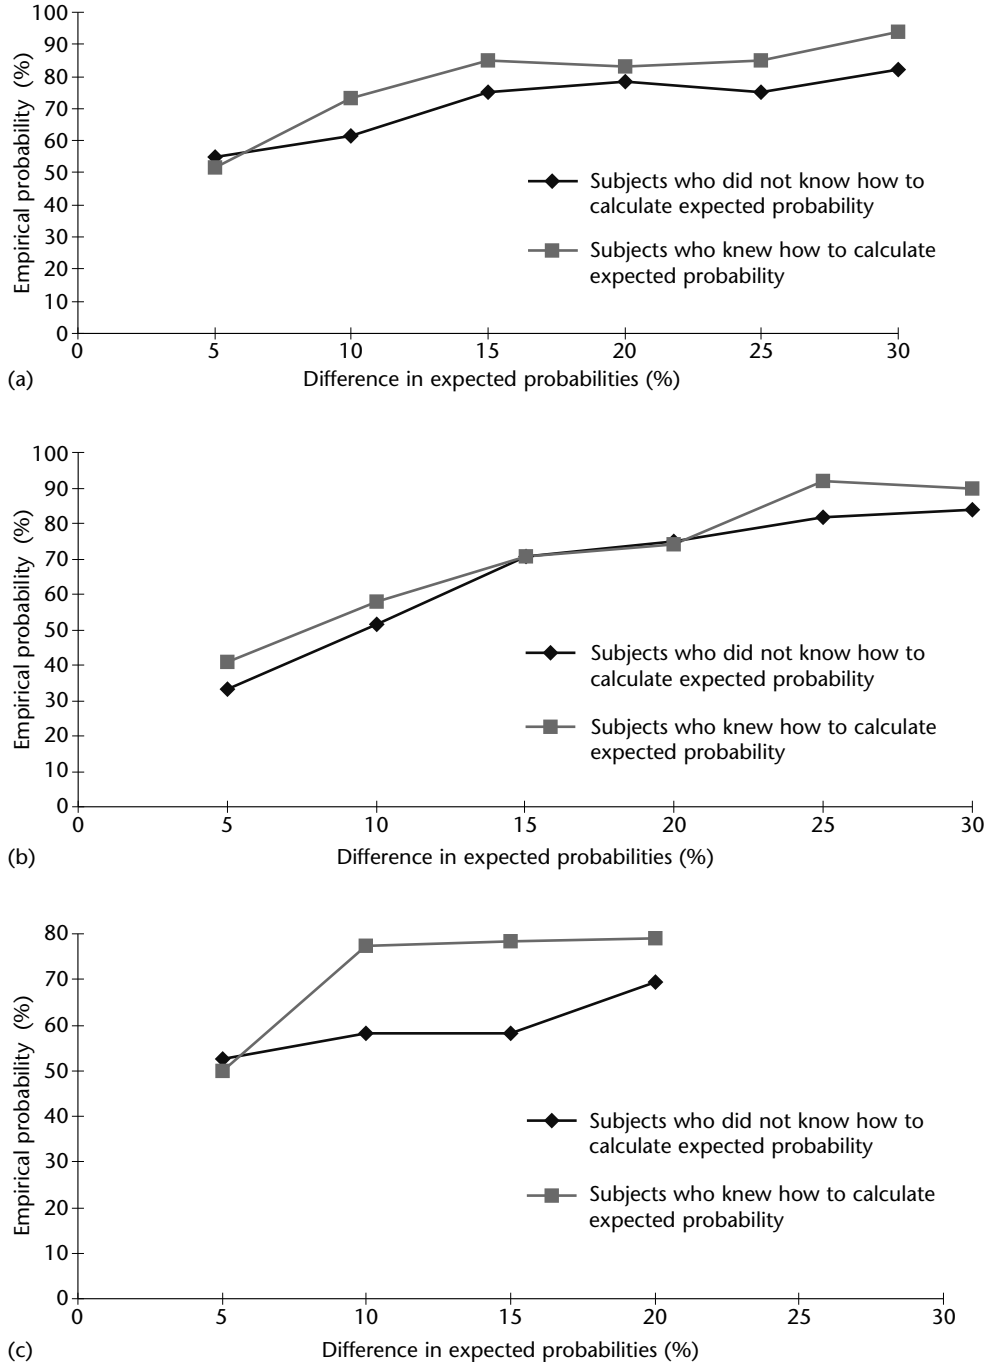

Figure 3. Empirical probability of making the predicted choice, as a function of the difference in expected probabilities for subjects who knew and subjects who did not know how to calculate the expected probability (Prasnikar, 2001). (a) Risk-averse induced preferences. (b) Risk-preferring induced preferences. (c) Risk-neutral induced preferences.

(column 3) is not statistically significant. Therefore the observed relationship between risk preferences and performance of the induction technique was positive; i.e., the higher a subject's natural risk-aversion, the higher was his or her estimated coefficient of risk-aversion for econos.

Interaction of Natural Risk Preferences and Knowledge Level

Next, Prasnikar addresses the question of whether this result represents the behavior of the whole sample, or only subjects who did not know how

Table 2. The sequence of choices given to subjects to test their natural risk-aversion for money

$5.00	for sure	< >	95 per cent	chance for	$10.00	or	$0.00

to calculate the expected probability (squares in Figure 4) or subjects who knew how to calculate the expected probability (circles in Figure 4). She examines these hypotheses by estimating the probit model of the form $\beta = \beta_0 + \beta_1 p$ separately for the subjects who did not know how to calculate the expected probability and the subjects who knew how to calculate the expected probability. The results are reported in Table 4.

For subjects who knew how to calculate the expected probability, Prasnikar finds no evidence that natural risk-aversion (as measured by the minimum probability p) influences the decision making. The estimated coefficient for the natural risk-aversion β_1 is never significantly different from zero for subjects who understand compound lotteries. For subjects who did not know how to calculate the expected probability, the estimates of natural risk-aversion become significant for the risk-preferring and risk-neutral samples. However, in the risk-averse sample the effect of natural risk-aversion is insignificant.

CONCLUSION

The research to date on inducing risk preferences is generally consistent with the hypothesis that the performance of the induction technique depends on the incentives. Simply stated, pay-offs matter. Knowledge of how to calculate joint probabilities affects the performance, but natural risk preferences seem to affect risk preferences only when knowledge of how to calculate joint probabilities is absent. When the differences between expected rewards are small, knowledge does not relate to performance (all subjects make a lot of mistakes). When the difference in expected rewards increases, everybody makes fewer mistakes, and subjects with computational knowledge perform better.

A related interpretation of the results can be based on research on attention. It is generally believed that there is no 'control homunculus', no central agent that allocates attention according to some rational principle; rather, attention can be easily diverted by slight environmental factors (Newell, 1980). Klien and Shore (2000) examined this issue in terms of 'covert' versus 'overt' orienting.

From a rational perspective, the induction technique is independent of the level of incentives; yet by manipulating the incentives we can produce observed results much more consistent with the induction model. It seems reasonable to postulate that the level of incentives changes the orientation and/or attention of the subject.

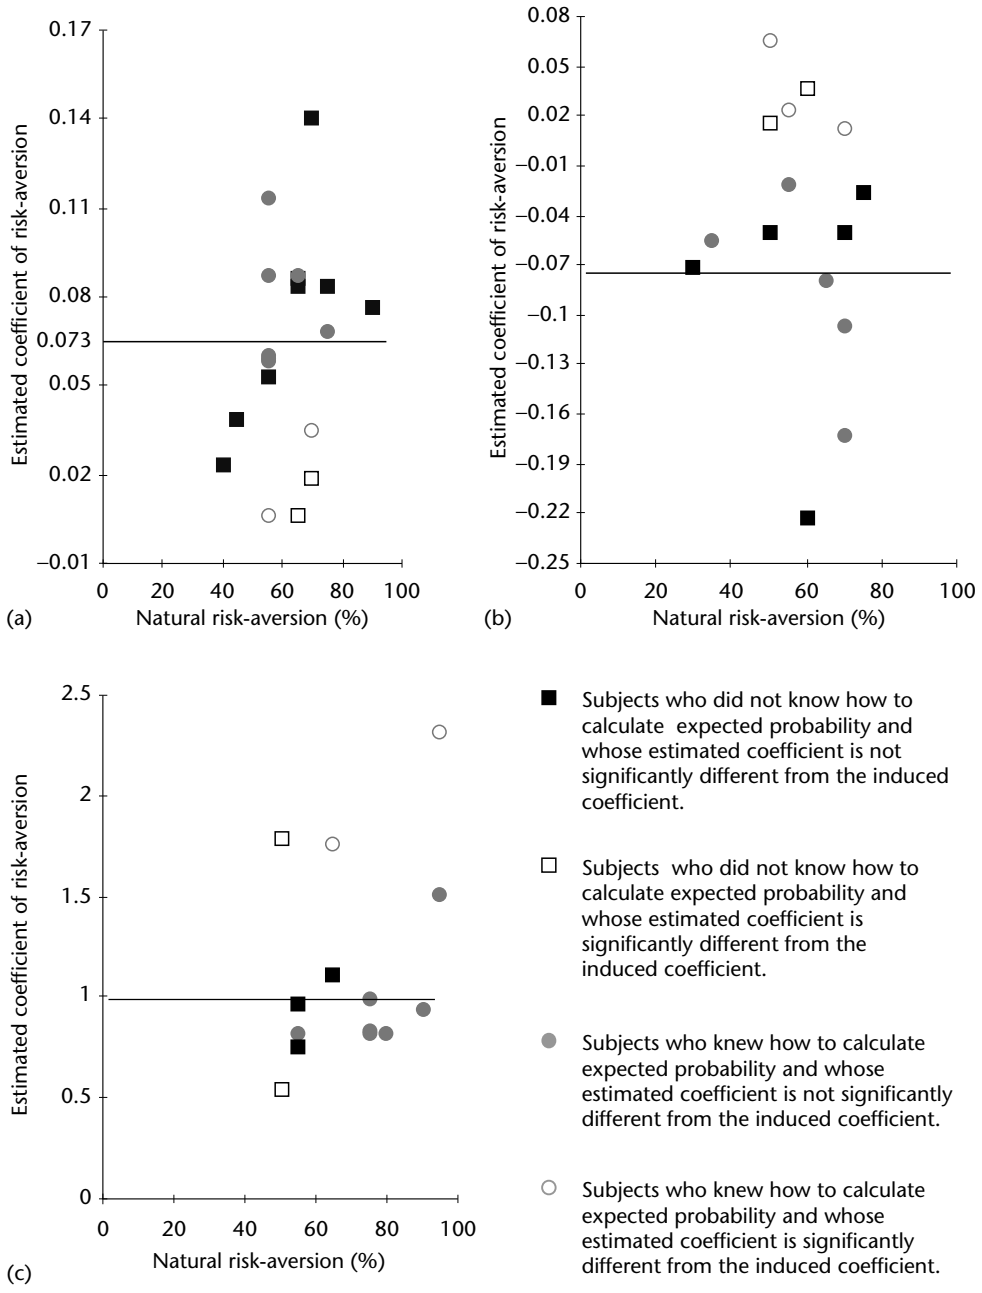

Figure 4. The relationship between the estimated coefficient of risk-aversion and natural risk-aversion for money (Prasnikar, 2001). (a) Risk-averse induced preferences. (b) Risk-preferring induced preferences. (c) Risk-neutral induced preferences.

From the standpoint of axiomatic choice, the critical assumption necessary to induce preferences is the compound-lottery axiom. As Luce (2000) points out, people's choices frequently violate this axiom. Camerer and Hogarth (1999) provide some understanding of incentive effects across studies, and suggest that incentives may very easily influence both mean and variance of performance levels. This may be the case with inducing preferences.

Information Cascades and Rational Conformity

Intermediate article

CONTENTS

An information cascade is a pattern of matching decisions. A cascade can occur when people observe and follow 'the crowd', which can be rational if the information revealed in others' earlier decisions outweighs one's own private information.

INTRODUCTION

When individuals obtain private information and make publicly observed decisions in a sequence, the first decisions tend to act as 'signals'. If early decisions show a clear pattern, the information inferred from them may outweigh any one person's private information. This inference can cause people to 'follow the crowd', even when the group consensus conflicts with their own private information. This type of sequential conformity is termed an 'informational cascade' in a seminal paper by Bikhchandani *et al*. (1992).

For example, consider an employer who interviews a job applicant and forms a good impression. The employer, however, does not offer the job after discovering that the worker has been turned down previously by other employers. Even though this decision is in conflict with the employer's own information, it may be rational if the employer concludes that the other interviews went badly, and that the aggregate information implied by past interviews more than offsets the employer's own positive evaluation. Even a qualified applicant may make a bad impression on any given day, so may have difficulty finding a job after several unsuccessful attempts.

Bannerjee (1992) uses the term 'herd behavior' to describe similar patterns of conformity that arise in models where individuals must decide which type of financial asset to purchase. Indeed, much of the interest in cascade behavior arises from attempts to explain temporary patterns in investment behavior.

CONFORMITY INCENTIVES

There may, of course, be non-informational factors that produce conformity in social interactions. Sometimes people prefer to behave like the others in a group. Such behavior has even been recommended (Post, 1927, chap. XXXIII): 'to do *exactly as your neighbors* do is the only sensible rule'.

There may be social stigmas and punishments associated with nonconformity. For example, an economic forecaster may prefer the chance of being wrong with everybody else to the risk of providing a deviant forecast that turns out to be the only incorrect guess. In the words of John Maynard Keynes (1936, p. 158): 'worldly wisdom teaches that it is better for reputation to fail conventionally than to succeed unconventionally'.

Some research suggests that people prefer to maintain the status quo (Samuelson and Zeckhauser, 1988). For example, subjects in experiments were provided with a scenario in which they inherit a portfolio of cash and securities and are asked whether to leave the portfolio intact or to change it by investing in other securities. There was a strong tendency for individuals to retain portfolio A in preference to B when it was listed as the current portfolio, and to retain portfolio B in preference to A when it was listed as the current portfolio. A similar tendency was observed in response to other matched pairs of questions that alternated descriptions of the *status quo* choice.

Such a 'status quo bias' may explain herding behavior in sequential decision situations. But these decision patterns do not allow us to distinguish between behavior based on a preference for

conformity and behavior that is motivated by information inferred from prior decisions. Thus, someone inheriting a portfolio from a rich uncle might conclude that the uncle's wealth was due to wise portfolio choices that should be imitated. Laboratory experiments can be used to set up and control information flows in order to distinguish among alternative explanations of herding behavior.

RATIONAL INFORMATION CASCADES

We will use a numerical example to illustrate the concept of a rational information cascade (Anderson and Holt, 1997). In this example, there are two equally likely events, A and B, which might represent whether or not a particular patent is marketable. Decision-makers obtain private signals, *a* and *b*, which are correlated with the events. In particular, $P(a|\mathrm{A}) = P(b|\mathrm{B}) = \frac{2}{3}$, so the error rate is $\frac{1}{3}$ for each signal. (For example, the signal might be the result of a consultation with experts.) This model assumes that each person's private signal is correlated with the event but is independent of the other signals. After observing their signals, individuals are approached one by one in a sequence and are asked to make a prediction about which event has occurred. People find out the prior predictions, if any, made by others, but they cannot observe others' private signals. Thus the prediction made by the first person is based only on that person's signal, and hence will reveal that signal, since the signal is more likely to be correct than not.

Suppose the first person sees a *b* signal and publicly predicts event B. If the second person in the sequence sees a *b* signal, it is rational for this person to also predict B. If the second person sees an *a* signal, the observed and inferred signals essentially cancel each other, and each state is equally likely. We observe from laboratory experiments that individuals almost always use their own information in such cases, and therefore, the second decision will reveal the person's private signal, whether or not it conforms to the first prediction. When the first two individuals in the sequence observe the same signal, their decisions will also match. In this case, the information inferred from the matching decisions is greater than the information inferred from any one private signal. In particular, if the first two people choose B, then the third person should also choose B, even if that person's private signal is *a*. Information cascades form in this manner, and the effect is that all subsequent decision-makers will follow a pattern established by the first ones in the sequence.

This example was used by Anderson and Holt (1997) in a laboratory experiment in which subjects were paid a cash reward for each correct prediction. The events were referred to as 'urn A' and 'urn B'. Each urn was a cup with three colored balls, which we will refer to as *a* or *b* signals. There were two *a* balls and one *b* ball in urn A, and there were two *b* balls and one *a* ball in urn B.

A random device was used to select the urn, with each event being equally likely, and therefore, each of the six balls is equally likely to be drawn. Suppose that the draw is *b*. Since two of the three *b* balls are in urn B, the posterior probability of urn B given a draw of *b* is $\frac{2}{3}$. (This is an example of the application of Bayes' rule; or more precisely, the ball-counting heuristic used here corresponds to the conditional-probability calculations that are referred to as Bayes' rule. See Holt and Anderson (1996) for a discussion of how the simple counting heuristic can be used to make Bayesian calculations in more complicated settings, and an intuitive explanation of the mathematical expression of Bayes' rule.) Of course, it is intuitively obvious that the probability of urn B is greater than $\frac{1}{2}$ when the signal is *b*. Holt and Anderson (1996) show that the probability of urn B is still greater than $\frac{1}{2}$ when first two predictions are B and the third person's signal is *a*. Thus, a cascade can begin with two matching decisions, and all subsequent decision-makers should follow the pattern established in this manner.

Information cascades may not form immediately if there is not a bias in early predictions. Suppose, for example, that the first two predictions are A and B, so the third person would consider each urn to be equally likely, prior to seeing a private signal. If the third and fourth decision-makers both predict B, then this bias in favor of B would cause the fifth person to predict B, regardless of that person's private signal.

These calculations are based on a model of perfect rationality. The purpose of an experiment is to determine how people actually behave in such situations. Anderson and Holt (1997) used the 'ball and urn' scenario described above in order to remove any preference for conformity that is not based on informational considerations. Subjects were placed in small cubicles and were shown a single ball drawn from the relevant urn, but they could not see which urn was being used. Subjects were selected in a random order to make their predictions, which were announced by a neutral assistant who did not know the signals or which urn was being used. (Allowing subjects to announce their own predictions could have given them the chance

to convey additional uncontrolled information, by tone of voice, for example.) After all predictions had been announced, a non-decision-making subject serving as a 'monitor' announced which urn had actually been used. Those with correct predictions were paid $2, and others earned nothing for that trial. There were 15 trials and six decision-making subjects in each session. Altogether, there were 12 sessions in the experiment, each of which was conducted on a different day.

The sequences of draws made cascades possible in more than half of the trials, and cascades actually formed in about 70% of the trials in which they were possible. A particularly interesting trial is shown in Table 1. In this case, all six individuals earned $2, since urn B was actually used for the draws.

Generally, prior information is informative, and cascade behavior tends to increase the accuracy of predictions, and hence to increase earnings. It is possible, however, for initial predictions to be incorrect, which may create an incorrect cascade. This occurred in another trial, shown in Table 2. In this case the first person's prediction revealed their signal, but the second person made a serious error in predicting B after seeing an *a* signal and a prior A prediction. The third person predicted B, which was also an error, since previous predictions were balanced and their own signal suggested urn A. All of the remaining individuals predicted B, which turned out to be incorrect, since urn A was used.

The most common type of error occurred when a person saw a signal that was inconsistent with the implication of prior predictions. In this case, the optimal Bayesian prediction is to follow the established pattern, but subjects deviated in about a quarter of the cases in which their own private information was inconsistent with this pattern.

In summary, the general tendency was for subjects to use the information implied by previous decisions correctly, which produced rational information cascades. There were, however, deviations that could either break a cascade or result in an incorrect cascade. Incorrect cascades also occasionally resulted from 'unlucky' incorrect decisions observed by early decision-makers.

This pattern of results was replicated by Hung and Plott (2001), who added some interesting treatment variations. In one of their experiments, the incentive structure was altered so that subjects received a positive pay-off only if the majority of the group made the correct prediction. (This is somewhat like a jury whose decision is determined by a majority vote.) The effect was to reduce conformity for early decisions because individuals have an incentive to signal their information so that others can make better decisions. A second treatment rewarded conformity directly: subjects received a positive pay-off only if their decision matched that of the majority.

Table 1. A trial from Anderson and Holt's (1997) 'ball and urn' experiment. Three of the last four decision-makers follow the pattern established by the first two despite contradictory evidence

Predicts	A	B	B	B	B	B

APPLICATIONS TO MARKETS AND OTHER SOCIAL INSTITUTIONS

Strong movements in stock prices are sometimes attributed to herd-like behavior. Keynes (1936) noted the similarity between investment decisions and a guessing game in which participants have to predict which contestant in a beauty contest will get the most votes. In this game, each person has to think about whom the others think is attractive, and also about whom the others think others will find attractive, and so on. Similarly, when investing in stocks, one would like to guess which enterprises will become popular with other investors, since a strong demand will raise the prices of those stocks. A herd-like response may move asset prices out of line with market fundamentals, and thus set the stage for an equally strong 'stampede' in the other direction. Such behavior could be due to seemingly irrational 'animal spirits', to use Keynes's colorful term, or it could be due to a rational tendency to follow others' decisions when they are based on independent sources of information. Christie and Huang (1995), for example, argue that it can be rational to follow others' decisions during surges or declines in stock prices; i.e., to rely on inferences derived from information that is aggregated by market prices.

Other applications are suggested by the majority-voting treatment of Hung and Plott (2001). In a trial, for example, jurors may form independent judgments about the guilt or innocence of a defendant, but such judgments are often changed in the process of voting and deliberation. In this manner, herd behavior can create the consensus needed to avoid a 'hung jury'. Some experiments that simulate sequential jury voting have been conducted, and strong patterns of cascade-like conformity are observed in many cases.

Decisions may occur in sequence in these applications (e.g., as stock purchases appear on a ticker tape), but the order of decisions is not exogenously specified as it was in the experiments discussed above. The order of voting is not exogenous in jury voting unless the foreman chooses to take votes by going around the table. Similarly, stock purchases or responses to initial public offerings are not subject to order requirements. Plott *et al*. (1997) report some pari-mutuel betting experiments with an endogenously determined order of play. The incentive structure is like that of a horse race in which the purse is divided among those who bet on the winning horse, in proportion to their bets. The experiment was presented as a choice between six assets, with only one of them offering positive earnings, depending on the realized state of nature. Investors had private, noisy information about the assets, and they could observe others' bets as they were made. A considerable amount of information aggregation was observed in these experiments, with the asset prices accurately indicating the correct state in most cases. In some cases, however, heavy purchases of an asset triggered more purchases, even though the asset being purchased turned out not to be the one that paid off. This corresponds to an incorrect cascade. The application of information cascade theory to asset markets in richer and more realistic settings is a prime area for future research.

CONCLUSION

Theoretical models of 'herding' pertain to situations where individuals observe private signals that are correlated with some unknown event. Predictions about the event are made in sequence, with later decision-makers being able to base their predictions on their own signal and on information inferred from prior decisions. The first few decisions tend to reveal the private signals, which may establish a pattern of matching predictions that others follow, even if the conforming predictions are different from the prediction that would be best given only the person's own private signal. This type of 'information cascade' can produce conformity that is rational, because the information content in prior decisions may outweigh that in one's own private signal. There is some laboratory evidence to support such theories of rational cascades, although individuals do make mistakes, and behavior is sometimes influenced by biases and heuristics that may lead to non-Bayesian decisions.

EXCHANGE, ECONOMIC THEORY, AND THE HAYEK CRITIQUE

Economics is about exchange. In modern economies this means that people trade tangible goods, services and rights, given and received for money, whose value is itself derived from the rights conveyed by the bearer. Money, however, is a recent social contrivance in the long dimly lit history of trade among early peoples. Such trade predates the state and even agriculture, which is only some 10 000 years old. The archaeological evidence for trade survives in the durables – weapons, tools, and ornaments – left behind in caves and campgrounds, such trade inferred largely from the fact that the geographical distribution of such artifacts is separated by great distances from the distribution of the raw materials from which they were manufactured.

Adam Smith saw that trade provided the foundation for specialization and a vast expansion in human productivity. Hence, the division of labor (among specialties) is limited by the extent of the market. It is the presence of market opportunities that permits one person to grow corn, another hogs, the baker to bake and the butcher to cut meat, as each specializes in that for which he is suited by temperament, experience, or natural skills, and then satisfies his general needs through markets. Smith understood that knowledge was dispersed in the market system, and that the individual, knowing his local situation, could better judge than the 'statesmen or the lawgiver' how to employ his capital to its greatest value. But it remained for F. Hayek (1984/1945) to articulate more fully the idea that the market order served to coordinate the utilization of this dispersed information through the price system and to see that it constituted an extended order of cooperation among thousands, indeed millions, of uncomprehending individuals. Markets are an example of a self-ordering system driven by cultural evolution and have important parallels with complex self-ordering systems in biology.

Economic theory traditionally has modeled the individual consumer in competitive markets as directed by the goal of maximizing his current period utility over a given commodity and work effort space, subject to a budget balance constraint requiring the income from sources, such as labor earnings, to equal expenditure on commodities, given commodity prices and wages. Similarly, producers maximize profit given wages, input and output prices, and their knowledge of technology. This way of representing the 'economic problem of society' leads to mathematical conditions defining a competitive equilibrium (CE) and the analysis of its existence and properties. The history of economic theory has suggested two different (equally unsatisfactory) answers to the question of how economic agents might be able to achieve a CE. One was to assert that a CE is simply an ideal state achievable only if the agents all have complete information on each other's individual preferences and production opportunities, i.e. on all data the theorist needs to calculate a CE. The second was that if all agents were 'price takers', having no power to control any price, then the CE would be attained.

The first begs the question of how an economy processes and utilizes information, while the second begs the question of how prices are formed.

ECONOMIC ENVIRONMENT

People trade because there are (expectations of) gains from exchange. What the seller vends is

worth more to the buyer than to the seller, and therefore the transfer can make each party better off. The term 'economic environment' will be used to describe the set of all individual circumstances in a market that defines the total potential gains from exchange. For simplicity most of our discussion will be confined to a single market where these statements can be defined unambiguously.

In an experimental market we need to motivate real people (the subjects) with real money (or other reward medium) to make consequential choices in trade. Subjects are recruited to the laboratory with the understanding that they will earn real money, depending largely upon their decisions, and that such earnings will be paid to them in US currency at the end of the experiment. Imagine that I have recruited you to an experiment. After being paid \$5 for reporting to the lab at the designed time, you and several other people are each assigned to a computer monitor and separated from one another so that you see only your own monitor screen. The instructions inform you that you will be a buyer (others in the room are buyers and sellers but you do not know who is which). You learn that you will have a capacity to buy up to three units of the identical items to be traded, the first with value to you of \$10, the second \$7, and the third \$4. You will have the opportunity to buy units against these values in each of a series of market trading periods, and you profit from selling below these values. Specifically, if in a given period you buy one unit for \$6, a second for \$5, and are unable to buy a third unit for less than \$4, then I (the experimenter) owe you \$6 ($10-6+7-5$). Hence, you are motivated to buy each unit in your assigned capacity at a low price, but if you attempt to buy at too low a price, you may not find a willing seller, and fail to earn a profit. The other buyers in the market have also been assigned values privately, but you know nothing of these and nothing of the costs assigned to sellers. Your values, \$10, \$7, and \$4 are a means of summarizing in concrete terms the fact that people have differing local circumstances, represented here by a maximum willingness-to-pay for each of three successive units. This is your little fragment of the dispersed information among all participants in the market.

Similarly, each seller is assigned values representing the costs incurred for transferring units owned by the seller to buyers. Sellers profit by selling at prices that are above these unit costs. Thus, a seller with unit costs of \$1 and \$3 for two units, if sold at the prices \$6 and \$5 respectively makes a profit of \$7 ($6-1+5-3$). Methodologically, this technique of using monetary rewards for inducing value on abstract items makes plain the fundamental truth that buyers as well as sellers profit from exchange.

The left panel of Figure 1 shows the value/cost environment for an early experiment consisting of four buyers and three sellers (Ketcham *et al*., 1984; reprinted in Smith, 1991, pp. 295–314). Note that the 'economic environment' (see Figure 2) becomes the effective demand and supply in the experimental market when we sort all buyer values from highest to lowest (demand) and all seller costs from lowest to highest (supply) regardless of 'ownership' identity. Thus 'demand' is the maximum willingness-to-pay schedule in the market, just as 'supply' is the minimum willingness-to-accept schedule. Observe for now that the sum total of this dispersed information in Figure 1 involves four buyers, each with a capacity to buy up to four units each (16 units total) and three sellers with a capacity to sell up to five units each (15 units total). Also note that the buyer's values are distinct for each unit demanded, while the sellers each incur a constant per unit cost up to their capacity, but these constant unit costs are distinct for each seller reflecting different individual circumstances, although each employs a constant unit cost technology.

INSTITUTIONS

All markets operate by rules, formal and explicit as in organized exchanges such as the Chicago Mercantile Exchange (Merc) for trading claims on assets or their derivatives, and the Automated Credit Exchange (ACE) for trading emission credits in Southern California, or by informal and implicit norms as in two-person social and economic exchange. Institutions define the language – the messages – of the market, such as bids, offers, and acceptances, the rules that govern the exchange of messages, and the rules that define the conditions under which messages lead to allocations and prices. If there are n agents, $i=1,2,\ldots,n$, and each i chooses a message m_i, then the allocation x_i to agent i is defined by the institution as a rule that we can express in the generic functional form

$$x_i = h(m_1, \ldots, m_i, \ldots, m_n).$$

Where the institution recognizes different agent classes subject to different rules, we would write $x_i = h_i(\cdot)$ indicating by means of the subscript i that the allocation rule also depends upon i's classification. Thus specialists on a stock exchange are subject to rules that differ from those of member traders.

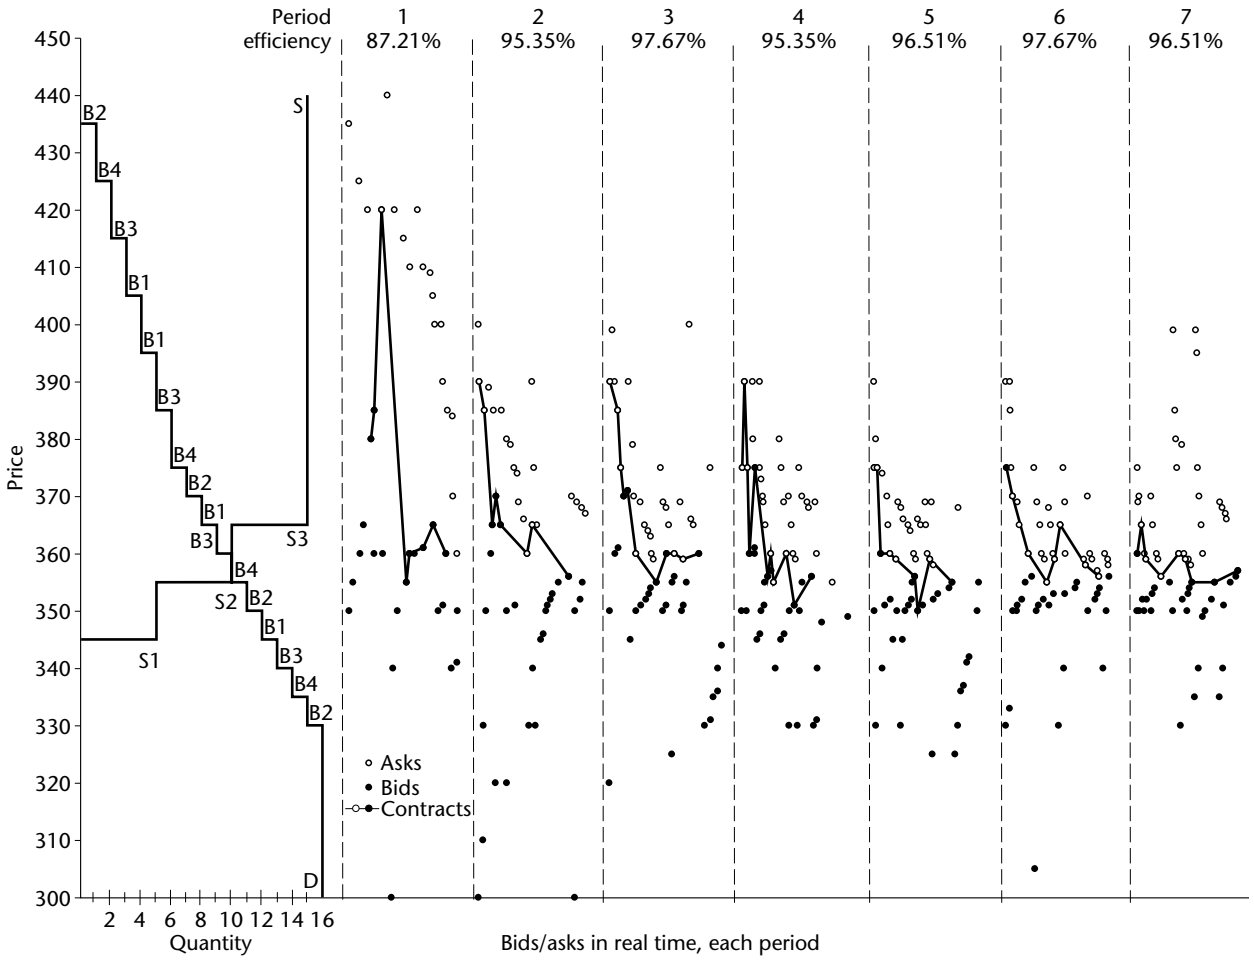

Figure 1. A double auction experiment. The economic environment for four buyers and three sellers is shown on the left. On the right is shown the sequence of bids, asks and contracts in each of the first seven periods of trading.

As an illustration of such institution-defining rules, in the ascending bid ('English') auction each new bid (message) must be higher than the standing bid, and the award is to the last bidder at a price equal to the last bid, when no new bids are forthcoming. That is, the English auction rules are

$$x_1 = h(m_1, \ldots, m_i, \ldots, m_n) = 1; x_k = 0 \quad \text{for all } k \neq 1,$$

where we have numbered the bidders so that $m_1 > m_2 > \ldots > m_n$, and $i = 1$ has the highest bid. Hence the single item for sale is awarded to Mr 1, and all others receive nothing. Note the important distinction between messages and awards: during the auction when Mr 1 announces the bid m_1, no one yet knows who will be awarded the item. Subsequently, all learn that no other agent, k, is willing to raise the bid, so that then and only then do the rules of the institution tell us that $x_1 = 1$, $x_k = 0$. Mr 1 does not choose to buy the item. He chooses to raise the standing bid. The institution subsequently declares him to be the buyer by virtue of the rules, under which it is discovered that no other bidder is willing to bid higher.

The advent of experimental economics in the mid-twentieth century has created a technology allowing the performance properties of institutions to be studied in controlled induced value/cost environments. In this article some simple but powerful cases will be used to illustrate what has been learned from the techniques of experiment. As we shall see, however, the institutions that survive are not born equal on any one measure of performance: efficiency, price volatility, demand responsivity, dependence on external information channels and the (transactions) cost of participation. Rather, each seems to be an adaptation to environmental wrinkles, or niches, that are not evident to the naked eye.

By the mid 1970s experimental auction market studies had become automated by computer/communication technology, i.e. participant messages were communicated by keyboard input and displayed on monitor screens; the institutional rules were encoded as algorithms applied to messages; and the data were time-stamped and recorded as specified. As noted in Rassenti *et al*. (2001) this had far reaching consequences, one of the more significant of which was the introduction of 'designer markets', of which ACE is a living, breathing, operating example (Ishikida *et al*., 2001).

BEHAVIOR

Behavior connects motivation in the environment with the institution to yield decisions and outcomes. Agents with differing circumstances have a differing urgency (maximum willingness to pay) to acquire goods/services and differing priorities (minimum willingness to accept) for relinquishing goods/services. The trading process is one in which people choose messages based on their circumstances, and knowledge of the language and rules of the market. Thus, if agent i's circumstances in the economic environment are represented by E_i and I is the set of institutional rules, behavior can be expressed by

$$m_i = \beta(E_i|I), i = 1, 2, \ldots, n.$$

Behavior is a mapping from individual circumstances, conditional on the market rules, into messages. The institution chooses outcomes by application of its rules to the messages, as indicated above by $x_i = h(m_1, \ldots, m_i, \ldots, m_n)$. This is illustrated in Figure 2. Each agent has an information state, preferences, costs, resources, knowledge, and, knowing the institutional rules, chooses messages. The institution processes the messages to determine allocations and prices. This pathway, from the economic environment down through choice and the institution, up to outcomes in Figure 2 represents the operation of the market. Across the top of Figure 2, the omniscient experimenter, whose information is not given to any one participant's mind, can use the information to compute the maximum gains from exchange and CE. This allows the observed outcomes to be used to compute performance measures: efficiency (percent of maximum gains realized by the agents), and the volatility or stability of observed prices relative to the CE. Because the rules of the market affect incentives, we expect, and experiments confirm, that institutions matter in the behavior we observe and in the outcomes that result.

This methodology allows different environments to be compared using the same institution. It also allows different institutions to be compared while holding constant the economic environment.

THE DOUBLE AUCTION INSTITUTION

This trading institution, used throughout the world in financial, commodity, and currency markets, is a two-sided multiple unit generalization of the ascending bid auction for unique items. Buyers submit bids to buy, while sellers submit offers or asks to sell, with a rich rule structure for defining priority based on price, quantity, and arrival time. We describe here a simple version used in the experiment shown in Figure 1, in which subjects trade single units in sequence. Each bid (ask) is understood to represent a buy (sell) order for a single unit. The moment that the first standing bid is entered by a subject it is displayed on all monitor screens. Any new bid is admissible only if it specifies a higher price than the standing bid, and so on in sequence as new bids are entered.

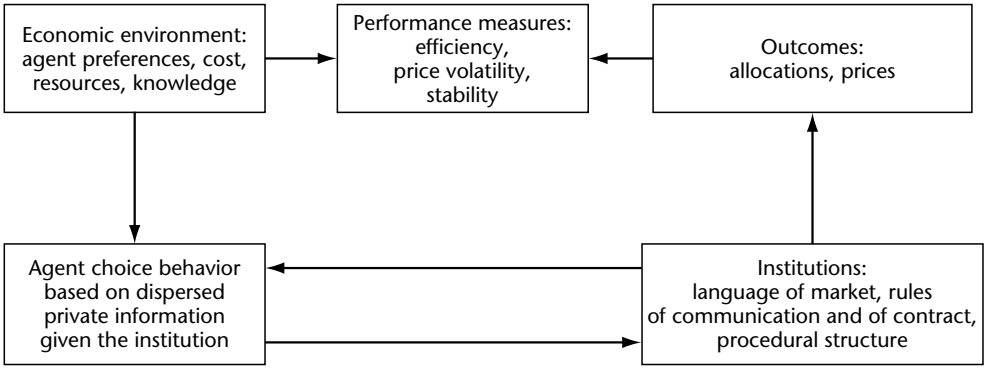

Figure 2. The components of every market: environment, institution and behavior.

Simultaneously, sellers are free to submit asks. When there is a standing ask, any new submission must specify a lower price. As soon as there is both a bid and an ask price, we have a bid/ask spread, say bid \$4, ask \$5.

The contract rule is simple: either a buyer accepts the standing ask price, or a seller accepts a standing bid. After each acceptance the auction ends and the computer waits for the submission of new bids and asks, as above. Note that the language of the market is bids, asks, and bid or ask acceptances. These are the only four messages that can be submitted by any subject agent to the trading system and the above filtering rules are applied to the messages as soon as they arrive.

A DOUBLE AUCTION EXPERIMENT: ENVIRONMENT AND BEHAVIOR

As we have seen, an economic environment is illustrated in the left panel of Figure 1. Notice that the demand crosses the supply at a range of market clearing prices, where demand = supply = 10 units, given by the interval (356, 360). Any whole number in this interval is a CE price. Only you and I know this; the subjects in this experiment know nothing of these facts. What Buyer 2 (B2) knows is that he or she can buy up to four units profitably at any prices below the values 435, 370, 350 and 330 respectively. Similarly, each of the other buyers knows only their own values and each of the sellers knows only their own costs. Units not purchased or sold incur no penalty.

The subjects were inexperienced, meaning that none had previously been in a double auction experiment. In Figure 1 we plot the displayed bids, asks, and contracts in a time sequence within each trading period. We show here the data for only the first seven of the 15 periods.

The behavior shown in the right panel of Figure 1 is typical. Efficiency in each period is the ratio of the total profits earned by all subjects in the period divided by the maximum possible profits (the area between the demand and supply schedules to the left of the intersection at 10 units). Note that after the first period, efficiency is always above 95 percent, implying that in each period the market participants realized at least 95 percent of the surplus due to exchange. Efficiency is 100 percent if and only if all buyer units valued at 360 and above are purchased and all seller units involving cost of 355 or below are sold. Efficiency is reduced if less than 10 units trade; it is also reduced if buyer valuation units at 355 or less are purchased and/or any seller cost units of 365 are sold. With experienced subjects efficiency tends to be 100 percent within the first few periods, even for subjects facing new and unfamiliar environments.

But Figure 1 is a static environment with demand and supply repeated in each period without any change throughout the experiment. Does the double auction institution perform well in tracking random shifts, up or down in the values (costs) assigned to buyers (sellers)? The answer is illustrated in Figure 3 which plots all contracts, and their mean price, over 15 periods with CE prices shifted for each period as shown. Observe that the mean price tracks the random shifts in the CE very closely, showing how this institution solves the problem of rapid adaptation to changes. Figure 3 also neatly illustrates that price volatility in a market has two components: variation due to exogenous fluctuations arising from changes in the economic environment, and endogenous variation within the market as traders search for the new equilibrium during each period. The former is represented by the random shifts in the CE, while the latter is represented by the dispersion of contract prices around their mean in each trading period.

The example in Figure 1 is for a single, isolated market. Do the strong equilibrating properties, demonstrated repeatedly in such examples, also hold for multiple markets? Yes, an example with two interdependent markets is reported in Smith (2000, pp. 245–247). Also see Williams *et al*. (2000). In these markets what a buyer is willing to pay for commodity A depends upon the price of B – the demand for A and B are opportunity cost demands. The equilibrium is defined by four simultaneous nonlinear equations in the price and quantity produced for A and B. In 10 out of 15 experiments prices are within 1 percent of their equilibrium predictions in period 10. With no knowledge of the equilibrium, or of the underlying equations defining it, six buyers and six sellers, each motivated by profit, unintentionally 'solve' the equations to reach the optimal equilibrium outcome. In effect subject behavior coordinated by the institution combines to provide algorithms that yield a competitive equilibrium.

All these examples show that it is not necessary for individuals to have complete information about the economic environment to achieve equilibrium outcomes. Some scholars may argue that the complete information condition was intended to provide only a strong sufficient, not necessary, condition for equilibrium to obtain. This has been tested. There are examples showing that when complete information on supply and demand is given to all individuals, the market performance

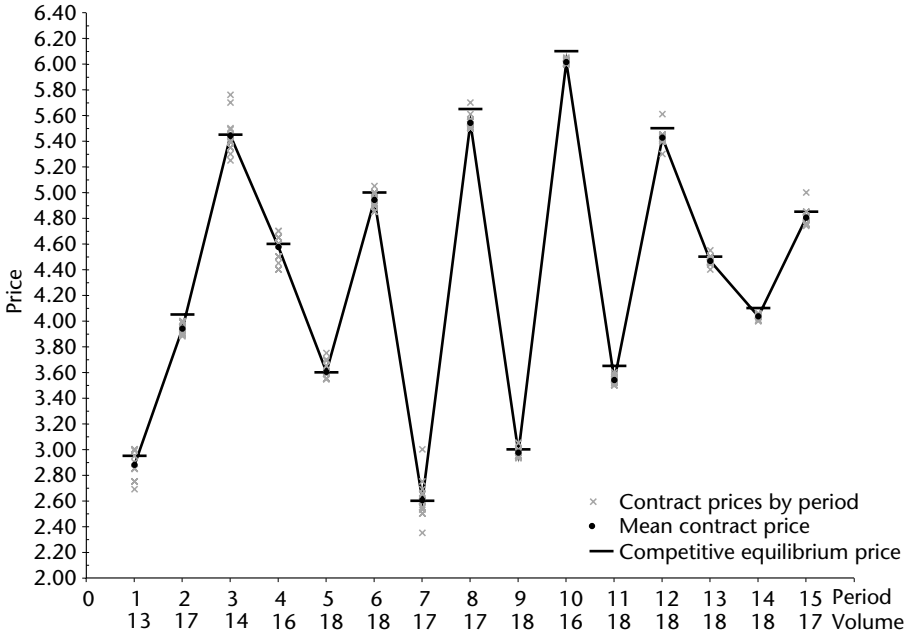

Figure 3. Effect of random shifts up or down in the supply and demand environment under double auction trading. Only the CE price was shifted, with CE volume always 18 units.

is worse than with private information (Smith, 1976/1991, pp. 103–105).

THE POSTED OFFER INSTITUTION

In ordinary retail trade the customer walks into the store (hardware, clothing, McDonalds) and observes a menu of take-it-or-leave-it price tags on each item offered for sale. Ketcham *et al*. (1984, reprinted in Smith, 1991) provide comparisons between the posted offer pricing and double auction institutions using identical environments. One of the environments held constant across the two institutions is the one exhibited in the left panel of Figure 1. Six experiments were run under each of the two institutions using this environment, using either an independent sample of eight subjects (five buyers and three sellers) or the same subjects for experienced sessions.

In Figure 4 we plot the mean double auction contract price for the experiment reported in Figure 1, and, on the same scale, the mean posted price (weighted by number of contracts at each price) for a matched comparison experiment, both using inexperienced subjects, and therefore strictly comparable; the institution is the only prominent treatment difference.

Observe that in every period in sequence the mean posted contract price strictly dominates the mean double auction contract price. Five of the six posted offer markets reported by KSW tend to converge to a price of 365, the cost of seller 3 in Figure 1, which is above the CE price range. For the double auction experiments it was the reverse: five converged to the CE price range, only one to 365. (The experimental environments all differed from each other by a random constant added to all values and costs, but all were equivalent when normalized on a standard CE price.)

In addition to prices being lower in the double auction, convergence to the CE price was more pronounced, the volume (number of units traded) was higher, and efficiency was higher. Thus as an exchange mechanism, the double auction dominates the posted offer in terms of efficiency and competitivity. Eventually, however, posted offer markets tend to converge to the CE, but the convergence is from initial prices that are above the CE price. In view of Figure 3 showing the good dynamic performance of the double auction, how does the posted offer compare? The answer is very poorly. Posted offer markets do not track shifts in demand well. Unlike the double auction such markets depend upon nonmarket sources of information concerning changes in the environment; the double auction does not because of its capacity for rapid adaptation. See Davis and Holt (1993, chap. 4) for further discussion and references.

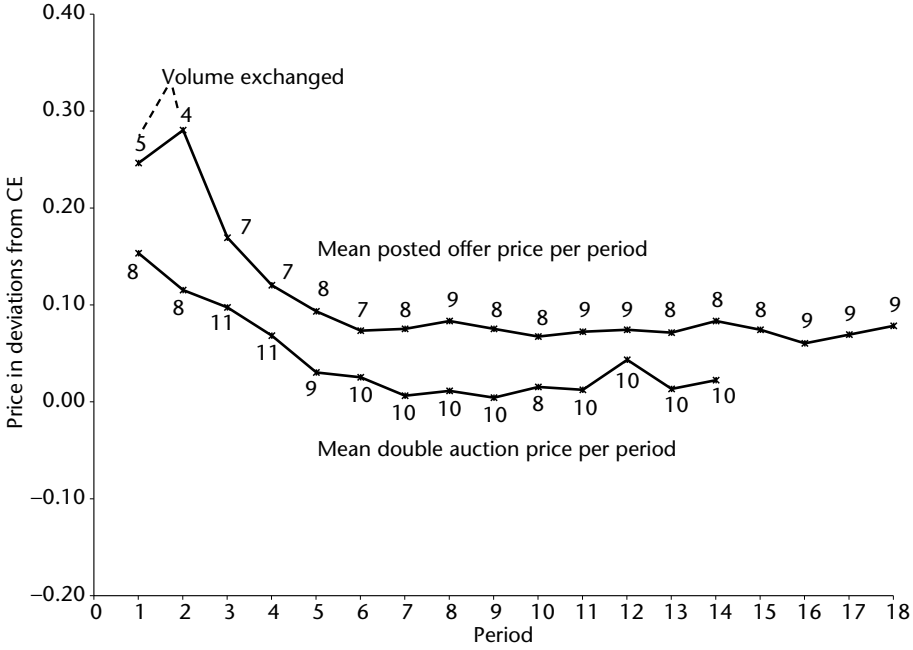

Figure 4. Plot of mean double auction price and volume (lower chart) for experiment shown in Figure 1, compared with posted offer mean price and volume (upper chart) with the same environment as in Figure 1.

THE CONCEPT OF A STRATEGY-PROOF EQUILIBRIUM

Although we can think of an allocation mechanism as an institutional procedure that allows the preferences of individuals to be mapped into final allocations, this abstract formulation does not take explicit account of the fact that preferences are private and unobservable, and institutions have to rely upon the messages reported by agents, not their true preferences. Consequently, the standard theoretical proposition is that it is possible for an agent to affect prices and outcomes in a market by strategically misreporting his or her preferences. Thus, in our example above of a buyer with a maximum willingness-to-pay of \$10, \$7, and \$4, respectively, for three units of a good – who believes sellers are willing to sell for less – might strategically bid for all three units at \$3 in an attempt to lower his or her purchase cost of the three units. Allocation mechanisms are actually mappings from preferences, and each agent's information or beliefs about other agents, into allocations. This state of affairs has motivated an intensive theoretical study of strategy-proof mechanisms designed to overcome the problem of strategic misrepresentation, but the results are negative and not encouraging. Thus, stated informally, 'an allocation mechanism is strategy-proof if every agent's utility-maximizing choice of what preferences to report depends only on his own preferences and not on his expectations concerning the preferences that other agents will report' (Satterthwaite, 1987, p. 519). This comes down to the strong requirement that each agent has a dominant strategy to report true preferences, and has led to impossibility theorems establishing the nonexistence of such a mechanism under certain minimal requirements.

Given these negative results, it is of particular interest to ask what people actually do in experimental environments in which the experimenter induces preferences on individual subjects so that the experimenter knows each agent's preferences, but the subjects know only their own preferences. Although it is possible that an agent can obtain an advantage by strategically underrevealing his/her demand or supply, whether or not such action is successful depends upon the actions – possibly countervailing – of others. In particular, has society stumbled upon institutions in which forms of behavior arise that approximate practical solutions to the problem of 'strategy-proofness' in economic environments with dispersed information?

The best-known example in which the answer to this question is 'yes' is the continuous double oral auction discussed above. Our theoretical understanding of why and how this is so is weak and

represents one of the outstanding unsolved problems in economic/game theory.

Are there other examples, offering good (if not perfect) solutions to the problem of achieving strategy-proof equilibria? If so, what are the strategic behavioral mechanisms that people adopt to solve it? A partial answer, based on what we have learned from experiments, is in the form of two versions of uniform price auctions: the uniform-price sealed bid-offer auction, and the uniform-price double auction (UPDA). For a more complete discussion see the chapters by Cason and Friedman, Friedman, and Wilson in Friedman and Rust (1991).

CONCLUSIONS

This article has briefly examined two historically common trading institutions – the continuous double auction and posted offer pricing. In each institution the experimental results show that order emerges out of an interaction between the choices of individuals with dispersed private information and the (property) rights to act specified by the institution. The institutions vary in terms of their exhaustion of the gains from trade, the speed and completeness of convergence to efficient, competitive outcomes, and the volatility of prices, but in both cases the participants are better off than if they were unable to trade.

Several propositions follow from these examples.

1. Many market institutions exist in the economy that are a complex product of cultural evolution, each invented by no one yet by everyone, and which exhibit the capacity to produce an exchange order from dispersed information.
2. What emerges is a form of 'social mind' that solves complex organization problems without conscious cognition. This 'social mind' is born of the interaction among all individuals through the rules of the institution.
3. In these institutions some are price takers, some price makers, some both. Hence, the idea that all must be price takers is neither necessary nor sufficient to yield an extended cooperative order of the market.
4. Participant knowledge of the circumstances of others is neither necessary nor sufficient to yield an extended order of cooperation.
5. The double auction, and other markets, provide rapid adaptation to random dynamic changes in individual circumstances.

Markets are rule-governed institutions representing algorithms that select, process, and order the exploratory messages of agents who are better informed about their personal circumstances than those of others. As precautionary probes yield to contracts, agents become more sure of what they must give in order to receive and the gains they can hope to capture. Out of this interaction between minds through the intermediary of rules the process tends to converge more-or-less rapidly to an equilibrium if one exists. The emergent order is invisible to the participants, unlike the visible gains they reap. They find out what they need to know to achieve optimal outcomes against the constraining limits imposed by the actions of others. The resulting order accommodates trade offs between the cost of transacting, attending, and monitoring and the efficiency of the allocations so that the institution itself generates an order that fits the problem it evolved to solve. Hence, the hundreds of variations on the fine structure of institutions, each designed without a designer to accommodate disparate conditions but all subservient to the reality of dispersed agent information.

Minimal Group Experiments

Intermediate article

Robert Kurzban, UCLA, Los Angeles, California, USA

CONTENTS

The 'minimal group paradigm' is an experimental method in which people are assigned to arbitrary groups, and then required to allocate rewards to members of their group or another group. The surprising result of these studies is that ingroup favoritism is elicited under these conditions, suggesting that merely placing people into different groups, even meaningless ones, leads to discrimination.

THE MINIMAL GROUP EXPERIMENTS

Henri Tajfel and colleagues were interested in the origins of discrimination, particularly when it was based on the group membership of the person against whom discrimination was being directed (Tajfel *et al*., 1971). At the time when they conducted their experiments, although it was well known that people often discriminated against members of other groups, the circumstances that were necessary and sufficient for such discrimination were less well understood. Tajfel *et al*. wanted to look more closely at what these conditions were.

Their experimental program was designed to begin with a situation in which discrimination was *not* expected to occur. Subsequently, changes could be made to the experimental context, and the experimenters could observe the features of the situation that elicited discrimination.

The first condition was to be minimal indeed. Participants were brought into the laboratory and asked to perform a relatively simple task: estimating the number of dots on a screen. They were then assigned to groups ostensibly based on their performance on this task. In one condition, participants were told that they were being grouped according to whether they were more or less accurate at estimating the number of dots. Because grouping was based on participants' skill at this task, which was presumed therefore to have a degree of meaning to the participants, it was hypothesized that this sort of grouping would lead to discrimination. In contrast, in a condition in which participants were grouped based on whether they overestimated or underestimated the number of dots, a division that had no obvious value either positive or negative attached to it, no discrimination based on this assignment of group membership was predicted. In fact, the assignment to groups in both conditions was made randomly, although participants were not aware of this. Because the assignment of participants to groups was based on these meaningless procedures, this experimental program came to be known as the 'minimal group paradigm'.

After the dot estimation task, participants were presented with a series of 'allocation tasks' in which they had to decide how to allocate money between two individuals. In some cases, both of these individuals were members of the same group. However, in the condition of interest to the experimenters, one of the two people was a member of the same group as the participant (an 'ingroup' member), and one was a member of the other group (the 'outgroup').

The allocation was done by a set of matrices. Each matrix consisted of two rows of 14 numbers corresponding to monetary rewards or punishments. Each row corresponded to the payoff to either an ingroup member or an outgroup member. Participants had to select one of the 14 columns for each matrix, and the corresponding values in the columns would be paid to the other participants. In no case could a participant allocate any money to himself or herself – it was always to another participant in the experiment.

The allocation decisions were structured so that the participant was required to make a series of tradeoffs. Consider Figure 1. In this case, a participant allocating the largest number of points possible (19) to the ingroup member would be forced to simultaneously allocate an even greater number of points (25) to the outgroup. This allocation would lead to the greatest number of points overall, but would lead to an outcome in which the outgroup member was favored over the ingroup member.

Ingroup	7	8	9	10	11	12	13	14	15	16	17	18	19
Outgroup	1	3	5	7	9	11	13	15	17	19	21	23	25

Figure 1. Matrix from the minimal group paradigm.

A series of matrices of this type generated a number of different possible tradeoffs. In each, the extent to which a participant favored the ingroup relative to the outgroup (or the reverse) could be assessed by looking at the column selected. In the above example, the number of columns to the left of the center of the matrix was a measure of how much the participant wanted to ensure the ingroup member received more than the outgroup member, sacrificing both total overall points allocated and the equity in allocation.

The surprising result was that when grouping was based on either accuracy or over- versus underestimation, participants allocated points with a bias toward their own group members. This contradicted the idea that categorization had to have some value (e.g. accuracy) in order for discrimination to occur.

In a second experiment, participants were asked to indicate their preference for paintings by two impressionist artists, Klee and Kandinsky. Participants were then told they were being assigned to one of two groups, each group consisting of people who preferred one of the artists. In this experiment, using a slightly different set of matrices for the allocation task, it was found that participants allocated less money to their ingroup member than they could have in order that the outgroup member received still less. Assignment to a group seems to have made the participants competitive, even when this competitiveness led to an overall drop in both the total amount of money allocated to a pair and the amount of money allocated to the ingroup member. It is important to point out, however, that ingroup favoritism and competitiveness were balanced by concerns about fairness – participants tended not to choose the extreme scores in the allocation task, but instead reached a kind of compromise in their motivations.

Since these original experiments, these basic results have been replicated a large number of times, and with a number of variations on the basic design. For example, the same type of ingroup bias occurs when participants are given the task of evaluating ingroup and outgroup members, rather than allocating money to them (Turner, 1978). A second important result is that these effects hold even when subjects are told that they are being randomly assigned to groups, instead of on the basis of the dot estimation task (Billig and Tajfel, 1973).

Perhaps most significantly, effects of the minimal group manipulation are observed even when the participants' own interests are at stake. Diverting from the procedures of most experiments of this type, Turner (1978) had his participants make allocation decisions in which the participant had to divide money between himself or herself and a member of either an ingroup or an outgroup. In this study, participants sacrificed their own monetary earnings to benefit the ingroup member significantly more than they did with the outgroup member. This showed that categorization into minimal groups affected distribution of rewards not only when two unknown, anonymous others were the recipients, but also when the participant's own outcomes were at stake.

EXPLANATIONS FOR MGP RESULTS: SOCIAL IDENTITY THEORY

Existing theory in psychology at the time could not easily explain these surprising results. A general view among many psychologists was that intergroup bias and discrimination was the result of genuine conflicts between members of groups for valued resources (Campbell, 1965; Sherif, 1967). However, in the minimal group experiments, because participants are allocating to other people, not themselves, this functional view of bias does not seem to apply. The people in the study could make themselves no better off, nor worse off, in making their allocation decisions. A new theory, one with more of an emphasis on the consequences of group membership *per se*, rather than functional relations between groups, was necessary.

The inadequacy of existing theories led to the development of social identity theory (SIT) (Tajfel and Turner, 1986). 'Social identity' was defined as 'those aspects of an individual's self-image that derive from the social categories to which he perceives himself as belonging' (Tajfel and Turner, 1986, p. 16). That is, social identity has to do with how the groups a person belongs to are part of the way that individual sees him or herself.

The focal element of SIT was the concept of self-esteem. The theory assumed that people want to have high self-esteem, and that an individual's social identity played an important role in determining self-esteem. So, belonging to a group that one viewed positively would increase self-esteem. In addition, evaluation of the individual's own

group was a comparative process. That is, people judged how good their group was by comparing it with other relevant groups.

According to this theory, then, when someone is a member of a group that they view unfavorably, this should diminish their self-esteem and the individual should be motivated to improve their social identity. This can be achieved by leaving the group that they view negatively, if it is possible. Alternatively, and more relevantly in the context of the minimal group experiments, the individual can try to improve their view of the group to which they belong, and, in particular, improve it relative to a group which they are comparing with their own group.

Social identity theory was able to account for the minimal group findings in a way that theories that depended on actual conflict of interest could not, because SIT implied that people are concerned with comparing favorably with other groups even when nothing except self-esteem was at stake. In these experiments, it is presumed that participants were using the monetary rewards to allow the allocators a way to compare favorably with the other group and to raise self-regard by discriminating against the outgroup.

An important additional conceptual element that has been incorporated by some researchers into SIT is the idea that categorizing an individual as in the MGP is not all that matters. For discrimination to occur, people must come to identify with the category in question. Further, the extent to which someone identifies with a particular category to which they belong can change with the situation. In some contexts, identity as a male or a female might be particularly relevant, while in others, national or religious identity might matter. Current construal of identity is therefore taken to be the critical determinant of discrimination, rather than the simple fact of category membership.

ADDITIONAL EXPERIMENTAL EVIDENCE

The minimal group paradigm has served both as the inspiration and as a testing ground for the ideas behind SIT. Michael Hogg of the University of Queensland in Australia and his colleagues (e.g. Hogg and Abrams, 1988; Hogg and Sunderland, 1991) have tried to clarify exactly what predictions SIT makes in the context of MGP studies and the extent to which existing evidence supports these predictions. In particular, they have argued that SIT can be separated into two corollaries. The first is that discrimination against the outgroup improves self-esteem. The second is the idea that when self-esteem is threatened, the individual is motivated to discriminate against the outgroup.

Unfortunately for exponents of the theory, evidence for these corollaries has been inconsistent and weak. In terms of the first, while some researchers have found that those who discriminate experience higher self-esteem (e.g. Lemyre and Smith, 1985), a careful experiment conducted by Hogg and Sunderland (1991) found that discriminating in a MGP allocation task did not raise participants' self-esteem. However, in the same experiment, participants who were made to feel low self-esteem by being told that they had performed poorly on an 'interpersonal empathy' task did indeed show more discriminatory behavior. While this finding tends to support the second corollary, other evidence contradicts it, including Crocker and McGraw's (1985) finding that, for certain groups, discrimination is greater among those with high self-esteem (cited in Hogg and Sunderland, 1991).

Ongoing research continues to examine the conditions under which the corollaries of SIT hold. There is growing consensus that whatever the relationship between self-esteem and discrimination turns out to be, it is not as simple and straightforward as initially conceived by social identity theorists. In particular, while it appears that being categorized as a member of a particular group as in the MGP can lead to discrimination, it does not necessarily do so, and the conditions under which it does are beginning to be better understood (Grieve and Hogg, 1999).

Mixture Models of Individual Heterogeneity

Intermediate article

DO Stahl, University of Texas, Austin, Texas, USA

CONTENTS

Mixture models of individual heterogeneity are models of a population consisting of heterogeneous types of individuals, each type exhibiting a distinct probabilistic behavior, with the probability of each type equal to that type's proportion in the population.

INTRODUCTION

That all humans do not behave alike is obvious to even the most casual observer. How to represent this heterogeneity in a model that allows us to predict behavior is far less obvious. The simplist model of heterogeneity assumes that behavior is normally distributed about a mean for the population. An important feature of this model is that there is a single mode of behavior: i.e. if one graphed a histrogram of the behavior, one would find a single hump. We focus here on the countless cases where behavior is 'multimodal': a histogram of the behavior would have multiple humps. For example, when voting on the level of federal spending for education, Democrats might be a unimodal population, and Repulicans might be a unimodal population, but the mean desired spending level of these populations would be quite different, so Congress as a whole would be a bimodal population.

Formally, suppose there are $K+1$ unimodal subpopulations, which we will index $k=0,1,\ldots,K$. An individual member of subpopulation k will be refered to as a type-k individual. Suppose some member of the whole population faces a situation that calls for a behavioral response. Let s denote this situation and all the relevant data about the situation, and let $X(s)$ denote the set of possible behaviors in this situation. Let $P_k(x|s)$ denote the probability that a type-k individual will exhibit behavior x from the set $X(s)$. Note that x could be a whole dynamic sequence of behaviors. Finally, let α_k denote the proportion of the whole population comprising subpopulation k (or equivalently, the probability that a randomly drawn individual from the whole population is type k). Then, the probability that a random individual from the whole population will exhibit behavior x in situation s is given by

$$P(x|s) \equiv \sum_{k=0}^{K} \alpha_k P_k(x|s) \qquad (1)$$

Equation (1) is a canonical 'mixture model'.

When the probabilistic behavior of each subpopulation, $P_k(x|s)$, is predetermined, then only the population proportions, α_k, need be estimated from the behavioral data. Identifcation only requires that $P_k(x|s) \neq P_j(x|s)$, for $k \neq j$.

In other cases, the probabilistic behavior might be specified parametrically as $P_k(x|s, \beta_k)$, where β_k is a vector of parameters for the subpopulation k. For example, β_k might represent the mean and variance of a normal distribution. Since $\beta_j = \beta_k$ would yield identical probabilistic behavior, this parametric case generally requires identifying restrictions on the parameter space (such as $\beta_j < \beta_k$).

In the next section, we illustrate the application of mixture models with the level-n model of bounded rationality by Stahl and Wilson (1994, p. 5).

LEVEL-N MODEL OF BOUNDED RATIONALITY

Consider a two-player finite normal-form game in which the payoff to player i is U_{ijk} when player i chooses action j and the other player chooses action k. Let $A \equiv \{1,\ldots,J\}$ denote the set of actions available to both players. The Stahl–Wilson (1994) model begins with the assumption that a proportion, α_0 of the population, has no understanding of the game and by virtue of the principle of insufficient reason a type-0 individual is equally likely to

choose any action in A. Hence, $P_0(j|s)$ is the uniform distribution over A, and s in this context represents the data for the game (i.e. A and U). In the language of Stahl–Wilson, these players are called 'level-0' types.

A Bayesian rational player must have a belief about what the other player will do. The simplist noninformative model of other players is that they are level-0 types. A player who believes all others are level-0 types is called a 'level-1' type and chooses an error-prone best response to this belief. Specifically, define

$$y_{1ij} \equiv \sum_{k=1}^{J} U_{ijk} P_0(k|s), \tag{2}$$

which is the expected payoff to player i when choosing action j against a level-0 player. Then, the probabilistic choice function for a level-1 type is specified logistically as

$$P_{1i}(j|s,\beta_1) \equiv \exp(\beta_1 y_{1ij}) / \sum_{k=1}^{J} \exp(\beta_1 y_{1ik}), \tag{3}$$

where β_1 is the precision of a level-1 type; the higher the precision, the higher the likelihood the choice will be the best response to the belief, and the lower the precision, the more equally probable will be all the actions. Moreover, a logistic choice function has the property that the order of the choice probabilities corresponds to the order of the expected payoffs, y_{1ij}. The proportion of level-1 types in the population is denoted α_1, and for simplicity of presentation we implicitly assume the same proportion for both player 1 and player 2 (i.e. a single population model).

The level-n theory proposes a hierarchy of types in which a level-n type believes that all other players are level-k types with $k < n$. For simplicity of explanation and as an example, let us assume that a level-2 type believes that all other players are level-1 types. Then, the expected payoff to player i when choosing action j against a level-1 player is

$$y_{2ij} \equiv \sum_{k=1}^{J} U_{ijk} P_{-i1}(k|s,\beta_1), \tag{4}$$

where '$-i$' means 'the other player, not i'. The logistic probabilistic choice function is

$$P_{2i}(j|s,\beta) \equiv \exp(\beta_2 y_{2ij}) / \sum_{k=1}^{J} \exp(\beta_2 y_{2ik}), \tag{5}$$

where $\beta \equiv (\beta_1, \beta_2)$.

This simple three-type, level-n model yields a mixture model of the form:

$$P_i(j|s,\alpha,\beta) \equiv \alpha_0 P_0(j|s) + \alpha_1 P_{1i}(j|s,\beta_1) + \alpha_2 P_{2i}(j|s,\beta), \tag{6}$$

where $\alpha \equiv (\alpha_0, \alpha_1)$, and $\alpha_2 = 1 - \alpha_0 - \alpha_1$, leaving only four free parameters. This mixture model can be expanded in a straightforward manner to test for the presense of additional types in the population.

Identification Issues

Since all the types in equation (6) collapse to uniformly random choice when $\beta_n = 0$, we need to impose identifying restrictions so $P_0(j|s)$, $P_{1i}(j|s,\beta_1)$, and $P_{2i}(j|s,\beta_1)$ are distinguishable given the sample size of the observed data. A Monte Carlo simulation can be used to determine appropriate lower bounds for the β_n.

Even having imposed these parameter restrictions, for many games both level-1 and level-2 types will behave the same, so such games will be inadequate to identify the α_n parameters. The solution to this identification problem is to use a variety of games, so that each type predicts distinctly different patterns of behavior across all the games. Stahl and Wilson (1994) use 10 symmetric 3×3 games; which permits 3^{10} (59,049) distinct patterns of choice for an individual, and an underlying space of probabilistic behavior of dimension 2^{10}. While this approach creates more than enough possibilites to identify the parameters of the proposed mixture model, the curse of dimensionality renders it impossible in practice to use nonparametric methods to characterize the underlying distribution of behavior, and therefore specification tests vis-à-vis the true data generation process are hopeless.

Hypothesis Testing

On the other hand, likelihood ratio comparisons can be used to test alternative model specifications. For example, the hypothesis that there are no level-2 types in the population sampled is equivalent to restricting $\alpha_2 = 0$. However, there is a complication because 0 is on the boundary of the parameter space (see Self and Liang, 1987; Feng and McCulloch, 1996). Although the classical regularity conditions (as typically stated in advanced econometrics textbooks) are not met, the maximum likelihood estimators remain consistent. Self and Liang (1987) suggest that the true asymptotic distribution of the likelihood ratio statistic under the null hypothesis is a mixture of chi-squares with 0 and 1 degree of freedom. Since the right tail of the

density of any such mixture lies to the left of a chi-square (1) density, the conventional chi-square (1) test would be too conservative, increasing the p-value of the observed statistic and lowering the probability of rejection; hence, a rejection of the null hypothesis $(\alpha_2 = 0)$ using the conventional chi-square tests would hold under the true asymptotic distribution.

Alternative theories of behavior naturally suggest different types that can be easily added to the mixture model. For example, when each game has a unique pure-strategy Nash equilibrium, a 'Nash' type can be added. If the Nash type is specified as putting probability one on the unique Nash equilibrium, then it is highly likely that one will be able to reject the hypothesis that there are pure Nash types in the population, because just one non-Nash choice by an individual would imply a zero probability of being such a pure Nash type. In general, theories that make extreme predictions are easily rejected, and beg to be augmented with a theory of 'errors'.

There are two simple and reasonable theories of errors. The first entails uniform trembles: with probability $(1 - \varepsilon)$ the individual chooses the Nash equilibrium, and with probability ε any action is equally likely to be chosen. This specification introduces an additional parameter to be estimated. The second model of errors is prior-based: as in equation (2), we define the expected payoff of each action given the prior belief that all other players will choose the Nash equilibrium. Then, we define the logistic Nash choice function as in equation (3). Again, one parameter is introduced, but now the choice probabilities are positively correlated with the expected payoffs. Haruvy and Stahl (1999) find that the logistic theory fits laboratory data much better than the uniform tremble theory. When a game has multiple Nash equilibria, they find that the logistic theory using the prior belief that each Nash equilibrium action is equally likely fits the data much better than any equilibrium selection criteria (including payoff dominance, risk dominance, and security).

Given the huge variety of behavior that is possible, one might expect that adding virtually any type to a mixture model will improve the fit. However, we have often failed to reject the hypothesis that certain types are absent. For instance, Stahl and Wilson (1995) failed to reject the absense of a rational expectations type, Haruvy *et al*. (1999) failed to reject the absense of a maximin type, and Haruvy and Stahl (1999) failed to reject the absense of payoff-dominance and risk-dominance types. All of these tests had adequate power.

As pointed out, using a variety of games to identify the model parameters creates the potential for enormous behavioral diversity and highlights the poverty of typical laboratory sample sizes. Given this diversity, it is often possible to reject the hypothesis that the parameters that maximize the likelihood of one small sample (of 10–30 individuals) are the same as the parameters that maximize the likelihood of another similarly sized sample. However, we caution the reader that these rejections are artifacts of overfitting small samples. In the absense of any predetermined, observeable criteria for distinguishing among different groups of laboratory subjects, we learn nothing useful from separate parameter estimates for each group. Rather, it is better to pool all the data and obtain one estimate for the general population.

Posterior Probabilities of Individual Types

Given parameter estimates $(\hat{\alpha}, \hat{\beta})$, Bayes theorem allows us to compute the posterior probability that any given individual is type-n, denoted α^p_{ni}.

$$\alpha^p_{ni} = \hat{\alpha}_n P_{ni}(x_i|s, \hat{\beta}_n) / \sum_{k=0}^{K} \hat{\alpha}_k P_{ki}(x_i|s, \hat{\beta}_k), \tag{7}$$

where x_i stands for the choices of individual i over all the games. Stahl and Wilson (1995) show how to modify this formula to account for the uncertainty inherent in the parameter estimates. They also find that 38 of 48 participants in their experiments can be identified with one type (i.e. $\alpha^p_{ni} > 90$ percent for some n). We suggest that this would hardly have been the case if the level-n model were not capturing a significant part of the true data-generating process.

Constancy of Types

The mixture model discussed and estimated assumes that individuals are one type for all situations they face. The above results on the posterior probabilites supports that assumption. However, we need to consider alternatives to obtain a more rigorous conclusion. One alternative is the hypothesis that individuals draw their type from the population of types (charactertized by the α_k's) independently for each game. This implicitly entails that all individuals are ex ante alike. This ex ante homogeneity hypothesis is strongly rejected by our data.

Consider instead the hypothesis that a type-k individual is highly likely to behave in the typical

way but with some small probability can behave like another type. Specifically, suppose that with probability $(1-\varepsilon)$ the individual behaves like a type-k but with probability ε is equally likely to behave like any type. For the Stahl–Wilson (1995) data, we found a statistically significant improvement in the maximized log-likelihood with an estimate of $\hat{\varepsilon} = 0.05$. In other words, individuals appear to be true to one type of behavior 95 percent of the time, and otherwise tremble to other types of behavior. Since the level-0 type is part of the model, not surprisingly, allowing type trembles lowers the estimated proportion of the population that is type-0. Another attractive feature of this type-tremble mixture model is that it feeds easily into the rule learning framework of Stahl (2000, 2001).

EQUIVALENT MIXTURE MODELS

For any distribution of behavior, $P(x|s)$, there are obviously innumerable ways to represent that distribution as a mixture model, equation (1). All of these are equivalent mixture models, and as such none can be rejected in favor of any other. Does this fact mean that mixture models are nonfalsifiable and hence unworthy of scientific research? The answer is no for three reasons.

First, the true data-generating process may be a mixture of types, in which case clever ways of isolating subpopulations of types would lead to falsifiable predictions. Second, representing the data-generating process as a mixture is a constructive approach that starts with archetypes and aggregates to population behavior. This process does produce falsifiable hypotheses about the constituent types and also provides a practical means of making predictions for novel situations. Third, the curse of dimensionality prevents us from obtaining a full characertization of $P(x|s)$, while the mixture model allows us to construct an approximation from simple constituent types.

Furthermore, when faced with two competing mixture models, it is always possible to create an encompassing model and use nested hypothesis tesing to select the best model. See, for example, Haruvy *et al*. (1998).

INDIVIDUAL VERSUS POPULATION MODELS

While psychologists are primarily interested in the behavior of individuals (even in social settings), other social scientists such as economists and sociologists are more interested in aggregate population behavior. Indeed, in many applications, the economist or sociologist may have only aggregate data. Although theoretically models of individual behavior can be aggregated to produce models of population behavior, there are often informational and computational constraints to exact aggregation. For example, because each individual has a unique history at any point in a repeated game, exact aggregation must keep track of all these unique histories, which grow in number exponentially with time. Models which entail integration over possible histories can be computationally infeasible. There is also the information conservation principle which states that a given sample of data contains only so much information – if you use that data to find the best fit for models of individual behavior, the information gained will not give you the best fit for models of population behavior.

The mixture models discussed above can be applied in a straightforward manner to population data. The only difference is in the construction of the likelihood function for the data. In an individual model, one first computes the likelihood of the behavior of each individual for all the games by type (a product of probabilities over the games), then sums these type-conditional likelihoods, and finally takes the product of these summed likelihoods over all individuals. In a population model, one first computes the sum of the type-conditional probabilistic choice functions for each game, then computes the multinomial probability of the observed aggregate choices using the summed probabilities, and finally takes the product of these multinomial likelihoods over all the games. The latter model does not impose the restriction that an individual's behavior is of one type for all games. Since the likelihood functions are different, the maximum-likelihood estimates of the individual model will differ from the maximum-likelihood estimates of the population model.

CONCLUSION

Human behavior is often multimodal, so we need multimodal models to represent and predict such heterogeneous behavior. The mixture model is ideally suited for this purpose. The major challenge is the specification of constituent subpopulation types. In accordance with the scientific method, we advocate theory-based hypothesis generation and testing. Since the best mixture model at any point in time will be an approximation of the true data-generating process, there will always be the possibility of discovering a better approximation.

Neuroeconomics

Intermediate article

Kevin McCabe, George Mason University, Fairfax, Virginia, USA

CONTENTS

Neuroeconomics is the study of how the embodied brain interacts with its external environment to produce economic behavior. Research in this field will allow social scientists to better understand individuals' decision making, and consequently to better predict economic behavior.

INTRODUCTION

Recent breakthroughs in neuroscience models and technologies allow us to study *in vivo* brain activity as individuals solve problems involving tasks such as making choices between alternative actions, forming expectations about the future, carrying out plans, and cooperating, producing, investing and trading with others. Knowledge of how the brain interacts with its environment to produce economic behavior will allow social scientists to better understand the variation both within and between individuals' decision making, and consequently to better predict economic behavior. In addition, understanding how the brain processes information can facilitate the building of economic institutions that better serve as extensions of our minds' capacities for social exchange.

A FRAMEWORK FOR DECISION MAKING

Figure 1 shows an abstract flowchart of the steps involved in decision making. Information inputs include internal states associated with the homeostasis of the decision maker, sensory information from the external world, and prior knowledge of the decision maker. This information is used to form subjective beliefs about the likelihood of different outcomes and an objective that the decision maker will try to attain. Choices interact with events outside the control of the decision maker to produce outcomes, which are then valued. Feedback allows the decision maker to improve his or her prior knowledge and leads to a return to homeostasis. Outcomes from choices may also affect future events and consequently influence new sensory data.

We can model the ultimate decision-making system as one that results in choices that maximize the genetic fitness of the organism as studied by sociobiology and evolutionary psychology. This leads to hypotheses about the neuronal encoding of decision-making variables that can be tested with a variety of neuroscientific methods.

DECISION MAKING BY NEUROLOGICAL PATIENTS

A famous early case illustrating the importance of prefrontal lobe lesions in decision making is that of Phineas Gage (Harlow, 1848). More recently, Bechara *et al*. (1997) have studied patients with similar ventromedial prefrontal damage in an individual-choice problem called the 'gambling task'. In this task, a subject is asked to choose cards from one of four decks starting with 40 cards each. Each deck has a fixed pay-off per card of $50 in decks C and D and $100 in decks A and B. Behind each card is a cost, ranging from $0 to $1250. The subject

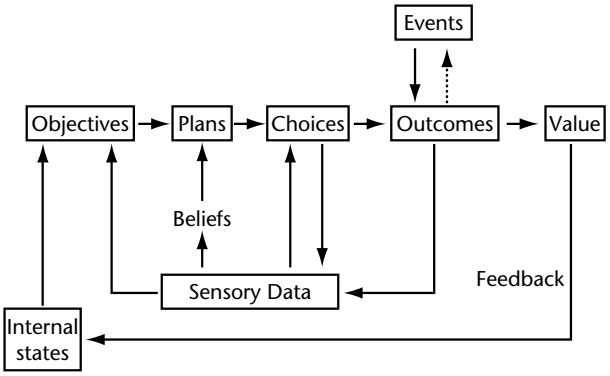

Figure 1. The steps involved in decision making.

must choose a card with a fixed pay-off, only then to learn the cost, if any, associated with the card. The subject starts with 2000 fictional dollars. On each draw, the fixed pay-off minus the cost is added to the initial amount. Although subjects did not get paid the final amount of dollars, it is assumed that they were motivated to do as well as possible in maximizing their fictional earnings.

While the subjects learn fairly quickly the location of the $50 and $100 decks, they must also learn which decks have positive net pay-offs. The decks are designed by the experimenter to have large punishments in the $100 decks, resulting in an overall loss if decks C and D are played for too long. The punishments in the $50 decks are much smaller resulting in an overall expected gain if decks A and B are played for long enough. Thus, the subject must learn to ignore the favorable signals of the $100 decks and instead play the $50 decks.

The typical behavior of a control subject is to shift play largely to the $50 (C and D) decks by period 60. By contrast, patients with ventromedial prefrontal damage do not shift away from the disadvantageous decks (A and B). Further research helped eliminate working-memory impairments as the reason for poor performance (Bechara *et al*., 1997). However, subjects with bilateral amygdala damage not only show similar behavioral impairment in the gambling task, but they also fail to show skin conductivity responses to rewards, punishments, or anticipation.

This research leads Bechara *et al*. to hypothesize that the amygdala couples a stimulus configuration with a 'somatic state' triggered by primary reward or punishment. The ventromedial prefrontal cortex is then responsible for coupling a strategy with a somatic state elicited by beliefs about how that strategy may produce outcomes.

To what extent do patients with similar ventromedial damage have difficulty with real-world decision making? In a series of articles, Jordan Grafman and colleagues have looked at the role of prefrontal cortex in allowing individuals to solve complex decision problems involving sophisticated planning and feedback. Goel *et al*. (1997) study the performance of ten patients with frontal lobe lesions in a financial planning task in which they were asked to prepare a budget, with planned projections, for a fictional couple's cash flow, in order to solve the following problems. First, get the couple out of the red. Second, allow them to buy a house in the next two years. Third, send their two children to college (in 15 to 20 years). Fourth, allow them to retire at the age of 65 (in 35 years). When compared to ten normal controls, the patients take much longer than normal subjects in structuring the problem, and in inferring abstract principles from particular instances, both of which are necessary in formulating a plan. Patients are also bad at processing feedback and judging performance, causing them to finish the task before the four problems have been adequately solved.

CHOICES BETWEEN COMPETING ALTERNATIVES

Economists have long studied decision making as the maximization of objective functions, such as utility or profit, subject to individual budgetary constraints. An important question is whether specified collections of neurons encode decision variables critical for optimization. For example, consider the simple utility-maximization problem of choosing x_1* and x_2* so as to maximize $U(x_1, x_2)$ subject to the budget constraint $p_1x_1 + p_2x_2 \leq m$, where x_1 and x_2 represent quantities of two different goods, p_1 and p_2 represent the prices of the goods, and m represents the money the person has at his or her disposal.

In Figure 1, the step marked 'choices' involves the ability to balance the relative gains of the two goods against the relative costs. The marginal utility of good 1 is the change in utility that the decision maker would receive for an additional unit of good, holding the amount of good 2 constant, or more formally, the partial derivative of the utility function, i.e. $U^1(x_1, x_2) = \partial U(x_1, x_2)/\partial x_1$, and similarly for good 2. Relative gains can then be measured as the ratio of marginal utilities $U^1(x_1, x_2)/U^2(x_1, x_2)$. A necessary condition for (x_1^*, x_2^*) to be a solution to this utility-maximization problem is that the ratio of marginal utilities should equal the ratio of the costs of acquiring the goods, i.e. $U^1(x_1^*, x_2^*)/\ U^2(x_1^*, x_2^*) = p_1/p_2$.

In making trade-offs between alternatives, we would expect the objective function to be sensitive to the relative reward value of the alternatives, independently of the alternatives in question. Is there any evidence that the brain encodes this kind of information? Tremblay and Schultz (1999) show that the firing rates of orbitofrontal neurons in two *Macaca fascicularis* monkeys were modulated by the relative reward values of different food (or, in separate trials, different drink) items. For example, the authors knew *a priori* that the monkeys preferred a piece of banana (B) to a piece of apple (A), which was in turn preferred to a piece of lettuce (L). Within a block of choice, symbols for two of the rewards were alternatively

shown on the left or right side of the screen. After a delay the monkey had to press a lever indicating where the picture was presented in order to get the reward symbolized. In different blocks, the monkeys were presented with all combinations of rewards.

Prior to choice, the same neurons in the orbitofrontal cortex would fire more frequently when the more desired food item symbol was displayed, compared with the less desired food item. Similarly, other neurons would fire more frequently when the symbol for the less desired item was presented. The authors conclude that such neurons encode relative preferences of food items, independently of the items themselves. However, it is still an open question how neurons encode the balancing of relative gains with relative costs.

MONETARY REWARD

Notice that money is not directly valuable to decision makers. But with fixed prices p_1 and p_2, we can always write $x_1^* = m_1/p_1$,where m_1 is the amount of money budgeted for good 1. In economics experiments human subjects are paid money as their salient reward. This raises the question: is there neuronal activity specifically associated with decision making over money? In general, neuroscientists predict that rewards are processed in the ventral striatum and orbitofrontal regions of the brain (Schultz, 2000). Using positronic emission tomography, Thut *et al*. (1997) studied brain activation in ten humans who received either a monetary reward or a simple 'OK' reinforcer for performance on a delayed 'go–no-go' task. The monetary reward resulted in significantly higher activation of the dorsolateral and orbitofrontal cortex, and also involved the midbrain and thalamus.

In an event-related functional magentic resonance imaging study, Knutson *et al*. (2000) studied brain activation in 12 subjects who engaged in a monetary-incentive delay task similar to a task orginally designed for monkeys (Schultz *et al*., 1997). In the human task, subjects were shown a cue indicating that they would receive some level of monetary reward ($0.20, $1.00, or $5.00), or nothing, or a punishments represented as a monetary loss ($0.20, $1.00, or $5.00). This was followed by a random delay of 2000–2500 ms, and then the appearance of a white target lasting 160–260 ms. Subjects received the relevant reward if they had got that reward cue and pressed a response button while the white target was visible. Subjects paid the relevant punishment if they were cued for that punishment and they failed to press the response button when the white target was visible. Levels of activation in the nucleus accumbens increased as anticipated rewards (but not punishments) increased.

CHOICES UNDER UNCERTAINTY

A simple example is the choice between two gambles g_1 and g_2. If the gamble g_1 is played, the decision maker gains $10 or $6, each with probability ½. Playing the gamble g_2 results in a gain of $14 or $2, each with probability ½. We assume that the decision maker prefers more money to less, so the utility function U satisfies $U(\$14) > U(\$10) > U(\$6) > U(\$2)$. In an experiment, these probabilities are likely to be shown to the subject in frequency terms, such as an urn containing 50 red balls and 50 blue balls. A subject is asked to pick a gamble. A ball is then randomly chosen. A red ball is worth $10 if g_1 is chosen and $14 if g_2 is chosen; and a blue ball is worth $6 if g_1 is chosen and $2 if g_2 is chosen.

Returning to our example, the expected value (calculated as $\frac{1}{2}(\$10) + \frac{1}{2}(\$6)$ for gamble g_1) is $8 for both gambles. However, if, in comparing the two gambles, the decision maker is more concerned about the potential loss of $4 ($6 − $2) when a blue ball is chosen, compared with the potential gain of $4 ($14 − $10) when a red ball is chosen, then the decision maker may choose to play the 'less risky' gamble g_1. This decision is consistent with an expected-utility calculation of the form $EU(g_1) = \frac{1}{2}U(\$10) + \frac{1}{2}U(\$6) > EU(g_2) = \frac{1}{2}U(\$14) + \frac{1}{2}U(\$2)$, which holds when the function U is concave, implying that $U(\$6) - U(\$2) \geq U(\$14) - U(\$10)$.

Suppose now that the dollar amounts in both gambles are replaced with negative amounts of the same magnitude: for example, $\bar{g}_1$ is a gamble whereby a subject loses $10 or $6, each with probability ½, giving an expected loss of $8. While $\bar{g}_1$ and $\bar{g}_2$ both have an expected loss of $8, our subject may prefer to play the gamble $\bar{g}_2$ in order possibly to lose only $2, and take the risk of losing $14. In this case we would call the person a 'risk-taker', since he or she prefers the possibility of avoiding a $4 loss (by going from $6 to $2) to the prospect of losing an additional $4 (by going from $10 to $14). In this case, the utility function over losses is convex to the origin, satisfying $U(-\$10) - U(-\$14) < U(-2\$) - U(-\$6)$. Behavioral data support the hypothesis that individuals are risk-taking over losses, and risk-averse over gains (Friedman and Savage, 1948; Tversky and Kahneman, 1986). (See Figure 2.)

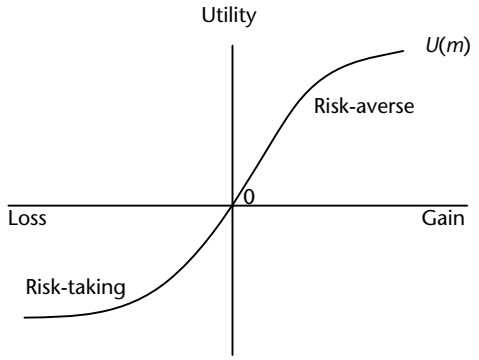

Figure 2. Utility $U(m)$ as a function of monetary gain ($m > 0$) or loss ($m < 0$). In experiments, subjects tend to apply a convex utility function for gains and a concave utility function for losses (see Friedman and Savage, 1948).

What objective function will the decision maker use to choose between the gambles? We would expect it to be sensitive to both probabilities and outcomes. Is there any evidence that the brain encodes this kind of information? Platt and Glimcher (1999) showed that the firing rates of lateral intraparietal neurons, in the posterior parietal cortex of rhesus monkeys, were modulated by the ratio of expected gains between two (juice reward) gambles, and consistent with the choices of the monkeys. In these cued saccade tasks, the experimenters varied both the gain associated with a particular response and the probability that a specific task would be required. As these variables were increased there was a commensurate increase in firing rates of specific lateral intraparietal neurons. The effects of both expected gain and outcome probability were strongest just before the monkey knew which response would be rewarded. Finally, in a free-choice task, where the monkey was not instructed, behavioral response frequency (towards the more favorable outcome) and the firing rate of posterior parietal neurons were correlated.

Using event-related functional magnetic resonance imaging, Breiter *et al*. (2001) studied brain activation in 12 humans who received monetary rewards or losses based on the outcome of a gamble chosen by the experimenter. Three different gambles were presented visually as spinners to subjects in a pseudorandom sequence. Each spinner had three equally likely outcomes. There was a 'good' spinner with outcomes of \$10, \$2.50 and \$0, an 'intermediate' spinner with outcomes of \$2.50, \$0 and −\$1.50, and a 'bad' spinner with outcomes of \$0, −\$1.50 and −\$6. Subjects were paid the cumulative results from the gambles they played. This allowed the experimenters to examine the activation associated with reward expectancy, prospect stage, and the actual outcome stage. They observed a broadly distributed set of brain regions active in both the prospect and outcome stages of the gamble. They also observed significant hemodyanmic response in the sublenticular extended amygdala and orbital gyrus, with both regions of interest rising monotonically with the expected value of the spinner, that is, from the bad spinner to the intermediate spinner to the good spinner. Finally, they observed some evidence for hemispherical specialization, with the right hemisphere predominantly active for gains, and the left hemisphere predominantly active for losses.

Using positron emission tomography, Smith *et al*. (2002) studied brain activation in nine humans who made choices between gambles resulting in monetary gains or losses based on the outcome of the gamble they had chosen. Within each block of choices, subjects chose several times between two different gambles. Each gamble had three possible outcomes, which depended on the random draw of a red, green, or blue ball from a container of balls at the end of the experiment. Each of the four blocks of choices consisted of either risky choices or ambiguous choices over either monetary gains or monetary losses. In the risky-choice treatment, subjects were shown a depiction of each gamble as a container with the number of balls of each color and the monetary payoff associated with each color, either positive (in the gain condition) or negative (in the loss condition). In the ambiguous treatment, the total number of balls was given, but not completely broken down by color, that is, the subjects could not be sure of the color of some of the balls in the container.

As expected from previous studies, subjects were risk-averse in the risky–gain condition and risk-taking in the risky–loss condition. Subjects showed ambiguity-aversion over both the loss and gain treatments. They showed a set of ventromedial activations consistent with the observations of Bechara *et al*. (1997) and Breiter *et al*. (2001) in the risky–gain condition. However, in the risky–loss condition, they showed a different set of dorsomedial activations.

STRATEGIC CHOICES WITH OTHERS

When the economic environment contains other individuals, their behavior must be anticipated in order to achieve good pay-offs. Figure 3 shows a

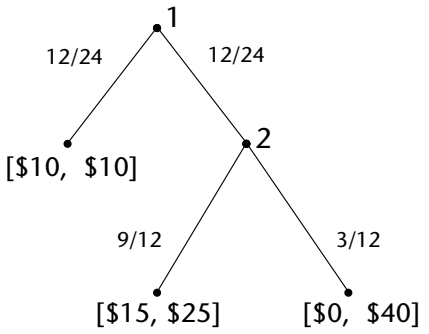

Figure 3. A simple game in which player 1 can either choose a pay-off vector of [$10, $10] or allow player 2 to choose between pay-off vectors of [$15, $25] and [$0, $40]. (The vectors represent the pay-offs to player 1 and player 2 in that order.) Out of 24 anonymously matched pairs, 12 player 1s chose to cooperate and 9 of their corresponding player 2s reciprocated.

simple example of a game in which cooperation can make both players better off. If player 1 moves right and player 2 moves left, then player 1 gets $15 and player 2 gets $25. However, player 2 may decide to move right in order to get $40. If player 1 believes that this is how player 2 will behave, then player 1 should move left, ending the game and resulting in $10 for each. In experiments where the game is played once between anonymously matched human subjects, half of player 1s moved right, and three-quarters of the player 2s who had the opportunity to move reciprocated by moving left. Therefore the expected gain for player 1 by moving right is greater than the $10 sure thing.

In a functional magnetic resonance imaging study, McCabe *et al*. (2001) studied brain activation in 12 humans who played sequential two-person games similar to that shown in Figure 3. Half the time they played as player 1, and half the time as player 2. Each time they played, their counterpart was either a computer playing a fixed probabilistic strategy, or a human who was recruited to play outside the scanner. Subjects were told before the game began whether they were playing the computer or the human.

On the basis of their individual plays, 7 of the 12 subjects were labeled as 'cooperators' while 5 were labeled as 'non-cooperators'. The cooperators all showed greater prefrontal activations in the computer condition than in the human condition, but with greater individual variation in and around BA-8. A conjunction analysis also suggested a common pattern of parietal, prefrontal, and frontal (BA-10) activations. By contrast, the non-cooperators did not generally display greater frontal activations in the human treatment than in the computer treatment. The observed activations in cooperators seem to be consistent with shared reciprocity intentions, resulting in both the inhibition of individual reward-seeking by player 2s and the inhibition of risk-avoiding behavior by player 1s.

Cognitive Assessment

Intermediate article

Jonna M Kulikowich, University of Connecticut, Storrs, Connecticut, USA
Patricia A Alexander, University of Maryland, College Park, Maryland, USA

CONTENTS

Cognitive assessment encompasses a wide variety of tests, tasks, and methods used to monitor and evaluate knowledge acquisition, strategic processing, and development of complex thinking.

INTRODUCTION

Measuring how we think and learn is not easy. Unlike behavior that can be observed directly, human cognitive processes are internal. Despite the difficulty in assessing cognitive processes, psychologists throughout history have designed many creative ways to represent them. In this article, we will introduce some of the assessments used by cognitive psychologists. We will consider assessment of domain-specific knowledge, strategic processing, and conceptual change. We will also discuss how researchers evaluate the effects of instruction, that is, academic achievement.

COGNITIVE PROCESSES

Anyone with an interest in science may wonder how experts like Albert Einstein or Marie Curie were able to make so many important contributions in physics and chemistry. Can we learn to think and solve problems like them?

It takes many years of hard work to become an expert. Experts possess vast amounts of knowledge related to their field of study, and this knowledge base has been acquired by working on complex problems, communicating with other experts, and making many mistakes. Fields of study, like physics and chemistry, are called 'domains'. Most researchers agree that domain-specific knowledge is of two primary kinds: 'declarative' and 'procedural' knowledge (Anderson, 1983). Declarative knowledge includes our knowledge of concepts, facts, and details. Experts possess an abundance of declarative knowledge, and this knowledge is structured in memory in representations, called 'schemata' in such a way that experts can quickly access the important principles of their domain. Procedural knowledge is knowing how to apply declarative knowledge. When we adjust the knob on a microscope to focus our view on a certain part of a cell, we use our procedural knowledge.

As well as possessing domain-specific knowledge, experts are also very strategic. 'Strategic learning' is effortful processing that helps experts link schemata and monitor and evaluate their progress while they are solving problems. Not all information can be immediately recalled or accessed. So, experts need a system of strategies that helps them put their existing knowledge to use. Some strategies are considered to be domain-specific because they are commonly used in one field of study while they may not be used to such extent in another field of study (mnemonics usually fall into this category). Other strategies can be used in any domain (for example, strategies for summarizing the main ideas in a passage of text).

We discuss how researchers have measured several important variables in the field of cognitive psychology. We begin with domain-specific knowledge and strategic learning and describe how these have been assessed. Then, we discuss how the study of expertise has influenced assessment of school students' performance. It is important to understand how students' cognitive processes develop over time. The topics of dynamic assessment and conceptual change pertain to developmental changes in students. Finally, we present some new developments in the analysis of student achievement. 'Achievement' relates specifically to what students know, and how they are able to solve problems, as a result of instruction. Performance-based assessment and portfolio

assessment are two testing techniques useful in the measurement of complex student achievement.

DOMAIN-SPECIFIC KNOWLEDGE

In studying how experts organize their knowledge and use it while solving problems, one of the simplest ways to assess domain-specific knowledge is by asking. Interview techniques are commonly used when studying experts. Psychologists develop lists of interview questions to ask experts, regarding what kinds of problems they like to solve, how long it takes them to solve problems, the challenges they face, and their evolving interests.

Two different types of interviews are popular: 'open-ended' and 'structured' interviews. In open-ended interviews, respondents are asked a general question that allows for a large variety of responses. Thus, we might ask Marie Curie: 'When did you realize that you were becoming an expert in chemistry?' Cognitive psychologists would hope to hear about how Curie realized that she knew a lot of information about chemistry that was more extensive than many of her peers. She might well mention that she could solve difficult problems quickly. She might mention that she recognized that her research was actually redefining the content of the field. In effect, Curie's discoveries, such as new chemical elements, became the declarative knowledge that others would have to know.

In structured interviews, cognitive psychologists seek very specific answers to detailed questions. These can be used in conjunction with observational records of the experts while they work. Thus, someone might observe an expert in chemistry like Curie while she is performing an experiment. After completion, a structured interview might be conducted, based on specific procedures that the expert used to solve a problem. Thus, we might ask her why she used one piece of equipment rather than another. Further, we might ask why and how she adjusted the Bunsen burner while heating a particular substance. We would compose these questions in an effort to assess the declarative and procedural knowledge of the expert based on our observations of her performance.

Expert–Novice Differences

Interview techniques are very useful when one has already identified an expert. But cognitive psychologists are also interested in assessing the differences between those who are experts and those who are not. Such work is usually referred to as the study of 'expert–novice differences' (Ericsson and Smith, 1991). Several methods of assessment have been very useful in studying these differences.

Concept maps

Concept maps allow cognitive psychologists to study how individuals organize their conceptual (primarily declarative) knowledge. Given a list of words that represent concepts in a domain, experts and novices are asked to create diagrams that show how these concepts are interrelated and how they lead to understanding of other concepts. Directional links show that concepts lead to one another, while nondirectional links simply show that concepts are related.

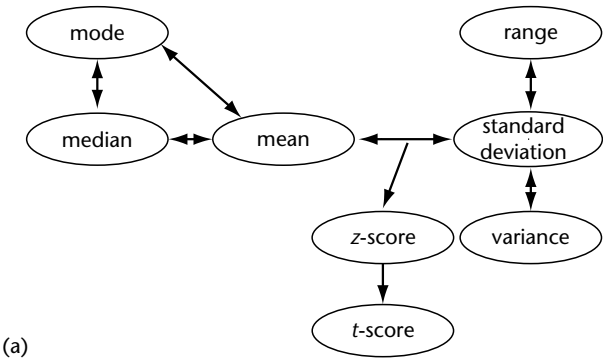
Expert statisticians, for example, know a lot about the normal distribution. Concepts related to the study of the normal distribution include central tendency, variability, and z-scores.

Figure 1 shows two concept maps. Figure 1(a) represents an expert's schematic understanding of the relations among a given list of statistical concepts, while Figure 1(b) represents a novice's understanding. The expert was also able to show how concepts lead to other concepts (for example, how means and standard deviations lead to computation of z-scores). The novice was not able to make these links. In general, cognitive maps demonstrate that experts organize their knowledge around important principles while novices rely on a rather fragmented organization of knowledge.

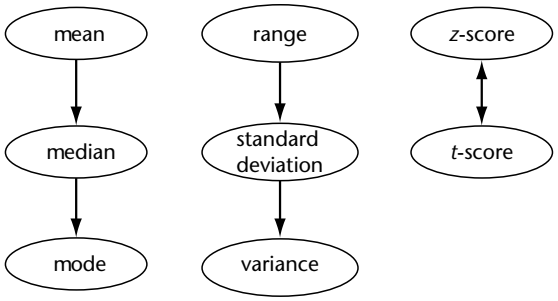
Think-aloud procedures

Think-aloud procedures can help in the assessment of procedural knowledge. Cognitive psychologists seeking to assess the processing that differentiates expert and novice performance might ask them to 'think aloud' while they are generating their solutions. Unlike interviews, which take place before or after the task, the think-aloud procedure takes place during the task. It can inform psychologists about such things as the information to which individuals attend as they solve problems (Ericsson and Simon, 1993). Further, it can provide hints as to the sequence of steps that problem solvers follow.

For example, if asked to think aloud while solving three essentially similar statistical problems all to do with examination results but expressed in different terms, experts in statistics are apt to study the problem structure in each task and compare those structures across tasks. Thus, an expert might say: 'All problems involve univariate distributions and require estimates of central tendency'. Novices, who have a more fragmented knowledge



(a)



(b)

Figure 1. Concept maps in the domain of statistics. The same list of eight concepts was given to an expert and to a novice. Directional links show that concepts lead to one another, while nondirectional links simply show that concepts are related. (a) The expert's concept map. (b) The novice's concept map.

base, do not tend to mention the principles that are common to all the problems as they think aloud. Instead, they tend to focus on surface features which are usually specific to a given problem. If we were to ask novices to think aloud while solving three statistics problems, they might mention that they all relate to experiences in school, particularly examinations; but they would probably not say that all involve the principle of central tendency.

Rating tasks

Analyzing interview and think-aloud protocols can take a long time. Studying them is like grading very long essay tests. A more simple way to assess cognitive processes is to ask individuals to rate the similarity between problems based on a specific characteristic. For example, experts and novices might be asked to rate the similarity between pairs of statistics problems as regards the principle of central tendency. Such ratings reveal that the experts see stronger association between pairs of problems that are essentially similar, compared with novices.

STRATEGIC KNOWLEDGE

Linking Domain-Specific Knowledge to Strategic Knowledge

Analogical reasoning relates the familiar to the unfamiliar. It is therefore relevant to the relationship between domain-specific knowledge and basic forms of strategic knowledge. Robert Sternberg (1977) has researched analogical reasoning and proposed that four component processes are used to solve problems: 'encoding', 'inferring', 'mapping', and 'applying'.

For example, consider a verbal analogy problem, such as: ' *boy* is to *man* as *girl* is to…?'. First, one has to define what the three terms *boy*, *man* and *girl* (in general, *A*, *B* and *C*) mean. This is the encoding step. Then, one has to infer the relationship between the *A* and *B* terms. The relationship between *boy* and *man* is that a boy is a male child while a man is a male adult. Then, one maps the relationship between the *A* and *C* terms. The common principle between boys and girls is that they are both children. The final component of analogical reasoning is to apply the rules learned in inferring and mapping to generate a solution, or construct a *D* term.

Essentially, the experts' ability to say that one problem is 'like' another problem because of the underlying theme of central tendency is a form of analogical reasoning.

Analogies and General Strategic Processing

Analogies are also relevant to general strategic processing, particularly when they are constructed in nonverbal, figural form. The same component processes (encoding, inferring, mapping and applying) seem to operate for these nonverbal analogies as for verbal analogies. Figure 2 is an example characteristic of those included on the 'Ravens Standard Progressive Matrices' tests (Raven, 1958). Items like this contain no content information, so they make for good measures of general strategic processing. Respondents have to track how the figures change in the matrix. Sometimes the strategic rules simply involve adding or deleting elements; sometimes the rules are very complex, involving rotations and transformations as well. Tracking complex rules requires considerable effort and concentration.

Psychologists have recently discovered that nonverbal analogy tests like the Ravens Standard Progressive Matrices assess not only general strategic

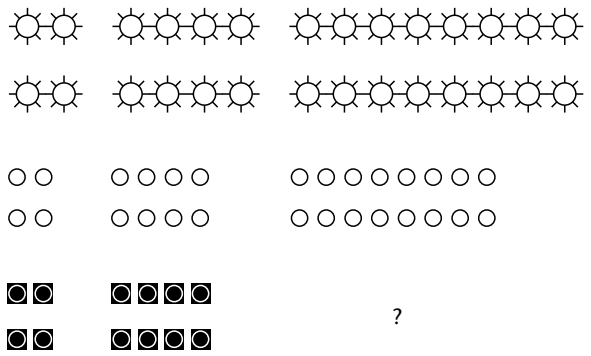


Figure 2. A nonverbal analogy matrix.

processing, but also metacognitive ability. Put simply, metacognition is thinking about our thinking. We use metacognition as we evaluate our progress, make plans, and consider possible new approaches to problem solving. As one works from matrix to matrix in solving the nonverbal analogies, one monitors how the rules change, from simple addition and deletion to more complex rotation and transformation problems.

The Link Between Metacognition and Complex Strategic Processing

For some, the analogy problems discussed above might seem easy to solve. Certainly, these types of problems are highly structured, and many items can be presented on one assessment tool. However, there are other types of tasks used to assess metacognition that are complex and less structured. These tasks reveal the degree to which project completion or problem solution require complex strategic processing. Consider the common situation where experts in many disciplines compose research papers to share their knowledge with others. Locating research material, taking good notes when reading research material, organizing notes into themes or summary statements, writing a draft of the paper so that main ideas are highlighted, and revising and editing the draft to produce a final version, are some of the many strategies that expert authors use to compose their research papers. Metacognition helps experts to select, monitor, and evaluate these strategies in an effort to produce papers of high quality that contribute new knowledge in their fields of study.

Cognitive psychologists have employed many methods to assess domain-specific and strategic knowledge. These methods have shed light on how expert processing differs from novice processing within and across domains. We will now turn our attention to assessment practices as they pertain to academic learning.

DYNAMIC ASSESSMENT

The goal of 'dynamic assessment' is to study cognitive development together with effectiveness of instruction. Dynamic assessment is therefore long-term: it is the study of one's potential to know more information in time. Dynamic assessment involves intermittent interventions of instruction. It is essential not only to provide feedback to a student, but also to instruct the student about concepts and strategies that contribute to proficient understanding. In their extensive review of dynamic testing, Grigorenko and Sternberg (1998) traced the roots of this assessment paradigm to the work of Lev Vygotsky (1962) in the 1930s. Vygotsky introduced the concept of the 'zone of proximal development', which reflects one's potential for growth in cognitive and social functioning facilitated through social interaction, such as learning from a teacher. The zone of proximal development is not to do with how one has developed, but with how one can become what one is not yet. Thus, rather than reflecting how an expert became proficient, it indicates how a novice might become proficient as a result of a synchronous interplay of evaluation and instruction.

CONCEPTUAL CHANGE

Like dynamic assessment, 'conceptual change' focuses on development. But while dynamic assessment attends to one's potential to learn, conceptual change attends to how knowledge is restructured as a result of learning and instruction (Pintrich *et al*., 1993). The study of human error patterns provides important insights as to how knowledge is restructured over time. From their study of the errors that participants produced given various types of tasks for various domains, Alexander *et al*. (1998) showed that the mistakes or errors we make are typically nonrandom; they occur in systematic patterns (e.g. we tend to make similar mistakes repeatedly); and they can provide the means for instructional intervention.

Multiple-Choice Questions and Error Patterns

Multiple-choice questions, for example, can be used to study how individuals choose options

that vary in their relatedness to the target domain. Consider the following example from the domain of statistics:

The standard deviation of a univariate distribution is:

1. The average distance from the mean. [correct statistics option]
2. The square root of the range. [incorrect statistics option]
3. A difference between a negative and a positive value. [incorrect mathematics option]
4. A common mistake made when spelling words. [incorrect non-mathematics option]

The four options have varying degree of correctness. All items on a test will employ the same hierarchy: there will always be a correct response in the domain of statistics; an incorrect response in the domain of statistics; an incorrect response in mathematics (not statistics) and an incorrect response outside the domain of mathematics.

Analysis of students' responses to such tests indicates that learners gravitate toward one error category rather than another, according to their familiarity with the domain. Such error patterns allow psychologists to profile learners according to their schematic knowledge. Thus, some students know a lot about the domain of statistics, and even when incorrect, they choose options that are representative of the correct domain. Other students do not have an initial sense of the domain: their errors indicate this. These error patterns are valuable to instructors, for they help them to modify the curriculum to meet the needs of learners with a wide range of abilities.

Error Patterns and Constructed-Response Tasks

Multiple-choice questions are referred to as choice tasks since the respondent is asked to check, circle, or mark an answer that is already presented on the test. Errors are also informative in so-called constructed-response tasks (Martinez, 1999). Alexander *et al*. (1998) demonstrated this in their study of domain-specific analogies. Using a categorization system to evaluate the types of response generated, they noted that even incorrect analogy solutions hinted at whether students lacked domain knowledge, strategic knowledge, or both. Table 1 presents this categorization scheme, using one analogy problem (in statistics) to illustrate the errors that inform researchers of the degree to which a student lacks knowledge. As with multiple-choice questions, error patterns help teachers to design intervention strategies. When such tests are applied at different times in studies of development, the transitions between error categories, leading toward correct responses, assist cognitive psychologists in their assessment of conceptual change: they can determine exactly when students' knowledge has been restructured to allow for principled use.

ACHIEVEMENT

'Achievement' refers to the assessment of knowledge acquisition, reading comprehension, or problem solving resulting from instruction. Traditionally, standardized assessments using multiple-choice formats have been used to evaluate student

Table 1. Categorization scheme for analysis of analogy problem responses

Category	*Example*	*Description*
No response	sample: statistic : : population:	No evidence of domain-specific or strategic knowledge.
Repetition	sample : statistic : : population : *statistic*	No strategic understanding of analogical relationships.
Non-domain response	sample : statistic : : population : *people*	Response is not related to target domain of statistics.
Structural dependency	sample : statistic : : population : *large statistic*	Response indicates use of component processes and some idea of the relationships among terms in statistics.
Domain response	sample : statistic : : population : *sigma*	Response indicates use of component processes and a response that is a term related to the correct response in statistics.
Target variant	sample : statistic : : population : *parametric*	Strong evidence of both domain-specific knowledge and strategic processing. The answer is a high-level error because it is merely a variation of the correct response. (The correct response should be a noun, not an adjective.)
Correct response	sample : statistic : : population : *parameter*	

achievement. However, poorly-constructed multiple-choice assessments encourage students to value rote memorization over more complex forms of thinking (Martinez, 1999). Constructed-response tasks in the forms of 'performance-based' and 'portfolio' assessments, are generally recommended by cognitive psychologists.

Performance-Based Assessment

Performance-based assessments require students to build objects, design plans, conduct experiments, deliver speeches and presentations, or stage plays and debates that are indicative of the kinds of tasks and procedures that experts perform. Psychologists develop 'rubrics' or scoring schemes, and train raters, or judges, to assign scores to student performance. Rubrics can take many forms, from simple checklists to complex rating scales. Imagine an instructor in physics who wants to assist students in their use of the internet to locate resources to conduct science experiments. The instructor finds a website that will be interesting to students. There are links at the site that allow students to study original scientific documents, visit virtual science museums, and communicate online with experts. Using the links on the site, the instructor hopes that students will learn to appreciate that finding information in the form of documents or dialogs with experts, and comprehending this information, is as important as working with equations or performing experiments in the laboratory. Knowing how to share this information with others in the form of a report is also important. Thus, the teacher creates the rubric presented in Figure 3 to evaluate student performance. This rubric is a simple rating scale that the teacher can use, the student can use for self-evaluation, or peers can use to provide feedback to one another.

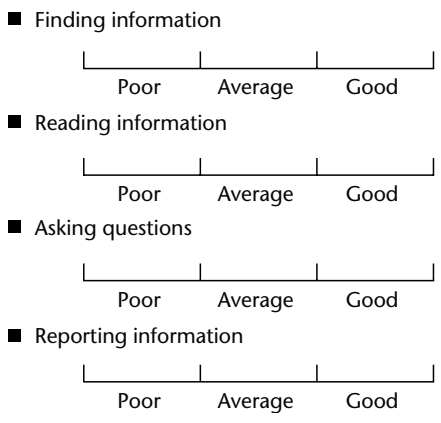

Figure 3. A possible rubric for a performance-based assessment of a research task.

Portfolio Assessment

Sometimes psychologists assess achievement over time using combinations of test formats that allow students to 'showcase' their best work. These 'portfolio assessments' not only provide information on the cognitive development of students, but also present examples of students' creative products and their interests. Interests and motivation are important to cognitive psychologists: according to models of academic development such as that proposed by Patricia Alexander (1997), one does not activate knowledge use and strategic processing without being motivated by one's domain of study. Indeed, being interested in the subject matter contributes as much to becoming an expert as does domain-specific knowledge, strategic processing, and metacognition. Portfolio assessments are a good way for students to express what is of interest to them, and they can show how these interests have changed over time in relation to changes in their knowledge.

FUTURE PROSPECTS

There are many more types of assessment than we have discussed in this article. With emergent technologies in areas like robotics and computer-aided and simulation design, and opportunities afforded by the internet, new ways to assess cognitive processes are emerging rapidly. Perhaps the only limitation of cognitive psychologists' ability to assess is their own creativity.

Instruction and Cognition

Introductory article

Richard E Mayer, University of California, Santa Barbara, California, USA

CONTENTS

During learning, instruction can guide cognitive processing, which in turn influences what is learned.

INTRODUCTION

Framework for Cognition and Instruction

What is the relation between cognition (in particular, cognitive processing during learning) and instruction? An important aspect of the relation concerns learning. Learning is a change in knowledge, and instruction is activity aimed at fostering this change. The premise of research on cognition and instruction is that if you want to improve instruction, it is useful to understand how people learn.

Figure 1 shows a framework for discussing cognition and instruction. Instruction (including instructional methods and materials) affects the cognitive processes of the learner during learning (including paying attention, mentally organizing the material, and mentally connecting the material with existing knowledge), which affects the knowledge changes in the learner (i.e., the learning outcome), which affects performance on tests. Instruction and performance are external and observable whereas cognitive processes and knowledge changes are internal and can only be inferred from performance. An important goal of research on cognition and instruction is to understand how instructional manipulations affect cognitive processing in the learner, and how this cognitive processing leads to changes in knowledge and, ultimately, performance.

Learning

'Learning' refers to enduring changes in a learner's knowledge that arise from the learner's cognitive processing of experiences. This definition contains: (1) learning results in a relatively permanent change (rather than a short-term change); (2) the change is caused by the learner's cognitive processing of his or her experiences (rather than by physical causes such as fatigue or drugs); and (3) the change occurs within the learner's mind (but must be inferred from changes in behavior). Examples include learning number facts, such as the fact that $5 \times 5 = 25$; learning to describe how a scientific system, such as the process of lightning formation, works; and learning to analyze a worldwide problem such as the consequences of global warming.

Instruction

'Instruction' refers to the teacher's manipulation of the learner's experiences that are intended to foster learning. This definition contains: (1) instruction involves the intentional creation of environments for learners to experience; and (2) instruction is intended to foster changes in the learner. Examples include drill and practice on arithmetic facts; multimedia presentations depicting how a lightning storm develops; and classroom discussions concerning the possible political ramifications of global warming.

THREE CONCEPTIONS OF LEARNING

The study of cognition and instruction is based on the search for an educationally relevant theory of learning – i.e. a theory of learning that links instructional manipulations with cognitive processing and knowledge change within the learner. The search for an educationally relevant theory of learning can be traced back to the work of E. L. Thorndike in the early twentieth century. During the past 100 years the conception of learning has been based on a progression of three metaphors: response

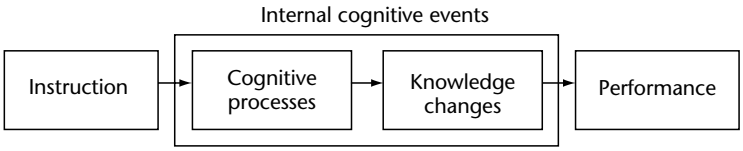

Figure 1. Four components in a model of cognition and instruction.

Table 1. Three conceptions of learning

	Learning as response strengthening	*Learning as information acquisition*	*Learning as knowledge construction*
Learning	Strengthening and weakening of stimulus–response associations	Adding information to memory	Building meaningful knowledge
Teacher	Dispenser of rewards and punishments	Dispenser of information	Cognitive guide
Learner	Recipient of rewards and punishments	Recipient of information	Sense maker
Instruction	Drill and practice	Textbooks, lectures and multimedia presentations	Guided exploration

strengthening, information acquisition, and knowledge construction. Table 1 lists the characteristics of each of these conceptions of learning.

Learning as Response Strengthening

The first conception listed in Table 1 is that learning involves the strengthening or weakening of the association between a stimulus and a response (S–R association), based on rewards and punishments. In this conception, the teacher becomes a dispenser of rewards and punishments, and the learner becomes a passive recipient of rewards and punishments. Following the four elements of Figure 1, the major instructional method is drill and practice, in which the learner is encouraged to make a short response to a stimulus (such as saying 'four' when the teacher says 'what is two plus two?'). The cognitive processing during learning is simply the strengthening or weakening of S–R associations. Thorndike's law of effect states that when a response is followed by a pleasurable state of affairs, the S–R link is strengthened; but when a response is followed by displeasure, its link with the stimulus situation is weakened. In its most strict form, this conception of learning holds that the change occurs without conscious mental effort, that is, the strengthening or weakening occurs automatically as a result of rewards and punishments. Thus, the link between the stimulus 'what is two plus two?' and the response 'four' gets stronger if the teacher says 'right', whereas the link between the stimulus 'what is two plus two?' and the response 'three' gets weaker if the teacher says 'wrong'. The learning outcome, or change in knowledge, involves an S–R link that is stronger or weaker than before learning. The resulting performance is that the learner is either more or less likely to make a certain response when confronted with a certain stimulus.

The conception of learning as response strengthening dominated psychology and education for most of the first half of the twentieth century, and was supported mainly by research with animals in contrived laboratory settings. It is still influential today, particularly where basic skills are taught, although there is mounting evidence that the learner's interpretation can influence the strengthening and weakening process.

Learning as Information Acquisition

The second conception listed in Table 1 is that learning involves the acquisition of information, in which presented information is added to the learner's memory bank. In this conception, the teacher's job is to present information as efficiently as possible and the learner's job is to add the presented information to memory. In this way, the learner is a passive recipient of information. Following the four elements listed in Figure 1, the major instructional methods involve techniques for presenting material to learners, such as textbooks, lectures, and multimedia presentations. The major

cognitive process during learning is encoding – that is, adding material to one's long-term memory. In computational terms, information from the outside world is input into the learner, held temporarily in a short-term memory store, and eventually transferred into a long-term memory store. Cognitive processing involves making mental manipulations (or computations) on the data that are input, and storing the results in a memory store. For example, if the teacher says 'Washington is capital of the United States' then this information may eventually be transferred for storage in the learner's memory. The outcome of learning is simply information that has been placed in long-term memory. Test performance is reflected in the learner's ability to answer questions based on the learned information.

The information acquisition conception became popular in the 1960s and 1970s, and was based largely on research with humans in contrived laboratory situations. It is still influential today, particularly concerning memorization of basic facts, although there is mounting evidence that the encoding process can be far more active than originally proposed.

Learning as Knowledge Construction

The third conception of learning listed in Table 1 is knowledge construction, in which learners actively build organized and meaningful representations in their minds. In this view, the teacher is a cognitive guide who influences the way the learner processes incoming material, and the learner is a sense maker who strives to understand the presented material. The major instructional methods involve forms of guided exploration, such as classroom discussion, or cognitive apprenticeship, in which students work with an expert on an authentic academic task. The cognitive processes during learning include paying attention to the relevant material, mentally organizing the material into a coherent structure, and mentally connecting the material with prior knowledge. F. C. Bartlett's research in the 1930s on people's memory for folk stories was among the first to portray learning as an active process in which the learner struggles to make sense of new material. In particular, Bartlett argued that active learning involved assimilating presented material with one's existing schemata in an attempt to make sense of the stories. The outcome of learning is a coherent mental representation that includes elements that were presented and elements from prior knowledge. The knowledge construction view rose in prominence during the 1980s and 1990s, and was based mainly on research with humans in realistic learning settings. It continues to influence psychology and education today, and has been expanded to include the social context of active learning.

HOW PEOPLE LEARN

Research in cognitive science has yielded three principles that are particularly useful in building an educationally relevant theory of learning: dual channels, limited capacity, and active learning. Figure 2 presents a cognitive theory of learning that incorporates these three principles. The boxes on the left represent material that is presented to the learner (in this case pictures and words). The next boxes show how the presented material is represented in sensory memory (through processing by the eyes and ears). The next boxes show how the presented material is represented in working memory (in pictorial and verbal codes). Next, the knowledge that is constructed in working memory is integrated with prior knowledge from long-term memory and ultimately stored in long-term memory. The final box represents performance of the learner based on the newly constructed knowledge.

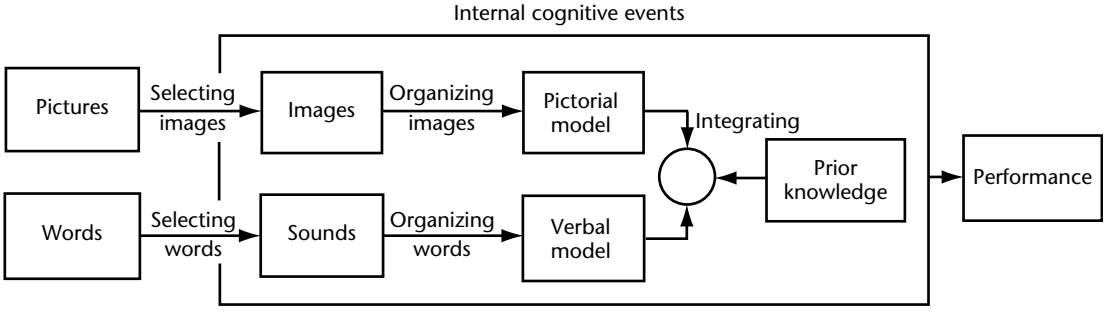

Figure 2. A cognitive theory of learning.

Dual Channels

The first principle is that humans possess separate information processing channels for verbal and pictorial material. The top row of Figure 2 shows the pictorial (or visual) channel, in which material is received by the eyes and is represented pictorially in working memory. The bottom row of Figure 2 shows the verbal (or auditory) channel, in which material is received by the ears (or initially by the eyes), and is represented verbally in working memory. Although verbal forms of presentation have dominated in most academic instruction for a long time, there is increasing evidence that learning can be enhanced when supporting visual material is also presented. Although humans possess channels for other modalities (such as haptic or vistibular), we focus on the visual and auditory modalities because they are the most relevant to classroom educational settings.

Limited Capacity

The second principle is that the capacity to process material in working memory is very limited. Humans are able to hold only a few items in visual working memory and only a few items in verbal working memory. These limitations make it inefficient to try to remember all of the presented material, so that learners have to focus on the most important aspects of the visual and verbal material.

Active Processing

The third principle is that meaningful learning occurs when learners engage in appropriate cognitive processing during learning. Three particularly important cognitive processes during learning are selecting, organizing, and integrating (see Figure 2). Selecting involves paying attention to relevant portions of the material in sensory memory for further processing in working memory. Organizing involves building coherent cognitive structures based on the selected material. Integrating involves building connections between the various verbal and pictorial models in working memory and relevant prior knowledge from long-term memory.

Meaningful learning depends on active cognitive processing during learning – whereby the learner selects, organizes, and integrates material – rather than on active behavior during learning, such as hands-on activities. While some hands-on activities (such as completing a laboratory project) may foster active cognitive processing, other hands-on activities may not; while some forms of passive instruction (such as lecturing) may foster active cognitive processing, others may not.

KINDS OF KNOWLEDGE

If learning involves the construction of knowledge, then it is useful to examine the kinds of knowledge that people build. Psychologists distinguish between declarative knowledge and procedural knowledge. Declarative knowledge is knowledge about the world that corresponds to questions about 'what', including factual and conceptual knowledge. Procedural knowledge is knowledge about how to do things that corresponds to questions about 'how to', including algorithmic and strategic knowledge. Educators distinguish between 'low-level' and 'high-level' knowledge. Low-level knowledge supports basic skills and consists of factual and procedural knowledge that forms the foundation of a subject. High-level knowledge supports higher-order skills and consists of conceptual and strategic knowledge that allow one to use a subject matter. Table 2 shows how the distinctions between declarative and procedural knowledge and between low-level and high-level knowledge give rise to four distinct kinds of knowledge.

Factual Knowledge

Factual knowledge is low-level declarative knowledge about the definitions or characteristics of elements. Factual knowledge includes knowing the definition of basic terms (e.g. 'factual knowledge is low-level declarative knowledge'), knowing the symbols used in a field (e.g. 'arrows refer to cognitive processes in Figure 2'), and knowing the features or properties of basic elements (e.g. 'knowledge exists only in the learner's mind').

Conceptual Knowledge

Conceptual knowledge is high-level declarative knowledge about the interrelations among elements within a meaningful structure. Conceptual knowledge includes knowing the classification relations among the main concepts or categories in a

Table 2. Four kinds of knowledge

	Declarative	*Procedural*
Low-level	Factual	Algorithmic
High-level	Conceptual	Strategic

field (e.g. the classification system shown in Table 2), knowing the principles or generalizations in a field (e.g. knowing what it means to say that working memory is limited in capacity), and knowing the theories or models in a field (e.g. the system of learning summarized in Figure 2).

Algorithmic Knowledge

Algorithmic knowledge is low-level procedural knowledge about how to carry out a precise procedure or skill. Algorithmic knowledge includes knowledge of specific procedures (e.g. how to compute a mean) or skills (e.g. how to change font style in a word processor).

Strategic Knowledge

Strategic knowledge is high-level procedural knowledge about how to use a general strategy or method, including knowing how to select an appropriate algorithm. Strategic knowledge includes knowing general methods (e.g. how to judge the scientific merits of a published research study), knowing general strategies (e.g. how to write an essay on a given topic), and knowing how to manage one's cognitive resources (e.g. how to determine whether a given paragraph conveys its intended meaning). This last example represents meta-cognitive strategic knowledge, that is, knowledge about one's own cognitive processing. In addition, the learner's attitudes and beliefs, such as the belief that 'I am good at learning about cognitive science', are important kinds of knowledge.

TYPES OF LEARNING PERFORMANCE

Learning is generally assessed by using two different kinds of tests: retention and transfer tests. This distinction is at the heart of Bloom's taxonomy of educational objectives, an important analysis originally published in the 1950s and recently updated.

Retention

Retention tests measure how much or how well the learner remembers the presented material. Retention is often the stated goal of training programs, and often focuses on the learner's low-level knowledge such as factual and procedural knowledge. Retention tests are the most straightforward way of measuring learning. They include recall and recognition tests. In a recall test, the learner is asked to produce some of the presented information (e.g. to answer the question 'what are the two kinds of tests used to assess learning?'). In a recognition test, the learner is asked to select or verify some of the presented information, as in a multiple-choice question (e.g. 'learning is generally measured by: (a) retention tests, (b) transfer tests, (c) both, (d) neither') or a true-or-false question (e.g. 'true or false: learning is generally assessed by retention and transfer tests').

Transfer

Transfer tests measure how well the learner can use what was learned in order to solve new problems or support new learning. Transfer is often the stated goal of schooling and often focuses on how well the learner can use high-level knowledge such as conceptual and strategic knowledge. Transfer tests are more complex than retention tests. They sometimes involve quantitative measurements (e.g. counting the number of correct answers to the question 'what are the advantages of transfer measures over retention measures?'), and sometimes qualitative measures (e.g. categorization of the mental model or strategy that the learner uses in describing his or her thought process in creating a transfer problem).

TYPES OF LEARNING OUTCOMES

According to the cognitive theory of learning, there are three broad classes of learning outcomes: no learning, rote learning, and meaningful learning.

No Learning

'No learning' is indicated by poor performance on tests of retention and transfer. In this case, the learner has failed to attend to the relevant material during learning (i.e. the cognitive process of selecting) or to retain it.

Rote Learning

Rote learning is indicated by good performance on tests of retention and poor performance on tests of transfer. In this case, the learner has attended to the relevant material during learning (i.e. the cognitive process of selecting) but has not mentally organized the material into a coherent structure or mentally integrated the material with existing knowledge. For example, after reading a lesson explaining how lightning storms develop, the learner remembers much of the factual material – such as the duration of a lightning strike – but is not

able to use the material to determine how to reduce the intensity of a lightning storm.

Meaningful Learning

Meaningful learning is indicated by good performance on retention and transfer tests. In this case, the learner has attended to the relevant material, and mentally organized and integrated it. For example, after reading a lesson on lightning formation, the learner remembers some of the basic facts and is able to answer transfer questions such as how to reduce the intensity of a lightning storm. According to cognitive theories of learning, meaningful learning is qualitatively different than rote learning. Rather than simply learning more than rote learners, meaningful learners construct knowledge that is structurally different from that of rote learners. In some cases, these differences can be described in terms of differences between the mental models – that is, representations of how a cause-and-effect system works – that rote and meaningful learners construct.

TEACHING FOR MEANINGFUL LEARNING

A major challenge is to understand how to create instructional methods that foster meaningful learning, as measured by superior retention and transfer performance. Such methods must guide appropriate cognitive processing during learning, including helping learners to select, organize, and integrate the presented material. Among the instructional methods that have been suggested to achieve this goal are: giving productive feedback, providing guided exploration, explaining worked examples, guiding cognitive processing of text, teaching learning strategies, creating cognitive apprenticeship, and priming learners' motivation to learn.

Giving Productive Feedback

Practice with feedback is a traditional instructional method, especially when teaching low-level knowledge such as algorithms and facts. The teacher encourages the learner to make some response and then provides feedback concerning it. For example, the learner may be asked to answer a question such as '$5 - (-3) = \ldots$'; if the learner replies '2', the teacher says 'wrong' and if the learner replies '8', the teacher says 'right'. This level of feedback – which may be called 'right–wrong feedback' – is consistent with the view of rewards and punishments as automatically increasing and decreasing response strengths, but inconsistent with the cognitive view that rewards and punishments are used as information that the learner interprets to adjust his or her knowledge. According to a cognitive view, for example, effective feedback might be to show a number line in which a bunny starting from 0 moves 5 steps to the right (positive direction), then turns backwards to face the left (negative) side, jumps backwards 3 steps, and lands on the number 8. This kind of feedback (given after wrong or right answers) is richer than right–wrong feedback, and is more likely to guide the learner in the process of knowledge building.

Providing Guided Exploration

Guided exploration is also a traditional instructional method, especially when teaching students how to understand algorithms, strategies, and concepts. The student is asked to solve a problem, or engage in a complex task, while the teacher provides some form of guidance. The guidance may involve giving hints (as in discovery methods), making the material more concrete (as in concrete methods), or linking the task to the learner's prior knowledge (as in inductive methods). For example, in teaching students how to find the area of a parallelogram, the teacher can allow learners to cut a triangle from one end of a cardboard parallelogram and place it on the other side to form a rectangle. The learners can then find the area because they know how to find the area of a rectangle. This procedure involves making the materials concrete (by using a cardboard parallelogram), giving hints (by suggesting that the learner use scissors), and linking the task to the learner's prior knowledge (by seeing how an unfamiliar shape – the parallelogram – is just a rectangle in disguise).

Explaining Worked Examples

When the goal is to help students learn strategies for solving problems, then it may be useful to teach by explaining how to solve example problems. When given worked examples, the learner is able to focus on realistic problems and reflect on successful ways of solving them. Two instructional approaches to teaching by example are example-based methods and case-based methods. In example-based methods, the learner is shown a step-by-step solution to an example problem. For example, when the goal is to teach learners how to troubleshoot a car that will not start, an example-based method would be to have an expert mechanic describe their thought process as they inspect

the car. In case-based methods, students learn to solve simulated cases – that is, realistic and authentic problems in a particular field. For example, when the goal is to teach learners how to diagnose symptoms in a patient, a case-based method would be to give the learners a full description of the patient and have them discuss possible diagnoses with each other and with a physician who explains his or her own thinking process.

Guiding Cognitive Processing of Text

When instructional material is presented in the form of prose – that is, printed or spoken text – then it may be useful to design the prose so that it guides the learner's cognitive processing. Guiding cognitive processing of text is most often used to teach factual and conceptual knowledge. For example, adjunct questions – questions placed before or after a passage – can help to guide the learner's attention. Signaling – whereby the passage begins with an outline, has headings keyed to the outline, and contains pointer words such as 'first', 'second' and 'third' – can help guide the learner's mental organizing of the material. Advance organizers – introductory material aimed at priming or providing a familiar context to which the material can be assimilated – can help the learner's mental integrating of the material with prior knowledge.

Teaching Learning Strategies

The process of learning depends both on the material that is presented and on how the material is processed by the learner. In teaching learning strategies, the teacher provides direct instruction in how to learn – that is, in helping learners to control their cognitive processing during learning. Learning strategies can range from mnemonic strategies for memorizing facts, to outlining strategies for organizing presented material, to summarizing strategies for integrating material with existing knowledge. In addition to building a collection of learning strategies, learners also need to know when to use them and how to monitor them; such skills may be called 'metacognitive strategies'.

Creating Cognitive Apprenticeship

Throughout human history, people have learned through various forms of apprenticeship in which they participate in authentic tasks under the supervision of more experienced mentors. In creating cognitive apprenticeship, teachers invite learners to join with them in tackling an authentic academic task such as making sense of a text passage or composing a persuasive essay. In working with learners, the teacher may provide scaffolding (taking away difficult portions of the task), coaching (giving advice about how to do part of the task), and modeling (showing how to complete parts of the task). Cognitive apprenticeship makes use of the social context of learning by creating a community of learners who help one another in the learning process.

Priming Learners' Motivation to Learn

Another instructional method focuses on the learner's motivation to learn, and is based on the idea that learners work harder to understand material when they are motivated to learn. Three ways to prime the learner's motivation to learn are: to teach topics that the student is interested in (motivation based on interest), to provide training aimed at bolstering the learner's perception of himself or herself as a competent learner (motivation based on self-efficacy), and to provide training aimed at creating the belief that successes and failures depend on the learner's effort rather than the learner's ability (motivation based on attributions).

ADVANCES IN COGNITION AND INSTRUCTION

Research on cognition and instruction can enrich both psychology and education. Education enriches psychology by challenging psychologists to develop theories of learning that apply in realistic settings beyond the laboratory. Psychology enriches education by searching for educationally relevant theories of learning. The interaction between cognition and instruction has allowed advances in several areas, including the psychology of subject matter, the teaching of cognitive strategies, and the analysis of cognitive abilities.

Psychology of Subject Matter

Psychologies of subject matter seek to create theories of how people learn and think within specific content areas (such as reading, writing, mathematics, science, or history). Instead of trying to build a general theory of learning applicable to all situations – an approach that has soundly failed in psychology in spite of decades of effort – researchers focus on understanding how people learn in specific content areas such as how they learn to read, write, or compute. Consistent with the larger

theme of domain-specificity of cognition, research in psychologies of subject matter demonstrates that ways of thinking differ between content areas.

Teaching of Cognitive Strategies

The teaching of cognitive strategies involves providing direct instruction in how to learn, remember, or reason. Instead of focusing solely on teaching of basic skills, researchers focus on understanding how to help learners develop strategies for using their knowledge and for processing new material to create new knowledge. Rather than trying to improve the mind in general – an approach that has failed despite decades of effort – researchers focus on identifying specific component strategies that are required for successful cognitive processing on various tasks.

Analysis of Cognitive Abilities

The analysis of cognitive abilities involves conceptualizing cognitive ability, (1) as a collection of component skills rather than as a single, monolithic trait, and (2) as a set of specific skills rather than as a general ability. An important advance in cognition and instruction is the attempt to analyze cognitive ability for any academic domain into smaller components that reflect differences in how people process information within that domain.

Overall, the interaction of the fields of cognition and instruction has generated useful advances for psychology and education. This process is likely to continue in the future.

CONCLUSION

Instruction (including instructional methods) affects the cognitive processes of the learner during learning (including paying attention, mentally organizing the material, and mentally connecting the material with existing knowledge), which affects knowledge changes in the learner (that is, the learning outcome), which affects performance on tests (such as retention and transfer). 'Learning' refers to enduring changes in a learner's knowledge that arise from the learner's cognitive processing of his or her experiences. 'Instruction' refers to the teacher's construction of experiences for learners that are intended to foster learning.

Three conceptions of learning are: learning as response strengthening, learning as information acquisition, and learning as knowledge construction.

Instructional practice should be based on a theory of how people learn. Three principles for building an educationally relevant theory of learning are: that people have separate channels for processing verbal and pictorial material (the dual channels principle); that processing capacity is severely limited within each channel (the limited capacity principle); and that active learning depends on the learner engaging in appropriate cognitive processing during learning (the active learning principle).

Four distinct kinds of knowledge are: factual, conceptual, algorithmic, and strategic. Two types of tests of learning are retention tests and transfer tests. Three kinds of learning outcomes are: no learning, rote learning, and meaningful learning.

Some instructional methods aimed at teaching for meaningful learning are: giving productive feedback, providing guided exploration, explaining worked examples, guiding cognitive processing of text, teaching learning strategies, creating cognitive apprenticeship, and priming learners' motivation to learn.

Three useful advances in research on cognition and instruction are: new conceptions of the psychology of subject matter, the teaching of cognitive strategies, and the analysis of cognitive abilities.

CONTENTS

Instructional design is that branch of knowledge concerned with theory and practice, related to instructional strategies and systematic procedures for developing and implementing those strategies.

INTRODUCTION

Instructional design is a construct that refers to the principles and procedures by which instructional materials, lessons, and whole systems can be developed in a consistent and reliable fashion. The principles and procedures can be applied to guide designers to work more efficiently while producing more effective and appealing instruction suitable for a wide range of learning environments.

As well as being a construct, instructional design is also a field of theory and practice within the larger field of instructional technology. Instructional designers work in many settings, including schools, colleges and universities, corporations, and military and government agencies.

This article will address in turn the underlying instructional principles, the procedural guides by which these principles are put into application, and finally the construction of learning environments as an alternative way of putting the principles into action.

PRINCIPLES

The design of instruction can be informed by principles drawn from many disciplines, including educational psychology, cognitive science, systems theory, communications, philosophy, anthropology, and organizational theory.

Behaviorist Psychology Sources

The original momentum for the modern concept of instructional design came from B.F. Skinner's suggestions regarding the application of operant conditioning principles to education (Skinner, 1954). His vision became instantiated in programmed instruction, which was based on the following set of prescriptive principles:

> (1) an ordered sequence of stimulus items, (2) to each of which a student responds in some specified way, (3) his responses being reinforced by immediate knowledge of results, (4) so that he moves by small steps, (5) therefore making few errors and practicing mostly correct responses, (6) from what he knows, by a process of successively closer approximations, toward what he is supposed to learn from the program. (Schramm, 1962, p. 2)

As research and practical experience accumulated, the generality of many of these principles came into question. That is, the sequence of experiences, the nature of the response, the timing of feedback, and the size of steps all appeared to be contingent on various learner and learning conditions. The prescriptions of programmed instruction were broadened and reduced by Popham (1971) to four principles:

> (1) Provide relevant practice for the learner. (2) Provide knowledge of results. (3) Avoid the inclusion of irrelevancies. (4) Make the material interesting. (Popham, 1971, p. 171)

Cognitive Sources

Since the 1960s, instructional design has been increasingly informed by principles drawn from other sources, especially cognitive science and cognitive psychology. Cognitive models for instruction emphasize the importance of the learner's cognitive and affective processes in mediating the effects of instruction. From this perspective, learners use their memory and thought processes to generate strategies as well as to store and manipulate mental representations of images and ideas.

Robert Gagné was a leading interpreter of learning theory into instructional theory. Early editions of his influential book, *The Conditions of Learning* (Gagné 1965), proposed that the information-processing model of learning could be combined with behaviorist concepts to provide a more complete view of learning tasks. From descriptive theories of information processing, Gagné deduced prescriptive theories about instruction methods ('external conditions of learning'). His list of nine 'instructional events' became a robust and influential conceptual schema for the planning of lessons:

> (1) gaining attention; (2) informing learners of the objective; (3) stimulating recall of prior learning; (4) presenting the content; (5) providing 'learning guidance'; (6) eliciting performance; (7) providing feedback; (8) assessing performance; (9) enhancing retention and transfer. (Gagné and Medsker, 1996, p. 140)

More recently, other descriptive theories of learning that are derived from a cognitive perspective have influenced further prescriptive theories and principles for instruction. Schema theory, which emphasizes the schematic structure of knowledge, is one of the major sources of influence. Ausubel (1980) described schemata as providing ideational scaffolding, which contains slots that can be instantiated with particular cases. These schemata allow learners to organize information into meaningful units. This theory implies that the learner's cognitive structure at the time of learning is the most important factor in determining the likelihood of successful learning. One instructional design principle derived from this theory pertains to the advance organizer – a brief outline based on the learner's existing knowledge, which serves as 'ideational scaffolding' for new learning. Ausubel proposed that advance organizers could activate broader and more inclusive knowledge, providing a cognitive structure for new meaningful learning.

Constructivist Sources

Other educational theories emphasize the importance of the ideas generated by learners themselves. Wittrock (1974) described a view of learning and instruction in which the 'generations' (mental activities such as summaries, pictures, analogies, and discussions) performed by learners influence the success of instruction. This emphasis on learner generation characterizes constructivism, which assumes that 'knowledge is individually constructed and socially co-constructed by learners based on their interpretations of experiences in the world' (Jonassen, 1999, p. 217). Prescriptive principles from constructivism include the following:

> (1) Embed learning in complex, realistic and relevant environments. (2) Provide for social negotiation as an integral part of learning. (3) Support multiple perspectives and the use of multiple modes of representation. (4) Encourage ownership in learning. (5) Nurture self-awareness of the knowledge construction process. (Driscoll, 2000, pp. 382–383)

An alternative view of constructivism, known as the 'situated cognition' perspective, which is derived from anthropology (Lave and Wenger, 1991; Barab *et al.*, 1999), proposes that the need to understand the learning context supersedes the need to understand the mental processes going on inside individual learners – that is, the learner and the environment are always interacting. For example, what is understood as memorized algorithms in a mathematics classroom differs from what is understood through grappling with a real-world carpentry problem.

The field offers a wide variety of theories of instructional design that prescribe specific methods of instruction and the conditions under which they can best be used. A growing number of instructional design theories have been developed to address a wide range of learning situations in order to foster cognitive, psychomotor, or affective development. These include theories for such diverse types of learning as experiential, collaborative, and self-regulated learning, as well as emotional, social, and even spiritual development (Reigeluth, 1999).

Comprehensive Set of Design Principles

A recent synthesis by M. David Merrill (Merrill, 2001) provides a coherent and comprehensive overview of instructional design principles from an eclectic perspective, incorporating behaviorist, cognitivist, and constructivist conceptions:

- *Problem*. Learning is facilitated when the learner:
  - …is engaged in solving a real-world problem;
  - …is engaged at the problem or task level, not just the operation or action level;
  - …solves a progression of problems;
  - …is guided to an explicit comparison of problems.
- *Activation*. Learning is facilitated when the learner:
  - …is directed to recall, relate, describe, or apply knowledge from relevant past experience that can be used as a foundation for the new knowledge;
  - …is provided with relevant experience that can be used as a foundation for the new knowledge.

- *Demonstration*. Learning is facilitated when:
  - …the learner is shown rather than told;
  - …the demonstration is consistent with the learning goal;
  - …the learner is shown multiple representations;
  - …the learner is directed to explicitly compare alternative representations;
  - …the media play a relevant instructional role.
- *Application*. Learning is facilitated when:
  - …the learner is required to use his or her new knowledge to solve problems;
  - …the problem-solving activity is consistent with the learning goal;
  - …the learner is shown how to detect and correct errors;
  - …the learner is guided in his or her problem-solving by appropriate coaching that is gradually withdrawn.
- *Integration*. Learning is facilitated when the learner:
  - …can demonstrate his or her new knowledge or skill;
  - …can reflect on, discuss, and defend his or her new knowledge;
  - …can create, invent, and explore new and personal ways to use his or her new knowledge.

(Merrill, 2001, pp. 5–7)

APPLICATIONS

Instructional design theories and principles are put into practice by being embedded in procedural guides or protocols for instructional development. These often take the form of instructional systems development (ISD) process models.

ISD Process Models

Historically, instructional design can be seen as having two parents, namely the systems approach and behaviorist psychology. The relative contributions of each are difficult to assess because at the time when instructional design was conceived the two sources were quite intertwined. During the post-World War II period each of the US military services had developed doctrines for training development, all of which were based on the systems approach – a 'soft' version of systems analysis, itself an offshoot of operations research. Behaviorist learning theory was a pervasive influence in US military training, and was being enthusiastically explored in school and university instruction during this same time period. Many of those who had been involved in military training development were applying their craft in university research and development centers. Thus the systems approach and behaviorist concepts became increasingly intertwined, both in the military services and in academia.

During the 1960s, the systems approach began to appear in procedural models of instruction in US higher education. Barson's (1967) instructional systems development project produced an influential model and set of heuristic guidelines for developers. If one looks at the form and language of these early models, the influence of the systems approach paradigm is obvious. Early models instantiate the principles of gathering and analyzing data prior to making decisions, and using feedback to correct deficiencies in work completed. They include systems terminology such as 'mission objectives,' 'transmission vehicles,' 'error detection,' and so on. The 'soft' systems concept continued to evolve in terms of its application to complex problems in human organizations, since it was recognized that 'hard' mathematical systems concepts did not apply directly to complex clusters of human activities, which represented systems only in the loosest sense of the term. Thus the systems concept came to be seen more as an analogy or as a 'means of *structuring a debate*, rather than as a recipe for guaranteed efficient achievement' (Checkland, 1981, p. 150).

The largest group of models is derived from the 'soft' systems paradigm, commonly referred to as the ADDIE model (an acronym derived from the key steps in the model: Analysis, Design, Development, Implementation, and Evaluation). These steps identify a generic systems approach, similar to that applied in other fields such as software engineering and product design. The ADDIE approach is systematic in that it recommends using the decisions made at each step (the output) as the input for the next step. That is, the *analysis* stage begins by surveying the learners and learning environment in order to determine which learning problems are of high priority and should be chosen as objectives. In the *design* stage, those learning objectives are translated into lesson plans or blueprints. In the *development* stage, specific materials and procedures are created to give life to the blueprints. In the *implementation* stage, learners actually use the materials and procedures that were created. In the *evaluation* stage, the learners are assessed in order to determine the extent to which they mastered the objectives specified at the beginning, and revisions are made as necessary. The ADDIE family of models, represented by 13 different variations on the systems approach, has been analyzed by Gustafson and Branch (1997).

Instructional Theory-based ISD Models

In addition to generic ISD process models, a number of alternative models have been developed as guides to the application of particular instructional design theories. One of the earliest was *structural communication*, developed in the UK by Bennett and Hodgson (Hodgson, 1974). Originating as a reaction to the limitations of programmed instruction, structural communication involved a process of analysis and development contingent on different levels of thinking, namely creative, conscious, sensitive, and automatic levels (whereas programmed instruction lent itself only to the sensitive and automatic levels). The form of the instruction resembles a guided discussion, emphasizing the role of the learner as an active inquirer.

A more recent attempt to mold a process model around the constructivist view is the *reflective recursive design and development* model of Willis and Wright (2000). Their process revolves around three focal points, namely definition, design/development, and dissemination. It assumes

> that designers will work on all three aspects of the design process in an intermittent and recursive pattern that is neither predictable nor prescribable. The focal points are, in essence, a convenient way of organizing our thoughts about the work. (Willis and Wright, 2000, p. 5)

LEARNING ENVIRONMENTS

Some approaches to instructional design focus not on the procedural steps involved in creating specific lessons, but on the construction of whole learning environments that have special features conducive to efficient, effective learning. Such learning environments can themselves be viewed as large-scale methods – frameworks that are created in order to immerse learners in a consistent set of instructional conditions. Examples include the personalized system of instruction (Semb, 1997), goal-based scenarios (Schank *et al*., 1999), problem-based learning (Boud and Feletti, 1997), open learning environments (Hannafin *et al*., 1999), and constructivist learning environments (Jonassen, 1999).

Intellectual Ability

Introductory article

Robert J Sternberg, Yale University, New Haven, Connecticut, USA

CONTENTS

Intellectual abilities comprise those higher-order cognitive skills that are involved in coping with the environments in which we live, including but not limited to learning and thinking skills. Intelligence, creativity, and wisdom are three of the major intellectual abilities.

INTELLIGENCE

Defining Intelligence

Intelligence involves the ability to adapt to the environment. But what specifically is involved in intelligent thinking?

Two symposia have sought to ascertain the essential features of intelligence, one in 1921 and the other in 1986. Features that have been proposed include: adaptation in order to meet the demands of the environment effectively; elementary processes of perception and attention; higher-level processes of abstract reasoning, mental representation, problem-solving, and decision-making; ability to learn; and effective behavior in response to problem situations.

Some researchers, such as Boring in 1923, have been content to define intelligence operationally, simply as the 'intelligence quotient' (IQ). Originally, IQ was defined in terms of a ratio of one's mental-age level of performance to one's chronological-age level of performance, but today IQs are defined in terms of how much one differs from the average. An average IQ is 100. Slightly more than two-thirds of IQs fall between 85 and 115.

Scientific definitions rely on tests such as those invented by Binet and Simon in 1916 to measure judgmental abilities or by Wechsler in 1939 to measure verbal and performance abilities. Earlier tests proposed by Galton in 1883 measured psychophysical abilities (such as sensitivity of hearing or touch). They proved to be less valid, in that they correlated neither with each other nor with success in educational settings.

Laypeople also can be asked to define intelligence, and it turns out that their definitions differ from scientists' definitions in placing somewhat greater emphasis on social competence. In one study by Sternberg and his colleagues, for example, laypeople defined intelligence in terms of three broad classes of skills: practical problem-solving; verbal ability; and social competence. But how people define intelligence varies across occupations. For example, one study found that philosophy professors tend to stress critical and logical thinking very heavily, whereas physicists tend to place more value on precise mathematical thinking, the ability to relate physical phenomena to theoretical concepts of physics, and the ability to grasp quickly the laws of nature.

How people define intelligence also depends on the culture in which they live. For example, in 1974 Wober studied two tribes in Uganda. He found that the Baganda tended to associate intelligence with mental order, whereas the Batoro associated it with mental turmoil. Super analyzed concepts of intelligence among the Kokwet of western Kenya. He found that intelligence meant different things for children and adults. Children who were responsible as well as quick in comprehension and effective in their management of interpersonal relationships were viewed as intelligent; while adults were viewed as intelligent if they were inventive and, sometimes, if they were wise and unselfish. Yang and Sternberg found that Chinese people in Taiwan characterize intelligence in terms of cognitive abilities, but also interpersonal and intrapersonal (self-understanding) skills, as well as knowing when to show one's abilities and when not to show them.

Heritability and Modifiability of Intelligence

Whatever human intelligence may be, that aspect of it measured as IQ is both partially heritable – with a heritability coefficient estimated at about 0.5

(somewhat lower in childhood and higher in adulthood) – and modifiable to some degree. Thus, roughly half the variation in scores on intelligence tests is due to heritable factors, and half to environmental factors.

Flynn has discovered that intelligence as measured by IQ tests rose steadily throughout most of the twentieth century. Because of the rapidity of the increase, the increase could not be due to genetic factors. There may be unknown factors in the environment that have produced these increases; or it may be that IQ tests really, to some extent, measure something other than intelligence.

Theories of Intelligence

A theory, in contrast to a definition, must provide an explanatory framework and be testable. Proposed theories of intelligence have been of several different kinds.

Psychometric theories

The best-known theories are probably the psychometric theories. Such theories are based on, and often tested by, analysis of individual differences in scores among people who take tests. Most conventional intelligence tests have arisen from psychometric theories. These tests, mostly originating in the early twentieth century, became especially popular during the First World War as a means of screening soldiers. Then and now, the tests have tended, on average, to favor individuals of higher socioeconomic status and, in the United States, who are European–American or Asian–American rather than African–American or Hispanic–American. There are many alternative explanations for these differences, but most researchers regard them as environmental in origin.

The earliest major psychometric theory was that of Spearman, who proposed in 1904 that intelligence comprises a 'general factor' (*g*) common to all intellectual tasks, as well as 'specific factors' (*s*), each of which is unique to a given test of intelligence. His proposal was based on his finding of a 'positive manifold' among intelligence tests: all tests seemed to be positively intercorrelated, suggesting the existence of a general factor. Spearman's theory still has many proponents today, such as Jensen, whose analyses of factor-analytic and other data suggest what he believes to be a single factor underlying virtually all intellectual performances.

In 1938, Thurstone disagreed with Spearman, arguing that the general factor was an artifact of the way Spearman analyzed his data. Thurstone suggested that seven primary mental abilities underlie intelligence: verbal comprehension, verbal fluency, number skills, spatial visualization, inductive reasoning, memory, and perceptual speed. More recent theorists, such as Cattell and Carroll, have attempted to integrate these two kinds of views, suggesting that intelligence is best understood hierarchically, with a general factor at the top of the hierarchy (i.e. more central to intelligence) and narrower factors under it. Cattell proposed two such factors: fluid intelligence, which is involved in reasoning with novel kinds of stimuli; and crystallized intelligence, or stored knowledge.

The principal limitations of psychometric theories are that they rely heavily, often exclusively, for their validation on correlational methods; that they depend heavily on the existence and strength of individual differences; and that what one gets out of a psychometric analysis is a transformation of what one puts in, so that if one puts in questionable tests, one gets out questionable results.

Computational theories

Unlike psychometric models, which map the structure of human intelligence, computational models emphasize the processes underlying intelligent behavior. In particular, theorists using these models are interested in studying how people engage in information processing – that is, the operations by which people mentally manipulate what they learn and know about the world. Such studies differ primarily in terms of the complexity of the processes being studied. One way to study the relation between intelligence and information processing is to examine simple information processing such as occurs when one must make rapid judgments about which of two lines is longer.

Deary and Stough have proposed that a very low-level psychophysical measure, inspection time, may provide us with insights into the fundamental nature of intelligence. Their basic idea is that individual differences in intelligence may derive, in part, from differences in the rate of intake and processing of very simple stimulus information. In the inspection-time task, a person looks at two vertical lines of unequal length, and simply has to say which line is longer. Inspection time is the length of time of stimulus presentation an individual needs in order correctly to decide which of the two lines is longer. Pairs of lines are presented for different periods of time, and psychophysical methods are used to determine how quickly an individual can distinguish their lengths. Investigators have found that more intelligent individuals (as defined by IQ) can discriminate the lengths of

the lines with smaller stimulus durations (inspection times).

Another computational approach considers complex information processing such as occurs in analogies (problems of the form '*A* is to *B* as *C* is to what?'), series problems (e.g. completing a numerical or figural series), and syllogisms (problems such as 'John is taller than Peter; Peter is taller than Robert; who is tallest?'). The goal of this approach has been to find out just what it is that makes some people more intelligent processors of information than others. The idea is to take the kinds of tasks used in conventional intelligence tests and to isolate the components of intelligence – the mental processes used in performing these tasks. Examples of such processes include translating sensory input into a mental representation, transforming one conceptual representation into another, and translating a conceptual representation into a motor output. Typically, measurements are made both in terms of response time to answer test items and in terms of whether the response given is correct.

In general, according to Sternberg, more intelligent people take longer during global planning (encoding the problem and formulating a general strategy for attacking the problem or set of problems) but they take less time for local planning (forming and implementing strategies for the details of the task). The advantage of spending more time on global planning is the increased likelihood that the overall strategy will be correct. For example, the brighter person might spend more time researching and planning for writing a term paper, but less time actually writing it. This differential in time allocation has also been shown in other tasks, including solving physics problems.

Whereas information-processing investigators study such differences at the level of hypothesized mental processes, biological investigators seek to understand the origins of such differences in terms of the functioning of the brain.

Some related work looks at the role of working memory in intelligence. For example, a number of investigators, such as Kyllonen and Christal, have proposed that general intelligence actually is, in large part, working memory. This is the kind of ability that is measured when, say, a person is asked to remember a series of numbers (such as '3-2-6-1-7-4') backwards.

Computational theories have certain limitations. Reaction-time and related methodologies may make assumptions (for example, assumptions of serial information processing) that are not valid. Computational theories also sometimes ignore the contexts in which mental processes occur, and thus may make claims for generality that exceed their scope.

Biological theories

Most biological theories have been of aspects of intelligence rather than of the phenomenon as a whole. However, one early theory that has had considerable influence did try to deal with the phenomenon as a whole. Hebb proposed three kinds of intelligence: 'A', 'B', and 'C'. Intelligence A, he proposed, is largely genetic and 'hard-wired' in its origins. Intelligence B is the result of the interaction between genes and environment. Intelligence C is one's performance on a standardized test of intelligence. This theory, although heuristically useful, is largely speculative.

Systems theories

Some theories of intelligence have viewed intelligence as a system. By far the best-known theory of this kind is that of Piaget, according to which intelligence involves an equilibration between two processes: assimilation of new information to fit existing cognitive structures, and accommodation of existing cognitive structures to incorporate information that does not fit into existing cognitive structures. Sternberg has proposed that intelligence comprises three aspects: analytical abilities (used to analyze, evaluate, and criticize), creative abilities (used to create, discover, and invent), and practical abilities (used to apply, implement, and use). Intelligent people, according to this 'theory of successful intelligence', make the most of their strengths and either correct or compensate for their weaknesses. Gardner has suggested instead that there are multiple intelligences: linguistic, logical–mathematical, spatial, musical, bodily–kinesthetic, naturalist, intrapersonal, and interpersonal intelligence; and perhaps also existential intelligence. The recent theory of 'emotional intelligence' also describes intelligence in a broad way. (*See* **Intelligence**)

Gardner's theory has not, so far, generated any predictive scientific data that test the model as a whole, so that questions about its validity cannot yet be adequately answered.

CREATIVITY

Creativity involves producing ideas that are original (novel), of high quality, and appropriate to the task being considered. Creativity often involves seeing problems and their solutions in a variety of different ways, and acting upon these different

ways of seeing things. Several accounts of creativity have been offered, which shed light on different aspects of it. Sternberg and Lubart have distinguished the types of approach described below.

Psychodynamic Approaches

The psychodynamic approach can be considered the first of the major twentieth-century theoretical approaches to the study of creativity. Starting from the idea that creativity arises from the tension between conscious reality and unconscious drives, Freud proposed that writers and artists produce creative work as a way to express their unconscious wishes in a publicly acceptable fashion. These unconscious wishes may concern power, riches, fame, honor, or love. Case studies of eminent creators, such as Leonardo da Vinci, were used to support these ideas.

Later, the psychodynamic approach as used by Kris introduced the concepts of 'adaptive regression' and 'elaboration' for creativity. Adaptive regression, the primary process, is the intrusion of unmodulated thoughts in consciousness. It occurs when one returns to states of consciousness typical of one's earlier life. Such returns can be adaptive if they help one to generate useful ideas. Unmodulated thoughts can occur during active problem-solving; but they also often occur during sleep, intoxication from drugs, fantasies or daydreams, or psychoses. Elaboration, the secondary process, is the reworking and transformation of primary-process material through reality-oriented, ego-controlled thinking.

Other theorists such as Kubie emphasized that the preconscious, which falls between conscious reality and the encrypted unconscious, is the true source of creativity because preconscious thoughts are loose and vague but interpretable. In contrast to Freud, Kubie claimed that unconscious conflicts actually have a negative effect on creativity because they lead to fixated, repetitive thoughts.

In general, the evidence in favor of psychodynamic approaches tends to be more anecdotal than experimental.

Psychometric Approaches

When we think of creativity, eminent artists or scientists such as Michelangelo or Einstein immediately come to mind. However, these highly creative people are rare and difficult to study in the psychological laboratory. In 1950, Guilford noted that this difficulty had limited research on creativity. He proposed that creativity could be studied in ordinary subjects using paper-and-pencil tasks. One of these was the 'unusual uses test', in which an examinee thinks of as many uses for a common object (such as a brick) as possible. Many researchers adopted Guilford's suggestion, and 'divergent thinking' tasks quickly became the main instruments for measuring creative thinking. The tests were a convenient way of comparing people on a standard 'creativity' scale.

Building on Guilford's work, Torrance in 1974 developed a set of tests of creative thinking. These tests consist of several relatively simple verbal and figural tasks that involve divergent thinking and other problem-solving skills. They can be scored for fluency (total number of relevant responses), flexibility (number of different categories of relevant responses), originality (statistical rarity of the responses) and elaboration (amount of detail in the responses). The Torrance tests include: asking questions (the examinee writes out all the questions he or she can think of, based on a drawing of a scene); improving an object (the examinee lists ways to change a toy monkey so that children will have more fun playing with it); thinking of unusual uses (the examinee lists interesting and unusual uses of a cardboard box); and developing circles (the examinee expands empty circles into different drawings and gives them titles).

Two obvious disadvantages of such tests and assessments are the time and expense involved in administering them, and the subjective scoring of them. In 1962, Mednick produced a 30-item, objectively scored, 40-minute test of creative ability called the 'remote associates test'. The test is based on his theory that the creative thinking process is the forming of associative elements into new combinations that are in some way useful. The more mutually remote the elements of the new combination, the more creative the process or solution is alleged to be. Because the ability to make these combinations and arrive at a creative solution depends on the existence of the necessary elements in a person's knowledge base, and because the probability and speed of attainment of a creative solution are influenced by the organization of the person's associations, Mednick's theory suggests that creativity and intelligence are closely related.

The remote associates test requires the subject to supply a fourth word that is remotely associated with three given words. For example: 'rat', 'blue', and 'cottage' may yield 'cheese'; 'surprise', 'line', and 'birthday' may yield 'party'; 'out', 'dog', and 'cat' may yield 'house'.

Cognitive Approaches

The cognitive approach to creativity seeks understanding of the mental representations and processes underlying creative thought. By studying, say, perception, or memory, one would already be studying the bases of creativity; thus, the study of creativity would merely represent an extension, and perhaps not a very large one, of work that is already being done under another guise. For example, creativity has often been subsumed under the study of intelligence. Creativity and intelligence are certainly related; however, the subsumption has often been so strong as to suggest that they need not be regarded as distinct – a view which researchers such as Wallach and Kogan have argued against.

More recently, Weisberg has proposed that creativity involves essentially ordinary cognitive processes yielding extraordinary products. Weisberg attempted to show that insights depend on subjects applying ordinary cognitive processes (such as analogical transfer) to knowledge already stored in memory. He used case studies of eminent creators, as well as laboratory research, such as studies with Duncker's candle problem (proposed in 1945). This problem requires participants to attach a candle to a wall using only objects available in a picture (candle, box of thumbtacks, and book of matches). Langley and his colleagues have made a similar claim about the ordinary nature of creative thinking.

As a concrete example of this approach, Weisberg and Alba asked people to solve the nine-dot problem. The problem is to connect all of the dots, which are arranged in the shape of a square with three rows of three dots each, using no more than four straight line segments, never arriving at a given dot twice, and never lifting their pencil from the page. It can be solved only if the line segments go outside the square of dots. Weisberg and Alba showed that even when people were given this insight, they still had difficulty in solving the problem. In other words, whatever is required to solve the nine-dot problem, it is not just this one extraordinary insight.

Finke, Ward, and Smith have proposed what they call the 'Geneplore' model, according to which there are two main processing phases in creative thought: a generative phase and an exploratory phase. In the generative phase, an individual constructs mental representations ('preinventive structures'), which have properties promoting creative discoveries. In the exploratory phase, these properties are used to produce creative ideas. A number of mental processes may enter into these phases of creative invention, such as retrieval, association, synthesis, transformation, analogical transfer, and categorical reduction (i.e. mentally reducing objects or elements to more primitive categorical descriptions). In a typical experimental test based on this model, participants are shown parts of objects, such as circles, cubes, parallelograms, or cylinders. On a given trial, three parts will be named, and participants will be asked to imagine combining the parts to produce a practical object or device. For example, participants might imagine a tool, a weapon, or a piece of furniture. The objects thus produced are then rated by judges for their practicality and originality.

Computer-simulation approaches have as their goal the production of creative thought by a computer in a manner that simulates what people do. Langley, Simon, Bradshaw, and Zytgow, for example, have developed a set of programs that rediscover basic scientific laws. These computational models rely on heuristics – problem-solving guidelines – for searching a data set or conceptual space and finding hidden relationships between input variables. The program, called BACON (after the philosopher Francis Bacon), uses heuristics such as 'if the values of two numerical terms increase together, consider their ratio' to search data for patterns. One of BACON's accomplishments was to examine some of the observational data on the orbits of planets available to Kepler and rediscover Kepler's third law of planetary motion. This program is unlike creative functioning, however, in that problems are given to it in structured form: creative functioning is largely about discovering what the problems are.

Other programs have extended the search heuristics, the ability to transform data sets, and the ability to reason with qualitative data and scientific concepts. There are also models of artistic creation. For example, Johnson-Laird has developed a jazz improvisation program in which novel deviations from the basic jazz chord sequences are guided by harmonic constraints (or tacit principles of jazz), and random choice when several allowable directions for the improvisation exist.

Social–Personality Approaches

Developing in parallel with the cognitive approach, work in the social–personality approach has focused on personality variables, motivational variables, and the sociocultural environment as sources of creativity. Researchers such as Amabile, Barron, Eysenck, Gough, and MacKinnon have noted that

certain personality traits often characterize creative people. Through correlational studies and research using samples of both eminent and ordinary people at high and low levels of creativity, a large set of potentially relevant traits has been identified. These traits include independence of judgment, self-confidence, attraction to complexity, aesthetic orientation, and risk-taking.

Proposals regarding self-actualization and creativity can also be considered within the personality tradition. According to Maslow, boldness, courage, freedom, spontaneity, self-acceptance, and other traits of this kind lead a person to realize his or her full potential. Rogers described the tendency toward self-actualization as having motivational force and being promoted by a supportive, evaluation-free environment.

Focusing on motivation for creativity, a number of theorists, such as Amabile, Crutchfield, McClelland, and Golann, have hypothesized the relevance of intrinsic motivation, need for order, need for achievement, and other motives. Amabile and her colleagues have conducted important research on intrinsic and extrinsic motivation. Studies using motivational training and other techniques have manipulated these motivations and observed effects on creative performance tasks, such as writing poems and making collages.

Finally, the relevance of the social environment to creativity has also been an active area of research. At the societal level, Simonton has conducted numerous studies in which levels of creativity in eminent people over large spans of time in diverse cultures have been statistically linked to environmental variables. These variables include, among others, cultural diversity, war, availability of role models, availability of resources (such as financial support), and number of competitors in a domain. Cross-cultural comparisons by Lubart, and anthropological case studies, have demonstrated cultural variability in the expression of creativity. Moreover, they have shown that cultures differ in the value they place on the creative enterprise.

Evolutionary Approaches

The evolutionary approach to creativity was instigated by Campbell in 1960. Campbell suggested that the same kinds of mechanisms that have been applied to the study of the evolution of organisms – namely, selection and retention – could be applied to the evolution of ideas. This suggestion has been enthusiastically followed by a number of investigators, such as Simonton.

The basic idea underlying this approach is that there are two basic steps in the generation and propagation of creative ideas. The first is 'blind variation', by which the creator generates an idea without any real idea of whether the idea will be successful, in the sense of being selected for, in the world of ideas. Indeed, Simonton has argued that creators have no knowledge of which of their ideas will succeed. Therefore, their best strategy for producing lasting ideas is to produce a large quantity of them. Simonton argued that their 'hit' rate remains relatively constant throughout their professional life; in other words, a fixed proportion of their ideas will succeed. The more ideas they have in all, the more of their ideas will achieve success.

The second step is 'selective retention'. In this step, the field in which the creator works either retains the idea for the future or lets it die. Thus, some ideas a creator believes are creative may not be so viewed by the field, and they are not picked up by others. Those ideas that are selectively retained are the ones that are judged by the field to be novel and of value, that is, creative. Blind variation and selective retention are described further by Cziko.

Confluence Approaches

Much recent work on creativity, by Amabile, Csikszentmihalyi, Gardner, Gruber, Sternberg, Lubart, Mumford, Gustafson, and others, hypothesizes that multiple components must converge for creativity to occur. Sternberg, for example, examined laypeople's and experts' conceptions of the creative person. People's implicit theories contain a combination of cognitive and personality elements, such as 'connects ideas', 'sees similarities and differences', 'has flexibility', 'has aesthetic taste', 'is unorthodox', 'is motivated', 'is inquisitive', and 'questions societal norms'.

At the level of explicit theories, Amabile has described creativity as the confluence of intrinsic motivation, domain-relevant knowledge and abilities, and creativity-relevant skills. The creativity-relevant skills include: a cognitive style that involves coping with complexities and breaking one's mental set (way of looking at problems) during problem-solving; knowledge of heuristics for generating novel ideas, such as trying a counterintuitive approach; and a work style characterized by concentrated effort, an ability to set problems aside, and high energy.

Gruber and his colleagues have proposed a developmental 'evolving-systems' model for understanding creativity. A person's knowledge,

purpose, and affect grow over time, amplify deviations that the person encounters, and lead to creative products. Developmental changes in the knowledge system have been documented in cases such as Charles Darwin's thoughts on evolution. 'Purpose' refers to a set of interrelated goals, which also develop and guide an individual's behavior. Finally, the affect or mood system records the influence of joy or frustration on the projects undertaken.

Csikszentmihalyi has taken a different 'systems' approach, highlighting the interaction between the individual, the domain, and the field. The individual draws upon information in a domain and transforms or extends it via cognitive processes, personality traits, and motivation. The field, consisting of people who control or influence a domain (e.g. art critics and gallery owners), evaluates and selects new ideas. The domain, a culturally defined symbol system, preserves and transmits creative products to other individuals and future generations.

Gardner has conducted retrospective case studies that suggest that the development of creative projects may stem from an anomaly within a system (e.g. tension between competing critics in a field) or moderate asynchronies between the individual, the domain, and the field (e.g. unusual individual talent for a domain). In particular, Gardner has analyzed the lives of seven individuals who made highly creative contributions in the twentieth century, each specializing in a different one of the 'multiple intelligences': Sigmund Freud (intrapersonal), Albert Einstein (logical–mathematical), Pablo Picasso (spatial), Igor Stravinsky (musical), T. S. Eliot (linguistic), Martha Graham (bodily–kinesthetic), and Mohandas Gandhi (interpersonal). Charles Darwin would be an example of someone with extremely high naturalist intelligence. Gardner points out, however, that most of these individuals actually had strengths in more than one intelligence, and that they had notable weaknesses in others (e.g. Freud's weaknesses may have been in spatial and musical intelligences). Of course, retrospective case studies are subject to biases due to selection of information, and eventually need to be supplemented by prospective analyses (i.e. prediction of future behavior).

Sternberg and Lubart have proposed an 'investment' approach to creativity, according to which creative people are viewed as 'good investors'. They are people who 'buy low and sell high' in the world of ideas. They generate ideas that may be seen by others as 'a bit odd' and perhaps even as undesirable ('buying low'). They then try to persuade other people of the value of their ideas. Having done so, at least to some extent, they 'sell high', moving on to the next seemingly strange idea.

Sternberg and Lubart suggest, therefore, that creative people 'defy the crowd': they see things in their own way and try to persuade others to see things in this way. Sternberg and Lubert measured creativity by asking people to do a variety of different tasks – for example, to write short stories with titles such as 'The Octopus's Sneakers' or 'Trapped'; or to draw sketches with titles such as 'The Beginning of Time' or 'The Earth from an Insect's Point of View'; or to produce interesting advertisements for 'dull' products such as a new brand of doorknob or the Internal Revenue Service; or to indicate how we would know if there were extraterrestrial aliens among us seeking to escape detection. Creativity was assessed for each task in terms of novelty, quality, and task appropriateness. Using these kinds of measures, Sternberg and Lubart found that creativity is largely domain-specific: people who are creative in one domain are not necessarily creative in another. They also found creativity to be only weakly related to intelligence as it is traditionally defined.

WISDOM

Wisdom is called into play for tasks requiring good judgment and common sense. How is wisdom to be understood?

Implicit-Theoretical Approaches

Implicit-theoretical approaches to wisdom have in common the search for an understanding of people's folk conceptions of what wisdom is. Thus, the goal is not to provide a 'psychologically true' account of wisdom, but rather an account that is true with respect to people's beliefs, whether these beliefs are right or wrong.

Some of the earliest work of this kind was done by Clayton, who found three factors underlying people's conceptions of wisdom: experience; pragmatism; understanding; and knowledge.

Holliday and Chandler also used an implicit-theoretical approach to understanding wisdom. Analysis of one of their studies revealed five underlying factors: exceptional understanding; judgment and communication skills; general competence; interpersonal skills; and social unobtrusiveness.

Sternberg reported a series of studies investigating implicit theories of wisdom. Six components emerged: reasoning ability; sagacity; learning from

ideas and environment; judgment; expeditious use of information; and perspicacity.

Explicit-Theoretical Approaches

Explicit theories are constructions of theorists and researchers rather than of laypeople. In the study of wisdom, most explicit-theoretical approaches are based on constructs from the psychology of human development.

The most extensive program of research has been that conducted by Baltes and his colleagues. For example, Baltes and Smith gave adult participants life-management problems, such as 'A 14-year-old girl is pregnant. What should she, what should one, consider and do?' and 'A 15-year-old girl wants to marry soon. What should she, what should one, consider and do?' Baltes and Smith tested a five-component model on participants' protocols in answering these and other questions, based on a notion of wisdom as expert knowledge about fundamental life matters or as good judgment and advice in important but uncertain matters of life.

Three kinds of factors – general person factors, expertise-specific factors, and facilitative experiential contexts – are proposed to facilitate wise judgments. These factors are used in life planning, life management, and life review. Wisdom is then reflected in five components: rich factual knowledge (general and specific knowledge about the conditions of life and its variations); rich procedural knowledge (general and specific knowledge about strategies of judgment and advice concerning matters of life); lifespan contextualism (knowledge about the contexts of life and their temporal (developmental) relationships); relativism (knowledge about differences in values, goals, and priorities); and uncertainty (knowledge about the relative indeterminacy and unpredictability of life and ways to manage this). An expert answer should reflect more of these components, whereas a novice answer should reflect fewer of them. The data collected have generally been supportive of the model.

Over time, Baltes, Staudinger, and their colleagues have collected a wide range of data showing the empirical utility of the proposed theoretical and quantitative approaches to wisdom. For example, Staudinger, Lopez, and Baltes found that measures of intelligence and personality, and their interface, overlap with but are not identical to measures of wisdom in terms of constructs measured; and Staudinger, Smith, and Baltes showed that human-services professionals outperformed a control group on wisdom-related tasks. They also showed that older adults performed as well on such tasks as did younger adults, and that older adults did better on such tasks if there was a match between their age and the age of the fictitious characters about whom they made judgments. Baltes, Staudinger, Maercker, and Smith found that older individuals nominated for their wisdom performed as well as did clinical psychologists on wisdom-related tasks. They also showed that up to the age of 80, older adults performed as well on such tasks as did younger adults. In a further set of studies, Staudinger and Baltes found that performance settings that were ecologically relevant to the lives of their participants and that provided for actual or 'virtual' interaction of minds increased wisdom-related performance substantially.

Although most developmental approaches to wisdom are ontogenetic, Csikszentmihalyi and Rathunde have taken a philogenetic or evolutionary approach, arguing that wise ideas must have been selected for over time, at least in a cultural sense. In other words, wise ideas should survive better over time than unwise ideas in a culture. They define wisdom as having three basic dimensions of meaning: a cognitive process, or a particular way of obtaining and processing information; a virtue, or socially valued pattern of behavior; and a good, or personally desirable, state or condition.

A definition of wisdom proposed by Sternberg draws upon the notion of balance. Wisdom is defined as the application of practical intelligence, as mediated by values, towards the goal of achieving a common good through a balance among multiple interests (intrapersonal, interpersonal, and extrapersonal), responses to environmental contexts (adaptation to and shaping of existing environmental contexts, and selection of new environmental contexts), and time frames (long-term and short-term).

According to this definition, the essence of wisdom is balance. People can be intelligent, in the sense of being analytically keen, but not wise, if they fail to balance others' interests or the interests of institutions with their own. Wisdom, then, requires a use of intellectual abilities to benefit not only oneself, but also others and society. Current research on this paradigm is seeking to validate the theory and to show that it is possible to teach wisdom-related thinking to young children.

Learning Aids and Strategies

Intermediate article

John Sweller, University of New South Wales, Sydney, Australia

CONTENTS

Knowledge about human cognitive architecture has transformed instructional design. The fact that we have a limited working memory and an effectively unlimited long-term memory holding automated schemata can be used to derive principles that guide the manner in which information is presented and the activities learners should engage in.

INTRODUCTION

Cognitive science has transformed our understanding of learning. That transformation has provided, for the first time, a coherent theoretical basis from which to generate and test instructional hypotheses. As a consequence, the field of instructional design now has a unity and integrity that was previously missing, and learning aids and strategies have been devised that would have been difficult or impossible to devise without a knowledge of human cognitive architecture. This article discusses that architecture along with the instructional principles that derive from our deepening understanding of cognitive theory.

HUMAN COGNITIVE ARCHITECTURE

Described below are several structural features and processes, along with their general implications for instructional design. In particular, working memory, long-term memory, schema construction, and automation will be discussed. Other important aspects of cognitive architecture (e.g. sensory memory) will not be discussed because they have not had a comparable impact on instructional design principles.

Working Memory

In describing the characteristics of working memory we are describing the characteristics of consciousness. The severe limitations of working memory and its division into auditory and visual components will be discussed here.

Working memory is limited both in duration and in capacity. If people attempt to recall lists of nonsense syllables and are prevented from rehearsing, 50% of what was memorized is lost after 3 seconds and almost everything is lost after 18 seconds. These results indicate that working memory, the source of all conscious learning, thinking, and problem solving, is capable of holding new material for no more than a few seconds at a time. Capacity limitations are also severe. Working memory can hold no more than about four to seven items of new information at a time. Furthermore, it should be noted that working memory is not normally used to simply hold information. It is the processing engine of the human cognitive system, where processing involves combining, contrasting or manipulating information in some manner. The number of items of information that can be processed in working memory, as opposed to just held, is probably about two or three, depending on the nature of the manipulations required.

Working memory can be divided into separate auditory and visual components (Baddeley, 1992). Auditory working memory is used to deal with auditory material, primarily speech but also music and other sounds, while visual working memory deals with two- or three-dimensional objects. The two processors are partially independent. Total working memory capacity can be increased by providing different information to each. That the independence is partial rather than complete can be seen from the fact that the amount of information that can be handled by both processors simultaneously is substantially less than the sum of the amounts that can be handled by the processors in isolation.

Long-Term Memory

Over the last few decades, long-term memory has gradually and surprisingly emerged as central to human cognitive processing. Its importance may far exceed that of working memory. Several points concerning the characteristics of long-term memory need to be considered.

Firstly, all learning, from rote memorization to deep understanding, can be fully characterized by changes in long-term memory. If there are no changes in long-term memory, nothing has been understood or learned.

Secondly, since we are only conscious of the very limited material in working memory, at any given time we are unconscious of most of the material held in long-term memory.

Thirdly, long-term memory capacity is enormous and far beyond any current measurement techniques. It is effectively unlimited.

The importance of long-term memory in high-level cognitive processing was first revealed in the 1940s by de Groot's (1965) work using the game of chess. He found no differences between chess grandmasters and weekend players in depth or breadth of search. Both groups considered approximately the same number of alternative move sequences when faced with a board configuration taken from a real game. In contrast, there were dramatic differences in memory of configurations. If shown a board configuration taken from a real game for a few seconds, grandmasters could reproduce almost the entire configuration, while novices could reproduce very little of it. This difference was not due to working-memory differences because it disappeared when random board configurations were used. The ability of chess grandmasters derives not from a mysterious reasoning skill but from holding tens of thousands of board configurations, and the best move associated with each configuration, in long-term memory. Less able players must make constant use of limited working memory to attempt to derive appropriate moves for most configurations. Grandmasters can defeat them because they know which move is superior for many more configurations. All educated people learn similar skills in the variety of areas covered by their education.

Schemata

The structure of knowledge held in long-term memory is described by schemata, cognitive constructs that allow us to treat several elements of information as a single element classified according to the way it will be used (Chi *et al*., 1981). We have schemata for trees which allow us to treat the myriad of elements that go to make up a tree as a single element. Schemata for trees allow us to recognize something as a tree despite the fact that every tree has a unique shape, color, and context in time and place. Schemata for the letter *a* allow us to recognize this letter despite its having an infinite variety of forms when handwritten. Higher-order schemata allow us to recognize combinations of letters that make up words and combinations of words that make up phrases and sentences. If we have elementary algebraic knowledge a schema tells us instantly that the first move to solve the equation $(a+b)/c=d$ for a is to multiply by c. Chess grandmasters have schemata that allow them to recognize board configurations and the best moves associated with them.

Schemata, held in long-term memory, can be brought into working memory, where they may indicate appropriate actions and problem-solving procedures in everything from everyday life to the complex and sophisticated processes taught in educational institutions. Furthermore, because they can be treated as single elements in working memory, they massively reduce the load on working memory. Once learning through schema construction has occurred, the temporal and capacity limitations of working memory become irrelevant (Ericsson and Kintsch, 1995).

Automation

Information can be processed in working memory either consciously or automatically (Shiffrin and Schneider, 1977). Conscious processing is bound by the limitations of working memory discussed above. In contrast, a schema that has been automated can be processed in working memory with a minimal cognitive load. We can read text easily and rapidly because of the automated schemata we have developed for letters, words, and combinations of words. We can solve mathematical problems, including very complex problems, because a sufficient number of the required schemata have been constructed and automated to permit the additional processing in working memory needed to find a solution.

In summary, the learning mechanisms of schema acquisition and automation locate large numbers of automated schemata in long-term memory. Those schemata permit working memory to engage in the processes required to govern not only everyday life but also the more sophisticated activities required in educational contexts.

DIRECT INSTRUCTION

Our cognitive architecture has implications for the manner in which information should be presented to learners and the activities that they should engage in. If learning requires alterations to schematic structures in long-term memory then instruction should be primarily concerned with techniques that will facilitate schema construction and automation. Furthermore, if all new information must be processed in a limited working memory prior to incorporation into schemata held in long-term memory, then it is imperative that instructional techniques be organized in a manner that takes account of the limitations of working memory. Until the relatively recent incorporation of knowledge of cognitive architecture into instructional design principles, most instructional design recommendations ignored both the limitations of human working memory and the fact that sophisticated cognitive processing is dependent on the prior construction of innumerable schemata held in long-term memory.

The characteristics of human cognitive architecture demand the use of direct instruction rather than the indirect instruction associated with discovery learning, investigatory learning, learning through problem-solving or constructivist learning procedures. While the terminology has periodically changed, all of these techniques are essentially indistinguishable. They all require direct instruction to be reduced, or in extreme cases eliminated entirely, with learners discovering principles and procedures by constructing them with minimal direct input from external sources. On the 'investigatory learning' view, teachers should minimize direct presentation of information and maximize opportunities for students to elucidate information themselves. It is a view that is incompatible with our knowledge of the structures of human cognitive architecture.

Consider people learning through problem-solving (Sweller, 1988). They might be given a series of mathematical problems to solve. If they lack previously acquired schemata that indicate which moves should be made to solve the problems, they must derive solutions using problem-solving search. Learners must consider their current problem state, the goal, differences between the current problem state and the goal, and problem moves that could be used to reduce those differences. These activities must occur in the only structure available for such activities: working memory. The limitations of working memory will always ensure that the process is cognitively demanding. Furthermore, while the ultimate aim of the exercise is the acquisition of schemata, the problem-solving process bears no relation to schema construction.

One alternative, discussed in more detail below, is to directly demonstrate the solution procedure to students. Such direct instruction reduces cognitive load by reducing or eliminating search and substituting a procedure that shows students which problem states or configurations should be associated with which moves. Learning to recognize problem configurations and their associated moves is the essence of schema construction.

On this analysis, direct instruction is normally preferable to investigatory alternatives. Using limited working memory to discover procedures and relations that could easily and simply be demonstrated is an inefficient way to construct schemata. Not only should direct instruction be a preferred mode of teaching because it conforms with human cognitive architecture, but that instruction itself should be structured to reduce the load on working memory and facilitate schema construction. We will now look at procedures designed to accomplish these aims.

COGNITIVE LOAD THEORY

Cognitive load theory uses the cognitive architecture described above, along with some structural features of information, to design effective instruction (Sweller, 1999). If learning involves the construction of schemata held in long-term memory and processing of information occurs in a limited working memory, then instruction should be directed to assisting students to acquire the specific schemata required in a given subject area, and should be organized in a manner that reduces the load on working memory. The reduction of cognitive load on working memory is especially important if the subject matter imposes a heavy cognitive load because of its intrinsic nature. Some material imposes a heavy load on working memory irrespective of how it is presented. It is essential that the instructional procedures used to teach such material do not impose an additional, unnecessary load. Below, we shall be looking at several of the learning procedures directly based on cognitive load theory. Later we will consider other learning aids and strategies that, although not based on cognitive load theory, derive from the cognitive architecture discussed above.

Worked Examples

Problem-solving has been used as a learning and teaching device in many areas, especially mathematics and science, for a long time. As indicated above, discovery learning and investigatory and constructivist techniques are all based on, and essentially indistinguishable from, problem-solving. These techniques became increasingly popular teaching and learning devices in the decades preceding the early 1990s. Since that time, their popularity in the academic literature appears to have waned. They are incompatible with basic human cognitive architecture; and empirical evidence for their effectiveness is extremely sparse. If, as indicated above, problem-solving imposes a heavy cognitive load which interferes with schema acquisition and automation, an alternative is required. Worked examples provide such an alternative.

A worked example poses a problem and provides a solution to that problem. It provides a 'road map' to a problem solution. The analogy is a good one. Just as we would consider it foolish to expect someone to find their way around a new region without a road map or direct instruction, so it is foolish to expect a learner to find their way around a problem in mathematics, science or any other area without explicitly being shown the way. It can be done, but it can be a long, slow, and frustrating exercise.

We continue to use road maps until we are reasonably confident that we know our way. Normally, we will only attempt a route without a map once we have learned it. Similarly, it is of benefit to students to continue studying worked examples until they are confident that they understand the solution to the particular type of problem they are studying. Only then does it becomes useful to commence solving problems without the assistance of worked examples.

There are both theoretical reasons and data supporting a heavy use of worked examples as a learning aid. From a theoretical perspective, based on cognitive load theory, searching for a problem solution imposes a heavy load on working memory. Search normally involves simultaneously considering the current problem state and the goal state, extracting differences between the two states, and finding a problem-solving operator to reduce those differences. Furthermore, for learners confronted with problems in a new area, neither the various problem states encountered nor the problem-solving operators required to move from one state to another state will be familiar – automated schemata will not be available. The load on working memory may be far in excess of its capacity. The entire problem-solving process may collapse, reducing the chances of the construction of problem-solving schemata.

As an example, consider a student attempting to solve the equation $(a+b)/c=d$ for a. The initial state is $(a+b)/c=d$ and the goal state is a valid equation with a as the subject of the equation. In order to reduce differences between the initial state and the goal state, elimination of the addend or denominator on the left-hand side is required, and the rules of algebra provide the problem-solving operators to accomplish this task. To make the first move, each of these elements, including the nine elements in the initial equation and also including the many relations between the various elements, must be processed in working memory. That task is simple for anyone with a relevant problem-solving schema which conglomerates all of these elements into a single entity that can be handled readily in working memory. But it is virtually impossible for a learner who has just begun to solve problems in this area. The learner must make repeated failed attempts until a sufficient part of the procedure has been incorporated into schemata that do not exceed the limits of working memory. The process is likely to be long and slow.

In contrast, consider a learner who is given the following worked example to study:

$$(a+b)/c=d \Rightarrow a+b=dc \Rightarrow a=dc-b \qquad (1)$$

There is very limited problem-solving search, and the load on working memory is minimal. The example demonstrates the elements needed to construct a schema to solve problems of this type. It provides the start state, the goal state, and the moves required to transform the start state into the goal state. Working-memory resources are not required for problem-solving search.

The empirical evidence that studying worked examples is superior to solving the equivalent problems is conclusive. In controlled experiments conducted by many researchers around the world, it has been repeatedly demonstrated that if learners study worked examples rather than solve the equivalent problems, learning is enhanced and test problems are solved more accurately and more rapidly. Furthermore, there are extensive data indicating that the reason for this superiority is the reduction in the load on working memory.

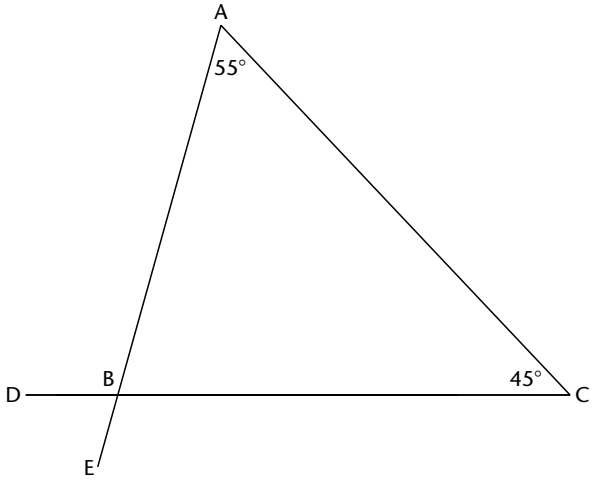
Designing Effective Instruction

Not all worked examples are effective. A worked example is only likely to be more effective than

solving the equivalent problem if it reduces unnecessary cognitive load. Unless they are appropriately structured, worked examples can also impose an unnecessary cognitive load. Cognitive load theory can be used to provide procedures for constructing effective worked examples. Furthermore, those procedures generalize to all instruction, not just worked examples.

Consider the geometry worked example of Figure 1. In isolation, the diagram does not indicate the solution; and the statements are unintelligible without the diagram. The example only becomes intelligible when the diagram and the statements have been mentally integrated. Integration requires working-memory resources, and those resources then become unavailable for schema acquisition. Geometry worked examples structured in this fashion are ineffective because they impose a heavy cognitive load.

In contrast, if they are restructured so that mental integration of disparate sources of information is not required, cognitive load is reduced and learning is enhanced. Figure 2 provides the same information in an integrated form, obviating the need for resource-demanding integration. Many experiments have demonstrated the advantages of physically integrated worked examples – and indeed of any other form of instruction consisting of multiple sources of information that cannot be understood in isolation. The advantage of integrated over split-attention instructions is known as the split-attention effect.



In the above figure, find angle DBE.

Solution:

Angle ABC = 180°– angle BAC – angle BCA (internal angles of a triangle sum to 180°)

= 180° – 55° – 45°

= 80°

Angle DBE = angle ABC (vertically opposite angles are equal)

= 80°

Figure 1. Geometry worked example in conventional split-source format.

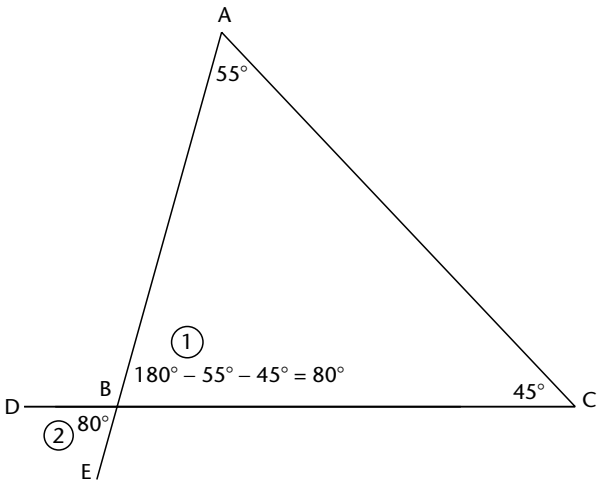


Figure 2. Geometry worked example in integrated format.

Physical integration of multiple sources of information is not always effective. It is required only when the two sources of information are unintelligible in isolation and so must be mentally or physically integrated. Frequently, multiple sources of information can be understood in isolation because one source is just a redescription of another source in a different mode or form. For example, textual material, rather than being essential to understanding a diagram (and vice versa), may simply describe the content of the diagram in verbal form. The text is redundant, and rather than being integrated with the diagram should be eliminated because processing it imposes an extra cognitive load. Because the diagram can be understood without the text, learning is enhanced by eliminating the text. This effect is called the redundancy effect, and has been demonstrated in many experiments.

There is an alternative to physical integration when faced with split-attention material. Working memory is divided into multiple channels or processors: at the least there are separate auditory and visual processors. While there is a large overlap between these processors, in the sense that using one processor does not leave the other completely free, they are sufficiently distinct to increase total working-memory capacity if used simultaneously. When faced with split-attention materials, such as a

diagram and text that must be processed together in order to be understood, rather than physically integrating them, the same advantage can be obtained by presenting the text in auditory rather than visual (written) form. Using both auditory and visual processors increases working-memory capacity, thus facilitating learning. This effect is known as the modality effect. It should be noted that dual-modality presentation should be used only under split-attention conditions. If used under redundancy conditions (where, for example, textual material is redundant), dual-modality presentation is ineffective. Redundant auditory text is no more useful than redundant written text. Accordingly, the common practice of presenting written material with an identical voice-over should be avoided.

All of the effects discussed above occur because different instructional designs impose different cognitive loads on working memory, and because the material being learned itself has a high intrinsic cognitive load. A high intrinsic cognitive load occurs when the structure of the elements being learned is such that they cannot be processed meaningfully in working memory serially, but instead must be processed simultaneously. For example, when considering the algebraic equation discussed above, we cannot conduct a manipulation and just consider the denominator on the left-hand side. The left-hand and right-hand sides must be considered simultaneously because any manipulation of one will have an effect on the other. The elements interact. Material with high element-interactivity imposes a high load on working memory, and it is only such material that requires instructional designs that reduce that load. Material with low element-interactivity, such as a second-language vocabulary, does not impose a heavy intrinsic cognitive load, and so instructional designs that derive their efficacy by reducing cognitive load will be ineffective. Other strategies are required for such material.

NOTE TAKING

Research on note taking has distinguished between the encoding that occurs when students take notes and the storage whereby students learn from notes (Kiewra, 1989). Encoding relies heavily on working memory, while storage occurs in long-term memory. Important findings from this area can be interpreted within the framework of the cognitive architecture discussed above.

With respect to encoding, one might expect that the act of encoding through taking notes might facilitate learning. In fact, the results are mixed, with some studies finding that students who take lecture notes learn more than students who merely listen to the lecture, others finding no effect, and a few finding listening to be superior to note taking. These mixed results may be a consequence of the attentional benefits of note taking being negated by the increased working-memory load associated with simultaneously taking notes and processing the lecture content.

Another finding is that students take better notes and learn more if they are provided with a framework for taking notes, such as incomplete outlines of a lecture that need to be filled in. Such a framework should reduce working-memory load by reducing the need for students to generate their own framework.

With respect to storage, reviewing notes has the expected effect of facilitating retention. Retention is improved if students are provided with notes rather than required to construct their own. This may be partly because the requirement to encode interferes with schema formation, and partly because provided notes tend to be better structured than student-constructed notes.

Notes presented to students need to be structured with human cognitive architecture in mind. In a clear example of the redundancy effect, experiments have indicated that students presented with a complete text of a lecture learn less than students presented with outlines or notes in tabular or matrix form. The redundant material of the complete set of notes is likely to overload working memory and interfere with schema construction. Another study has found that studying notes in an unrestricted manner results in superior learning to writing an essay based on the notes. In this context, essay writing is a redundant activity that interferes with learning. (In other contexts, such as learning to write, essay writing is, of course, a useful rather than a redundant activity.)

SIGNALING

Text signals (Lorch, 1989) are non-content devices intended to increase the intelligibility of text. They do not provide any substantive information, but rather direct the reader to process the information in a particular manner. The nature of text signals, and whether a particular text signal is effective, follow directly from the cognitive architecture discussed above.

The intelligibility of text will be increased if working-memory load is decreased. Text that reduces the extent to which inferences must be made and is organized to facilitate schema construction

will reduce cognitive load. Appropriate signals contribute to these aims.

Signals are important because of the structure of human cognitive architecture. If humans had unlimited working memory, the cognitive-load-reducing aspects of signaling would be unnecessary. If understanding and learning did not involve the acquisition of schemata held in long-term memory, text signals that assist in the construction of schemata would have no function. While not necessarily including essential content, signals help the reader to understand content. Because of the nature of human cognitive architecture, it is difficult to derive meaning from text consisting purely of content without signals.

There are many text signals used by effective writers. Several of the more important are discussed below.

Enumeration

Numbering a set of points or a list provides a signal that in some cases indicates a preferred or necessary order, but often signals that the content of the list is important and should be carefully noted. Readers will attend more closely to numbered points and will remember them better. While the numbers provide no content, they signal that the enumerated material should be given preference in limited working memory and that schema construction should be based on that material.

Print Style

While writers have schemata that tell them which aspects of a text are particularly important, readers of unfamiliar content do not, and in the absence of appropriate signals, must use working-memory resources to make inferences concerning levels of importance. Those memory resources then become unavailable for schema acquisition. Print styles such as italics, boldface text, or underlining reduce the need for readers to infer levels of importance, free working-memory capacity, and so can enhance schema acquisition.

Headings

Most text consists of a series of more or less connected ideas or topics. Where connectivity is relatively low, writers need to signal to readers that a new topic is beginning. Again, the reason is to reduce unnecessary inferencing on the part of the reader, reducing cognitive load. The reader is told by the heading that a new section is beginning, rather than having to infer it. Relevant signals can be included in the body of the text, but it is often easier and more effective to break the text by the use of appropriate headings. These not only indicate that a break has occurred, but can indicate the nature of the break.

Preview Sentences

Preview sentences signal the more important aspects of forthcoming information. Material signaled in preview sentences is more closely attended to and better remembered. This allows students to cluster together subsequent information, facilitating schema construction.

Recall Sentences

Recall sentences signal backwards, rather than forwards like preview sentences. Summary statements at the end of a section provide an example. Recall sentences signal to the reader the important aspects of the previous material, assisting in the reduction of cognitive load.

CONCEPTUAL MAPS

Schemata are not only essential structural features of human cognitive architecture; they can also be used as a learning aid. In this role, they have been called by a variety of names, including 'advance organisers', 'conceptual maps', and 'mental models'.

Pre-existing schemata can be used to organize and interpret new information. Learning is facilitated if learners are informed, before commencing learning, of how the new information relates to their previous knowledge. The previously acquired schemata can not only then organize the incoming information, but in the process can themselves be augmented by it. In effect, this form of learning consists of the construction of ever more sophisticated schemata.

As an example, consider a student beginning to learn algebra. The student is already familiar with arithmetic and knows that $3+4=7$. The schemata associated with addition and subtraction can be used to assist the student with the problem: '$\square+4=7$, fill in the box'. Once this procedure is established by the construction of a well-automated schema, the next step is to replace the box with a symbol, '$a+4=7$', indicating at the same time that calculating a value for a is identical to calculating the number that goes in the box. In this manner, schemata for basic algebra evolve from schemata

for addition and subtraction. The initial schemata for algebra can be considered to be alterations or derivations of the schemata for arithmetic. The precision and hierarchical nature of mathematics makes the need for connecting new material to previous schemata obvious. It is also usually obvious which previously-acquired schemata should be used. In other areas with a less well-defined knowledge base, the need to connect new material to previously acquired schemata is less obvious. Nevertheless, the advantages can be just as great.

The use of schemata to assimilate new information is more likely to be effective if the initial schemata are well established. Students are likely to find it difficult to use a newly-learned schema that is not yet automated to assist in the interpretation of new information. Working-memory resources are not likely to be available to both process the original schema and appropriately incorporate the new material into the recently-acquired schematic structures. A major reason for using previous schemata is to reduce working-memory load. The purpose is likely to be defeated if poorly-established initial schemata are used.

ELABORATION

New material that is to be learned can be processed and rehearsed at shallower or deeper levels. Material processed and rehearsed at a shallow level is simply repeated, as we might repeat a telephone number prior to telephoning. Elaborative processing and rehearsal require information to be related to other information, and in that sense, are deeper. The telephone number might be analyzed to see if it can be segmented in a manner that makes it easier to learn. For example, the number '306230' could be divided up as '306 230' or as '30 62 30'. The latter is likely to be easier to remember because '30' is repeated and can be treated as a single number for which there is likely to be a well-entrenched schema. Elaboration makes heavier demands on cognitive resources but provides a more effective form of learning.

In recent years, considerable work has been carried out on 'self-explanations' of information contained in instructional forms such as worked examples. Self-explanation is a form of elaboration that occurs when learners, rather than passively processing new information, attempt to explain it to themselves. When studying a worked example they might attempt to explain to themselves how and why each step is being made. Chi *et al*. (1989), who initiated this line of work, found that more able problem-solvers are more likely to elaborate worked examples in this manner than less able problem-solvers. That result has been replicated on several occasions and is now well established.

Why do better problem-solvers engage in greater self-explanation? One possibility is that a more able problem-solver has better-established schemata and greater working-memory capacity. Self-explanations are cognitively demanding and may require considerable working-memory capacity. A large working-memory capacity and established schemata will result in more capacity being available for self-explanations. On this interpretation, self-explanations do not improve problem-solving skill, but rather, working-memory capacity determines both problem-solving skill and self-explanation activity.

A more interesting possibility is that self-explanations assist learners to process information more deeply, resulting in increased problem-solving skill. Evidence for this explanation comes from results demonstrating improved problem-solving following instructions and training in self-explanations (e.g. Renkl *et al*., 1998). Results such as this indicate that training in self-explanations can be an effective learning aid.

ILLUSTRATIONS

The proverb 'a picture is worth a thousand words' expresses the truth that, for some types of material, a pictorial or diagrammatic representation is much easier to process than the equivalent text (Larkin and Simon, 1987). Diagrams can be a far more effective form of presenting information than text because diagrams make spatial relations explicit. Text does not clearly indicate the relations of elements to other elements, and so mental representations of those spatial relations must be constructed in working memory. In addition, text must be processed sequentially, while diagrams can be processed simultaneously, making it easier to detect multiple relations between elements. Levin and Mayer (1993) indicate that diagrams are more concise and perceptually clear than the equivalent textual statements. These factors combine to substantially reduce the cognitive load associated with diagrammatic, compared with textual, information. Illustrations work because they reduce working-memory load.

The different processing requirements of language-based and visually-based material have instructional design consequences. Whenever instruction deals with two- or three-dimensional space, it is likely to be more effective if it is

presented in pictorial form rather than in words. This effect is accentuated where the information is complex or difficult to understand (Levin and Mayer, 1993), because it is precisely such material that requires a reduction in cognitive load. By the same token, illustrations that do not reduce cognitive load appreciably are not likely to be effective. If cognitive load is low, or if illustrations have a purely decorative function, illustrations are not likely to act as an instructional aid.

MNEMONIC TECHNIQUES

Not only can the use of illustrations be an effective instructional device, but having learners generate their own images can, under appropriate circumstances, facilitate learning (Levin, 1986). Imagery, along with other mnemonic devices, can be a highly effective learning aid. Unlike the procedures described above, the effectiveness of mnemonic devices is restricted to learning low-element-interactivity material, which has very low levels of natural connectedness. Lists of items, such as a second-language or a scientific vocabulary, are examples. There is no evidence that mnemonic devices can assist in learning high-element-interactivity material that is difficult to understand because its natural structure imposes a heavy working-memory load.

Mnemonic devices rely on connecting new material to a well-established schema, often pictorial in nature. The 'peg' method requires learners to memorize a series of 'pegs' to which the new material must be attached using visual imagery. The pegs can consist of any well-memorized series of words to which the new material is attached by visualizing a connection between each of the words and each item of the new material. A grocery list might be remembered by imagining each grocery item in relation to one of the pegs in the previously-memorized list. Thus, if the memorized list consists of the common rhyme 'one is a bun, two is a shoe…', one might remember that milk is the second item on the grocery list by imagining milk poured into a shoe.

The method of loci is identical to the peg method except that, rather than a memorized list of words, a well-known location such as one's home is used. Items to be learned are attached to locations in one's home by imagining them in relation to those locations. A carton of milk might be imagined balancing on a door.

The 'link' method, use of stories, and initial-letter methods, are related techniques that do not require previously-memorized material. In the link method, an image of each item is constructed and then each image is linked to the next image. Milk being poured on bread enables one to remember to buy bread and milk. Stories link the items by inserting them into a story. The initial-letter method incorporates the first letter of each word into an acronym.

The 'keyword' method is a two-stage procedure that can be very effective in learning a language vocabulary. The first stage involves an acoustic link, the second a visual-imagery link. If one is learning that the Spanish word *caballo* means 'horse', the first step might be to connect *caballo* to the word 'cab' while the second might be to imagine a horse hailing a cab. There is a large body of evidence indicating that the keyword method can be very effective.

STUDY SKILLS

Many of the above descriptions have touched on study-skills instruction. The cognitive architecture that governs all instructional design principles equally governs the activities that learners should engage in when studying. Learners need to adopt procedures that reduce working-memory load and facilitate schema construction and automation. There are several study techniques that meet these requirements and that have empirical support (Pressley and Schneider, 1997).

Learners can be directly shown how to extract the main ideas from text by processes that resemble the use of worked examples. Demonstrating to students by underlining the main ideas of a text and having students practice underlining improves subsequent text comprehension. Modeling comprehension procedures such as connecting new material to previous knowledge, summarizing passages, thinking of questions associated with new material, and making inferences and predictions, can all be used to show students how to approach new material. Directly demonstrating these procedures rather than having students discover the procedures themselves reduces working-memory load and facilitates schema construction.

Having learners imagine procedures that need to be learned is a highly effective study technique (Cooper *et al*., 2001). If the material is already sufficiently well learned that it can be held in working memory, then instructing students to turn away from the material and imagine it is more effective than asking them to study it. If the material is not sufficiently well learned to be held in working memory, studying is more effective than imagining. If only very limited prior learning has occurred, instructions to imagine tend to fail

because insufficient working memory is available with which to imagine.

CONCLUSION

Until recently, instructional design principles and recommended learning aids and procedures tended to be more or less random. The lack of an effective theoretical base meant that there was no unifying set of principles that could be used to generate and test instructional hypotheses. Advances in cognitive science, and specifically a better appreciation of the relevance of our knowledge of cognitive architecture, have provided a secure base which can be used both to explain why some procedures are effective and to generate new procedures. As a consequence, cognitive science is now central to instructional design.

CONTENTS

Cognitive theory, which views cognition as symbolic computation, and situativity theory, which views cognition as (inter)action in the social and material world, are two alternative theoretical perspectives on the nature of human learning. These theories are contrasted in terms of their implications for educational research and practice.

INTRODUCTION

During the past 10 years, social science researchers have engaged in heated debate over which of two theoretical viewpoints can best guide both the study of human thinking and the design of environments for productive learning and work.

One view, the symbolic processing perspective, represents the tradition upon which cognitive science was founded. Although this perspective does not represent a unified, homogenous theory, influential theorists from Carnegie-Mellon University (e.g. Anderson *et al*., 1996) have been important voices in this debate, and their position is widely known and accepted. This viewpoint has encouraged not only cognitive scientists, but also the public, to think and talk about the mind using a computational metaphor, a metaphor based on thinking about the mind in terms of digital computers (some, but not all, current thinking based on distributed network computation is more supportive of the alternative viewpoint to be described). The mind is configured as an information processing 'machine' that receives input from the environment through the senses, selectively and actively processes that information by constructing and reconstructing mental symbols and symbol systems representing knowledge and action, and stores some of those constructions as memories for later recall and use, in an indexed 'in-the-head' repository called 'memory'. Cognitive scientists combine experimental methods and computational modeling to advance and test hypotheses and complex theories about the basic computational structures of mind and the symbols and mechanisms of a variety of forms of human thought, such as language acquisition, remembering, problem-solving, decision-making, and emotional response. Many claim that this 'traditional' cognitive program continues to significantly advance our basic scientific knowledge about human thought processes, as well as our knowledge about how to design educational and work environments that facilitate learning and performance.

Here, the symbolic processing perspective is interpreted broadly to include modern socio-cognitive theory. Evolving from Jean Piaget's (e.g. 1952) genetic epistemology, current versions of this view hold that people learn through a process in which their existing conceptual knowledge is challenged and transformed through social and physical interaction with the environment. Although many socio-cognitive theorists do not explicitly advocate a computer metaphor of mind, their viewpoint is nevertheless a symbolic processing one that posits existence and transformation of symbolic structures (schemas, concepts) within the mind.

A view that challenges this position is 'the situativity perspective' (e.g. Greeno, 1997), which references a family of important social science theories including 'situated cognition' (e.g. Lave, 1988), 'sociocultural theory' (Wertsch, 1998), 'embodiment theory' (Glenberg, 1997), 'distributed cognition' (e.g. Hutchins, 1995), and 'activity theory' (Nardi, 1996). Researchers associated with this view are united in their rejection of viewpoints

that separate study of an individual's mind from the environment of which that mind is an integral part. This is not to say that situativity theorists reject cognitive science entirely. However, symbolic theories of learning and thinking are often viewed as special cases of cognition – those cases in which there is conscious reasoning. These theorists point out many ways in which mind is connected to, extended and shaped by the cultures, body, and the physical surroundings of which it is a part, and they do not believe that all cognition involves symbolic representation or, indeed, that all cognition takes place within the mind itself. For example, a researcher using a computer program and consulting an expert in performing a statistical analysis is extending cognitive capacity by relying on social support and employing a cultural artifact (the statistical package) to perform a task that the researcher need not fully understand in all its complexity and depth, given the availability of the social environment and its tools. From the situativity perspective, the cognition is 'stretched' over the entire activity (the problem-solving task) and partly resides in the social context, as well as in the individual's mind. Moreover, the individual need not symbolically represent all cognition within the activity system. For example, a well-designed statistical program would extend cognitive capacity by being so easy and obvious, the researcher would not need to think much in order to use the tool correctly. Intelligent interactions are thus 'afforded' by tool design features, of which the users may not be aware.

Taken together, symbolic processing and situativity theories provide the foundations for an important and growing field of study known as 'the learning sciences', which is currently having tremendous impact on educational research. This article will elaborate and explain these positions in greater detail, discussing their implications for educational research and design of learning environments. A summary of these implications is provided in Table 1, which highlights important differences in the theoretical schools.

SYMBOLIC PROCESSING THEORY

Before symbolic processing theory began to emerge in the 1960s, psychology was dominated by theories of behaviorism that treated human behavior as nothing more than direct response to environmental stimuli ($S \rightarrow R$). Symbolic processing theory rejected this assumption, concluding that human behavior could not be explained without positing an intermediate stratum of mental processes that occur *between* input (stimuli from the environment) and output (behavior). Human beings, it was argued, mentally represent information from the environment, process that information, then select behaviors accordingly. The mind, from this perspective, is an information processing system analogous to a computer: a physical symbol system. Input/output processes connect the symbol system with its environment, but it is between perception and action that 'thinking' (symbolic computation) occurs. Detailed computer models of 'in-the-head' processes have been constructed and successfully tested against specific forms of human performance, such as solving verbal analogies or algebra problems with two unknowns; however, they have been less successful in explaining complex, adaptive performance, such as expert medical practice.

This modeling approach to theory building is contingent, however, on a set of basic ontological assumptions. Such models assume cognition is a bounded, dependent but autonomous physical symbol system. The system is dependent in the sense that it is open to information from the environment, yet it is autonomous in the sense that its basic architecture is closed to reorganization. Information from the external world is the material the system operates on, but basic architectural changes are not determined by the outside; therefore, events 'in the head' can be factored from external events in the social and material environment and thereby accurately modeled by computer programs.

Behind this 'factoring assumption', in turn, is a fundamental division between the individual knower, knowledge, and the independent world based on the dualist ontological tradition of Kant and Descartes. From this perspective, the individual is a container with a sort of substance (albeit, symbol-based) called 'knowledge' inside. Learning is the acquisition, construction, and qualitative reorganization of this substance (knowledge), and the success of the learning process is measured by the transfer (application) of this substance from one place (the context in which the knowledge was acquired) to another (a different context in which that knowledge should be used). Therefore, useful knowledge is knowledge that is sufficiently abstract and general to allow for successful behavior across a wide range of relevant contexts (Anderson *et al.*, 1996).

SITUATIVITY THEORY

If symbolic processing theory unpacked the black box of mental representation and procedures

Table 1. Situative and symbolic theories: alternative lenses for educational research and practice

Educational issue	*Situative emphases*	*Symbolic processing emphases*
Major epistemic categories	People acting in context Interwoven systems of activity Discourse structures Design and use of artifacts and tools Nonsymbolic processes	Minds in the environment Memory stores Information Attention Mental representations Symbolic processes
Learning and development	*Individual:* Internalization of practice Trajectories of participation Identity development Becoming a leader *Community:* Development of norms Development of artifacts Tool development and use Community knowledge growth	*Individual:* Comprehension Knowledge growth Knowledge restructuring Knowledge transfer Development of expertise
Transfer	Enhanced ability to participate in new, complex, community activities Enhanced ability to participate in new communities	Analogical (schema-based) reasoning Flexible situational construction (cognitive flexibility)
Learning environment characteristics	Discourse communities Classrooms and schools extend broader social community Authentic activities Tools of authentic practice Varied levels of participation Mentoring and apprenticeship	Cognitive objectives Mastery of prerequisites Explanation-based learning Group and individual work Problem-solving tasks Skill practice Memorization Use of representational tools and manipulatives
Teacher roles	Provide community leadership Design community infrastructure Promote development of social and discourse norms Share problem-solving Provide for mentoring, apprenticeship	Transmit and explain Set cognitive objectives Perform task analyses Design/select activities and materials Individualize instruction Provide feedback/guidance Lead discussions Challenge misconceptions Promote metacognitive reflection
Assessment	Evaluation of student-designed artifacts Portfolio assessments Evaluation of authentic performance in context Dynamic (formative) assessment	Measures of facts recall Comprehension tests Problem-solving tests Standardized summative assessments Standardized diagnostic assessments Performance-based assessments Transfer tasks

between environmental stimuli and individual behavior that behavioral theory refused to open, then 'situativity theory' (Greeno, 1997) is attempting to unpack the black box of activity structures (structures of interactions of individuals within their material and social contexts) de-emphasized by symbolic processing theory. Growing out of work in ecological psychology, ethnography, ethnomethodology, and philosophical situation theory (Greeno, 1997), situativity theory focuses

on interactive systems of activity of which the individual is only one part. Cognition, from this perspective, cannot be explained by computational models of structures and processes 'in the head'; rather, one must look to the intact activity systems in which the individual participates. Such systems always necessarily include social relationships, physical and temporal contexts, symbolic and material resources (such as tools), and historical change. From this perspective, cognition is 'a complex social phenomenon … distributed – stretched over, not divided among – mind, body, activity, and culturally organized settings (which include other actors)' (Lave, 1988, p. 1). The structures of interest, then, are the interactional structures of such social and material systems, not structures in the individual mind.

Thus, cognition is (inter)action in the social and material world. According to Lave (1988), the basic organizing structures of this world are the social, cultural, and professional groups, or the 'communities of practice', in which people choose to participate. Through participation in a community of practice, individuals come to understand the world (and themselves) from the perspective of that community. In contrast to symbolic processing theory, which takes the meaning of a symbol as given, situativity theory focuses on how meaning evolves through enculturation. Here, semantic interpretation is taken as part of what people do in the lived-in world; it arises through interaction with social and material resources in the context of a community with its own participant structures, values, and goals. An individual becomes attuned to a particular object's meanings and uses through the regular pattern of interaction that individual has with it, but this regular pattern of interaction is shaped by the individual's membership in a particular community for whom the object has meaning, usefulness, and relevance for accomplishing tasks associated with individual or collective goals.

Such activities have direct import for the identity of the individual. Who one *is* determines, and is reflexively determined by, one's participations in various communities (Greeno, 1997). A community delineates practices for its members, provides means of forging identities, of possible ways to apprehend and understand the environment through social and physical activity with tools and symbols. Thus, changes in knowing become changes in being: through participation in communities of practice, an individual does more than merely acquire and reorganize symbolic knowledge about the world; she or he is ontologically transformed by it.

This conception of cognition as a culturally mediated, historically developing, and activity-based process assumes a nondualist ontology in sharp contrast to the assumptions of symbolic processing theory. This nondualist tradition can be traced back through the work of theorists as diverse as Marx, Heidegger, Vygotsky, and Dewey, to the work of Hegel (1807/1967), who argued that 'the individual self is in no sense an immediately given element of consciousness (as Descartes claims of his *cognito*) but a socially created concept … we are wholly social products and social participants' (p. 514). The mind, the individual, and the world with which we interact are not natural entities but historical and cultural products determined by human practices; their meaning – what they 'are' – is constituted through human activity. As such, activities and contexts are mutually constitutive of each other rather than one nested inside the other.

While symbolic processing theory focuses on epistemological processes and the mental architecture and functions that sustain them, situative theory focuses on the genesis of participation in communities of practice. Accounts of how an individual interacts with her material and social contexts, and how these interactions change over time, replace accounts of individual knowledge construction occurring 'in the head'. Learning, from this perspective, is progress along 'trajectories of participation' and growth of identity within a given community of practice (Greeno, 1997). It is the gradual transformation of an individual from peripheral participant to central member of a community, through apprenticeship and increased acceptance of community values and increased participation in community practices. Thus, a new teacher (or lawyer, or doctor, or researcher) acquires professionally relevant knowledge and skill as she increases in prestige and power within a professional community. Importantly, learning also takes place at the aggregate level of the community, a process that involves emergent reorganization in the patterns of member activities, coupled with a growth of shared knowledge through changing practices and the creating of artifacts and tools that facilitate work.

ALTERNATIVE LENSES FOR EDUCATIONAL RESEARCH AND PRACTICE

The situativity and symbolic processing theory families represent fundamentally different lenses through which to analyze, design, and conduct research on educational environments. Some typical differences in points of view are highlighted

in Table 1 and discussed in the following paragraphs.

With respect to epistemic categories, situativity theory views knowledge, not as individual mental representation, but as something that resides within communities and manifests itself through what members of the community do and create. Thus, designers and researchers working from this perspective view learning environments in terms of their observable activity structures, including the systems of interaction and discourse among learners and teachers, and the development and use of tools and artifacts within those systems. An analytical problem for situativity researchers is decomposition of the environment for study, since activities are constituted by other activity structures as contexts. Thus, situativity researchers always study activity structures qualitatively and ethnographically *in situ*. Most studies place little emphasis on specifically describing internal cognitions. Rather, situativity researchers may postulate nonsymbolic 'cognitive' processes and structures that are external to the individual mind and can be inferred from classroom observations.

In contrast, the major analytical structures of the cognitive program are the unobservable symbols and processes within minds that are inferred from performance on tests and tasks designed to allow inferences about individuals' possession of facts, concepts and skills. For researchers, such inferences support theories about human learning, knowledge, and performance, and about the connection between learning and features of instructional design. These theories may be specified in detail and translated into computer models that are tested for matches against human performance. In such analyses, individual students or teachers, not activity structures in the environment, are the units for analysis. Moreover, because learning and performance can legitimately be examined separately from the broader social and physical contexts in which they take place, laboratories, as well as classrooms, may be sites for educational research.

Table 1 highlights the two theoretical families' differing conceptualizations of learning and development, and how these imply different ways of supporting the learning and assessment of students within educational environments. Situativity theorists see learning and development in terms of individuals' growing capabilities as participants in multiple authentic communities of practice, communities that can, themselves, learn and grow organically as knowledge-building entities. This viewpoint has implications for conceptualizing and designing learning environments, for the roles for teachers within those environments, and for assessing student performance. To the greatest extent possible, classrooms become extensions of authentic communities of practice found in broader society. For example, students of teacher education are not (conceptually speaking) taught or assessed on the skills and facts of teaching, but are apprenticed into a culture of professional practice. Mathematics students are likewise apprenticed into the culture of mathematicians (when appropriate) or (at other times) the culture of a mathematically informed citizenry. Teachers are viewed, not just as transmitters and challengers of knowledge and designers of instructional tasks that help students construct individual understandings of subject domains, but as founders of classroom learning communities that extend and connect to authentic cultures of practice, and as leaders and mentors and fellow learners within those communities. The emphasis of assessment in such communities is on production and critique of authentic, socially valued products and performances with concern for how individuals interact in social context while working.

In contrast, classrooms designed from the symbolic processing perspective tend to engage students in a variety of instructional activities that are designed to help them, as individuals, acquire specific cognitive objectives. While these objectives may be derived from an analysis of what knowledge is required for desired, complex performances in the real world, and while effort is made to connect classroom learning to real-world issues and problems, from the symbolic perspective, the classroom activity in which students participate need not replicate authentic, real-world practice in social context. Through various activities, some authentic and some nonauthentic, students are expected to acquire fundamental symbol structures that will later be recalled, combined, and used as analogies to guide thinking and behavior in the world outside of class. Understanding and transfer of knowledge is promoted through reflection (rather than enactment), and by teaching explicit symbolic knowledge about the conditions under which one will use what is learned. The teacher is expected to help students engage in thinking about their thinking (metacognition) during learning – asking themselves what they do and do not understand; how they will use it in future, etc. From the symbolic perspective, assessment focuses on design of reliable, repeatable tasks and instrumentation that can be used to measure use of specific ideas and skills across many individuals and different forms of tasks that require those ideas and skills.

A SUBSIDING DEBATE

Much debate continues between members of these two communities. Yet, many educational researchers, theorists, and practitioners today are successfully fusing both points of view within their work (e.g. Bransford *et al*., 1999). Researcher–designers and teachers working in school environments are likely to view classrooms as communities and to attend to activity and discourse structures and the authenticity of required activities and assessments but may also regard these as contexts or vehicles for individual learning viewed as symbolic processing. They may chart trajectories of participation for particular students, and simultaneously examine development of symbolic knowledge using a wide range of cognitive tasks and instruments. In larger studies, educational researchers may study classroom communities with varying activity and discourse structures, developing coding systems to capture these differences and statistically examining the impact of these variations on individual performance measured using standardized assessment tools.

Thus, although the symbolic and situative viewpoints have not yet merged to form a well-defined theory of educational practice, we see much evidence that a dialectic process is moving the field toward rapprochement between them. We believe the emerging result may be a complex systems theory of cognition understood in its broadest ecological sense, and that the resulting methodological approach will be superior to either theoretical viewpoint standing alone, capable of providing more complete understanding of learning and education.

Literacy: Reading (Early Stages)

Introductory article

Frank R Vellutino, State University of New York, Albany, New York, USA

CONTENTS

Literacy is the ability to read and write. Early literacy development consists of a prealphabetic period wherein the child begins to learn about the nature and purpose of print; an alphabetic period wherein the child becomes conversant with the alphabetic code and acquires increasingly functional word identification and text processing skills; and an advanced alphabetic/orthographic period wherein the child masters the alphabetic code and becomes increasingly fluent in word identification and text processing.

INTRODUCTION

Becoming fully literate is, perhaps, one of the greatest of the developing child's many achievements. It is also one of the most daunting. Whereas the acquisition of spoken language skills can be accomplished simply through immersion in a natural language environment, the acquisition of written language skills depends on formal instruction, deliberative intent, and cognitive effort. This is because learning to read and write entails the recoding of spoken language in the form of an arbitrary set of symbols, organized and implemented in accord with conventions that are unique to the orthography (writing system) that uses those symbols. Thus, whereas in an ideographic orthography, such as written Chinese, the individual characters represent meaning-bearing units of language, in alphabetic orthographies, such as written English, Spanish, Swedish, and German, the characters represent phonemes – that is, individual speech sounds such as the /c/, /a/, and /t/ in 'cat'. In the European orthographies the alphabetic characters representing written words are organized from left to right and the words themselves are read from left to right, whereas in written Hebrew the alphabetic characters are organized from right to left and the words are read from right to left. Accordingly, the first task of the novice reader is to learn about the nature and purpose of print, the structural properties and print conventions associated with the writing system to be studied, and, ultimately, the functional use of that system. This is a time-consuming and challenging enterprise which depends heavily on the normal development of relevant cognitive abilities, as well as on the enrichment and tuition provided by the child's home and school environments and on the child's motivation for and investment in becoming literate. The nature of the cognitive demands made on the child in acquiring early literacy skills will vary, depending on the properties of the orthography studied. The exposition below focuses on literacy acquisition in an alphabetically based orthography, exemplified by written English.

COGNITIVE FOUNDATIONS OF LITERACY

Written words are encoded (symbolized) representations of spoken words, which themselves are encoded representations of knowledge about concepts in the environment stored in permanent memory. Thus, the ability to learn to read and write depends heavily on linguistic coding processes that facilitate encoding (symbolizing) of concepts in the form of spoken words; linguistic and visual coding processes that facilitate encoding of linguistic units in the form of written words and word constituents; and visual-motor processes that, along with linguistic knowledge, facilitate writing. Given normal development of these processes, and adequate exposure to print and literacy instruction, early reading and writing development depends further on metalinguistic and metacognitive processes that allow the child to analyze and come to understand the structural characteristics of spoken and written words, in terms of the mapping relationships between them, as well as on memory processes that facilitate storage, retrieval, and integration of their visual, linguistic, and motor counterparts.

Figure 1 sets out the contribution made by each of these processes to the acquisition of literacy. The first steps depict the inception of literacy in terms of linguistic coding processes that facilitate the acquisition of lexical knowledge and language acquisition in general. These include phonological coding (the ability to use speech codes to represent information); semantic and morphological coding (the ability to store information about the meanings signified by words and word parts, such as 'ing', 'ed'); syntactic coding (the ability to store word order rules that govern how words are organized in sentences); and pragmatic coding. Pragmatic coding is the ability to store information about conventions governing the use of language as a medium for communication: for example, the relationship between a sentence and the broader context in which it is embedded (prior text, situations represented by the text, background knowledge, etc.) or the implicit contract between the speaker and hearer (or reader and writer) in terms of conventions that facilitate communication and understanding (choice of topic, turn-taking, etc.). Such processes not only facilitate the acquisition of lexical knowledge in the form of spoken and written words, but also the comprehension of spoken and written language during listening and reading respectively. (*See* **Language and Cognition**; **Language Comprehension**)

The linguistic coding processes are paralleled by the visual coding and visual-motor processes that contribute to spoken and written language acquisition. These include visualization ability (the ability to store and retrieve representations defining the visual characteristics of environmental stimuli, including the graphic symbols used to represent written words) and visual-motor ability (the ability to store and retrieve the motor programs required for learning to produce written letters and words). Both linguistic and visual coding processes contribute to the establishment of connective bonds between the spoken and written counterparts of printed words, in the interest of helping the child acquire 'sight words': printed words identified (named) on sight as unanalyzed wholes. However, given the heavy load on visual memory imposed by the high degree of visual similarity characteristic of printed words composed of alphabetic characters (e.g. 'pot' and 'top'; 'was' and 'saw'), linguistic abilities carry much greater weight as determinants of the ability to learn to read than do visual and visual-motor abilities, especially at the beginning of

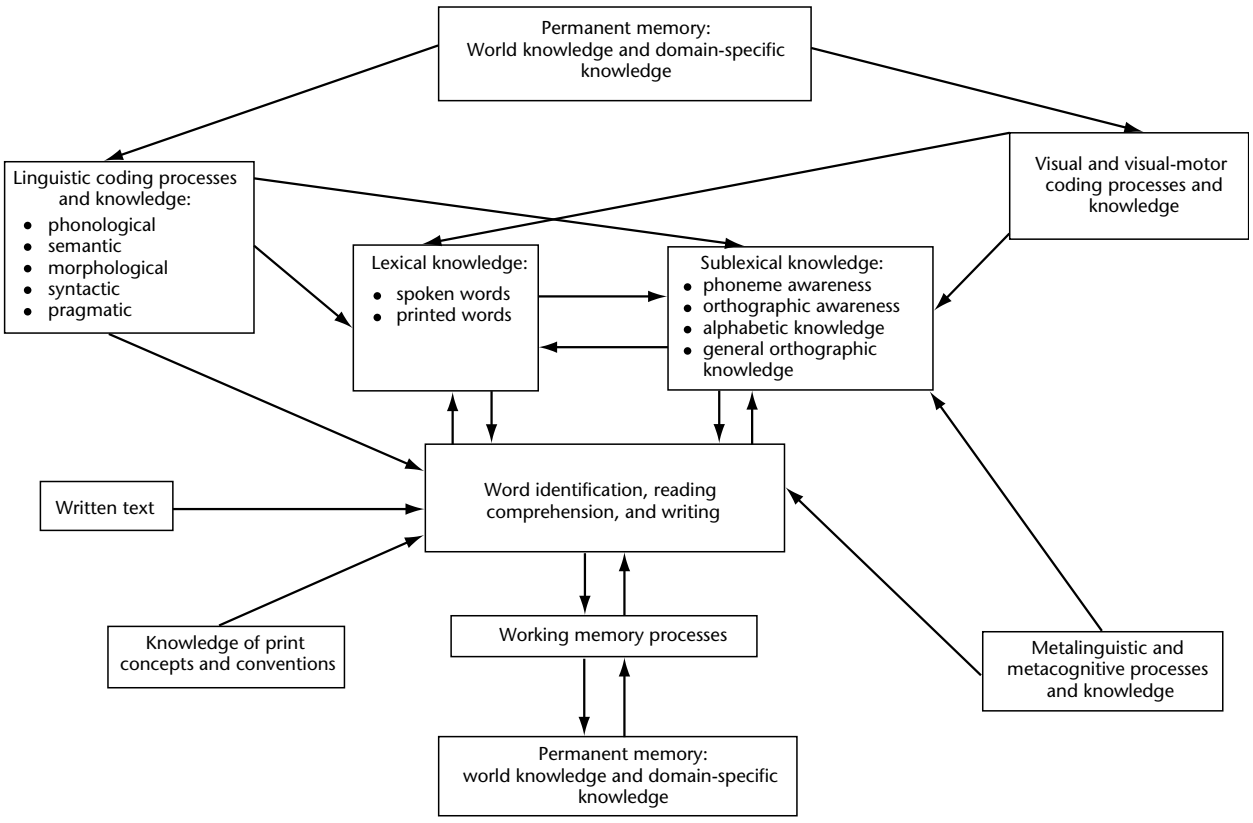

Figure 1. Cognitive processes and types of knowledge entailed in learning to read and write.

literacy development. Phonological coding ability is of special importance, not only because it helps the child learn sight words, but also because it facilitates acquisition of the types of sublexical knowledge that help the child acquire proficiency in letter-sound decoding, which is the primary vehicle that beginning readers use for reducing the load on visual memory imposed by an alphabetic writing system.

Sublexical knowledge is knowledge about the structural characteristics of spoken and written words. Such knowledge includes phoneme awareness – conceptual understanding and explicit awareness that spoken words consist of individual speech sounds (phonemes) – and orthographic awareness – sensitivity to the constraints on how letters in words are organized. Many scholars believe, and many studies have documented, that phoneme awareness is a prerequisite for acquiring alphabetic knowledge, that is, knowledge about letter-sound relationships. Similarly, orthographic awareness is believed to be important for distinguishing between 'legal' and 'illegal' combinations of letters in written English ('vid' is 'legal', 'xqr' is illegal), and both forms of conceptual knowledge are believed to have a mutually facilitative relationship to one another. Phoneme awareness facilitates orthographic awareness by virtue of the positive effect phoneme awareness has on letter-sound analysis, and, thereby, the proper sequencing of letters in both word identification and spelling. Orthographic awareness facilitates phoneme awareness, by virtue of the positive effect orthographic awareness has on letter organization and, thereby, letter-sound analysis in word identification and spelling. Together, these two types of knowledge help consolidate alphabetic knowledge. They also help the child detect and make functional use of orthographic regularities and redundancies (e.g. 'at' in 'cat' and 'rat'; 'ing' in 'running' and 'playing'), and successful acquisition of this more general and higher-level orthographic knowledge ultimately leads to mastery of the alphabetic code.

Two other types of conceptual knowledge are important components of early literacy development: knowledge of print concepts and conventions, and metalinguistic and metacognitive knowledge (Figure 1). Knowledge of print concepts and conventions reflects the child's understanding that printed words represent words and sentences in spoken language; that they are composed of letters carrying sound values; that they have spaces between them; that they are processed from left to right, and so forth. Metalinguistic knowledge is knowledge the child acquires through active analysis of the structural characteristics of spoken language – its sound structure, its syntax, and its conventional use. Metacognitive knowledge is a more general type of cognitive knowledge and is acquired through active analysis of the operations and strategies employed in any type of cognitive processing, not just language processing. Both types of knowledge help to lay the foundation for early literacy development by their contribution to the child's acquisition of basic word decoding and word identification skills, as well reading comprehension and text processing skills.

Finally, Figure 1 depicts both the permanent memory and the working memory processes involved in learning to read and write. It also depicts the interrelationships and reciprocity between the different coding and memory systems (double-direction arrows) involved in (a) establishing firm associations between lexical and sublexical components of spoken and printed words, and (b) encoding, storing, and retrieving information required for learning to read and write, and information processed during reading and writing. (*See* **Memory, Long-term**; **Working Memory**)

PERIODS OF LITERACY DEVELOPMENT

Prealphabetic Period

Literacy development begins long before the child enters school and is greatly dependent on the home environment. Such seminal experiences define what has often been called 'emergent literacy'. The child's home environment influences literacy development in three important ways: through language enrichment, through print enrichment, and through endorsement. Language enrichment is important because adequate language development is a prerequisite for adequate literacy development. The importance of phonological skills such as phoneme awareness and letter-sound decoding in learning to read has been well established by training, intervention, and classroom observation studies, which have shown that children who acquire these skills (among others) become better readers and spellers than children who do not acquire these skills. Preschool literacy studies have consistently found that children from language-enriched home environments that sensitize them to the phonological properties of spoken words tend to profit more from school literacy experiences and instruction than do children from less language-enriched environments. For example, preschool children who are exposed to nursery

rhymes (which typically involve much rhyme and alliterative language), rhyming games, and other activities that sensitize children to the similarities and differences in the sounds of words (e.g. word games such as 'Pig Latin') tend to be more successful in acquiring phoneme awareness, letter-sound decoding, and word identification skills in early reading development, than children who are not exposed to such activities.

Vocabulary enrichment can also positively influence early literacy development. It is easier for children to learn to read words that are already part of their speaking vocabulary than to learn to read words that do not have this standing. This has been established in research with children learning to read in a second language. It might also be expected that vocabulary knowledge would have a strong influence on language and reading comprehension; these expectations have been given some confirmation by prediction studies finding significant positive relationships between measures evaluating variability in the home language environments of preschool children and the acquisition of language and literacy skills in these children in later grades (kindergarten through middle school). The common finding among these studies is that children from homes where parents and siblings had well-developed speaking vocabularies and good language skills in general, and where dialog among family members was encouraged and reinforced, tended to perform better than children who came from less enriched home language environments on measures evaluating vocabulary knowledge, phoneme awareness, alphabetic knowledge, printed word identification, and reading comprehension.

Finally, a number of studies have evaluated other oral language skills in preschoolers such as comprehension and use of syntax and complexity of productive language, and have found significant positive relationships between measures of these abilities and measures of early and later literacy development.

The second way in which the child's home environment can influence early literacy development is by facilitating exposure to print. In the initial phases of the prealphabetic period (which some investigators have called the 'logographic' stage of literacy development), children do not have sufficient understanding that printed words represent functionally distinct and meaningful units of spoken language. In addition, they know little about letters of the alphabet or about the alphabetic principle, tend to treat printed words as logographs or picture-symbols, and often use incidental or even irrelevant features of these words (e.g. the two 'eyes' in the word 'look') as vehicles for retrieving the names of those words rather than their letters to do so. However, if the home environment provides the child with extensive contact with print, in the form of shared and guided reading and writing experiences (e.g. listening to and discussing stories, calling attention to the letters in words), availability of printed materials, and many opportunities to encounter environmental print (in street signs, supermarkets, etc.), the child will become increasingly conversant with print concepts and conventions and will begin to acquire seminal awareness of how the alphabet works. The child may also begin to make rudimentary attempts at writing, as manifested in random scribbles, alphanumeric characters, and perhaps even the letters of the child's name.

The third way in which the child's home environment facilitates literacy development is through endorsement: placing a high premium on learning to read and write, encouraging and reinforcing the child for actively engaging in these enterprises, and providing opportunities to do so. It will suffice to point out that there is abundant research evidence that children who come from highly enriching home environments that provide them with many opportunities for exposure to print and encouragement to actively engage print are better prepared to profit from beginning reading instruction than children who come from less enriching and less encouraging home environments.

Alphabetic Period

The acquisition of functional literacy skills occurs during what many scholars have called the 'alphabetic period' of early literacy development, which extends roughly from kindergarten through second grade for most children. During this period of literacy development, children become increasingly sensitized to the alphabetic nature of the writing system and become increasingly proficient at using letter sounds to help them read and spell printed words. In the initial phase of this period, which some have called the 'partial alphabetic' phase, children come to discriminate between and learn the names of letters of the alphabet. They also become increasingly sensitive to the structural characteristics of spoken words and begin to acquire phoneme segmentation and phoneme awareness skills. As a result, they begin to understand how the alphabet works and begin to use a few salient letter sounds to aid word identification. Although children rely heavily on a sight-word,

meaning-based approach to word identification during the partial alphabetic phase of literacy acquisition, and make generous use of rote memory as well as picture and sentence contexts to identify words they encounter in text reading, they also begin to use letter sounds to aid the identification process, especially initial and final consonant sounds. However, they are less proficient in using vowel sounds and redundant consonant clusters (e.g. 'ch', 'sh', 'th') to aid word identification during this phase of the alphabetic period, because these sounds are less salient, less reliable, and more complex than initial and final consonant sounds and require more extensive experience with print for full acquisition. Thus, children do not have word spellings fully represented in memory during the partial alphabetic period, and are often confused by words having similar spellings (e.g. 'pot/top', 'what/want', 'was/saw'). In addition, they are not yet able to use 'analogy' strategies for word identification; that is, using familiar words to help pronounce and spell unfamiliar words (e.g. using 'lamp' to help identify 'damp').

Children's writing during the initial phase of the alphabetic period is typified by what is commonly called 'invented spelling' – the use of novel, but principled and intuitively generated ways of using letter sounds to spell words the child has not yet learned to spell conventionally. Children's invented spellings during this period rely heavily on what is essentially a 'letter name' strategy for divining the sounds carried by given letters, whereby letter names are implicitly matched to salient phonemes in the words they attempt to spell (e.g. spelling 'hey' as 'ha') or to phonemes close in manner and place of articulation to given letter names (e.g. spelling 'jam' as 'gam' because 'j' and 'g' are pronounced alike). Some scholars believe that children's use of such intuitive spelling strategies constitutes the primary means by which they acquire phoneme awareness and come to understand the alphabetic principle. However, it is more likely to be the case that phoneme analysis and invented spelling are reciprocal and interdependent processes that both contribute to the child's understanding of the alphabetic principle.

With extensive experience in using letter sounds to decode and spell printed words, and given literacy instruction that facilitates alphabetic coding, children acquire a relatively complete command of grapheme–phoneme (letter–sound) correspondences. They also begin to learn about recurrent letter patterns within words that govern the way in which those words are pronounced, for example long vowel markers such as the 'silent e' (as in 'kite' and 'bike'), as well as digraphs such as 'ch' and 'sh', and diphthongs such as 'oi' that change the sounds of their component letters (as in 'chop' and 'join'). In addition, they increasingly discover words with similar spellings and pronunciations, and begin to use analogy strategies for decoding and encoding unfamiliar words. They also begin to discover words with similar spellings but dissimilar pronunciations (e.g. 'put' versus 'cut', 'nut' and 'but'), which helps make them aware of the need for diverse and flexible strategies for word decoding and spelling. Thus, as they expand their word level skills, children become less dependent on meaning-based strategies for word identification, and increasingly store new sight words in memory using both code-based and meaning-based strategies for word identification, spelling, and writing.

However, the child's alphabetic knowledge at this more mature phase of the alphabetic period (alternatively known as the 'full alphabetic' and 'within word pattern' phase) is limited to grapheme–phoneme correspondences, constraining the child's ability to decode and spell longer, multisyllabic words. This skill develops during the next period of early literacy development.

Advanced Alphabetic/Orthographic Period

During the advanced alphabetic/orthographic period of early literacy development (second grade and beyond), children increasingly discover and make functional use of the regularities and redundancies in the orthography, especially larger clusters of letters that occur in many words. These include letter clusters with regular spellings that can be sounded out letter by letter (e.g. 'est' in 'nest', 'best', and 'chest'), and irregularly spelled letter clusters that cannot be sounded out letter by letter but have relatively stable pronunciations ('ight' in 'night', 'sight', and 'light'). For example, whereas children having only grapheme–phoneme (letter–sound) correspondences stored in memory would have to use four grapheme–phoneme units to decode an unfamiliar sight word such as 'chest' ('ch', 'e', 's', 't'), children having both 'ch' and 'est' stored as units in memory would only need to use these two units to decode the word. As their inventory of redundant letter clusters grows, children become increasingly adroit at using analogy strategies for word identification and at combining newly acquired letter clusters with smaller alphabetic units already acquired (i.e. letter sounds, vowel patterns, digraphs, diphthongs) to learn new sight words. Such consolidation strategies

also help the child decode and spell multisyllabic words (e.g. 'in', 'ter', 'est', 'ing' – 'interesting'), including those governed by pattern–sound principles that cut across syllable boundaries (e.g. consonant doubling in words like 'rabbit'). Accordingly, this phase of the orthographic period has been called the 'consolidated alphabetic' or 'syllable juncture' phase of literacy development.

Some scholars also identify a more advanced phase of the orthographic period: the derivational constancy phase. During this phase, children learn about spellings and pronunciations derived from the semantic and syntactic properties of given words ('bomb/bombard', 'permit/permission'), along with other idiosyncratic features of the orthography, such as the different spellings associated with similar-sounding suffixes (e.g. 'ignorant', 'competent') and doubling conventions in words containing prefixes ('illiterate', 'immature').

The importance of alphabetic and orthographic knowledge in learning to read and spell in a writing system based on an alphabet has been well documented in empirical research, but the most compelling evidence comes from training, intervention, and classroom observation studies showing that children exposed to instructional programs that facilitate acquisition of phoneme awareness and alphabetic coding skills encounter fewer difficulties in learning to read, and perform at higher levels on measures evaluating word identification and phonological decoding skills, than children exposed to instructional programs that do not do so. Nevertheless, as the previous examples show, written English is a complex and abstract writing system that contains a large number of irregularly spelled and even many strange words ('epoch', 'aardvark') that cannot be identified or spelled accurately and fluently solely through the use of phonologically based strategies for word identification and spelling. Accordingly, several of the studies alluded to earlier have shown that the most effective classroom and remedial intervention programs are those that incorporate both code-based and meaning-based activities that promote text processing and comprehension skills along with word identification and alphabetic coding skills.

Fluency in Reading and Writing

Fluent reading is reading that is fast, accurate, effortless, and meaningful. During text reading, the meanings of the words in sentences in the text must be stored in working memory while the meanings of the sentences containing those words are 'computed'. Sentence meanings must also be stored in working memory, and because information in working memory is available only for a short period, successful computation of sentence meanings – and thereby comprehension of the text – is critically dependent on the speed and accuracy with which the words in the text are identified and understood. Fluent readers can identify and understand, with speed and accuracy, most or all of the words that might be encountered in a given text and do not have to spend much time using phonological decoding skills to identify and access the meanings of the words in the text. However, becoming a fluent reader takes a great deal of guided and appropriate practice in both word identification and text processing. Acquiring fluency in word identification depends not only on the ability to decode unfamiliar words using the alphabetic and orthographic strategies discussed above, but also on the frequency with which the child is exposed to (and successfully identifies) given words in reading and correctly spells those words in writing. It also depends on the amount and type of reading (and writing) the child does, and the availability of interesting reading materials at an appropriate level of difficulty.

Although fluency in word identification is a necessary condition for proficient reading comprehension, it is not a sufficient condition. Reading comprehension also depends on the acquisition of knowledge and skills in other areas: adequate language development in terms of both vocabulary knowledge and syntactic competence is critically important, as is the acquisition of metalinguistic and metacognitive text processing strategies such as those described above. Reading comprehension also depends on the child's exposure to different types of text and understanding of the features that define these texts (e.g. narrative versus exposition); on the child's general knowledge; and on the child's background knowledge for engaging and profiting from texts focusing on specific domains.

Reading and writing are reciprocally related skills that are mutually reinforcing. Thus, the acquisition of fluency in writing is highly dependent on the acquisition of fluency in reading, and on the amount of guided practice and feedback the child receives in spelling and writing. It also depends on whether the child's literacy experiences facilitate integration of reading and writing subskills. If children learn to spell and write the same words they are learning to read, and receive a great deal of practice in reading, spelling, and writing those words, then the words are more likely to become fully and strongly represented in memory and

be easily accessed in both reading and writing. Finally, the acquisition of fluency and proficiency in reading and writing is greatly dependent on the child's motivation, which in turn is influenced by the quality of the child's literacy experiences, both at home and at school.

That fluency in word identification is a prerequisite for reading comprehension has been amply documented in research demonstrating that speed and accuracy in word identification are the best predictors of performance on measures of reading comprehension in children whose language skills and background knowledge are sufficient for comprehending the text. The same research has demonstrated that when fluency in word identification is sufficient for text comprehension, the best predictors of performance on tests of reading comprehension are measures of language and text-processing skills and also measures of background knowledge and domain-specific knowledge. Similar results have been obtained in research evaluating creative writing skills. Finally, there is considerable evidence that motivated children have generally better reading skills than less motivated children, all other factors being equal. (*See* **Literacy: Reading (Later Stages)**; **Literacy: Writing**)

CAUSES OF EARLY READING AND WRITING DIFFICULTIES

Literacy researchers concerned with the question of why some children have difficulty becoming literate have distinguished between the immediate causes and ultimate causes of such difficulty. Immediate causes are observed deficiencies in component reading and writing subskills (e.g. word identification, letter-sound decoding, and visual-motor deficits), whereas ultimate causes are deficiencies in the cognitive abilities thought to underlie reading and writing.

Immediate Causes

A prerequisite for meaningful reading is fluent word identification, so it should not be surprising to find that a ubiquitous cause of reading comprehension difficulties is limited facility in word identification. However, this skill is itself highly dependent on the child's ability to acquire foundational skills such as knowledge of print concepts and conventions, phoneme awareness, alphabetic knowledge, higher-level orthographic knowledge, and flexible strategies for word identification. Accordingly, children who struggle with sight-word identification are generally found to have difficulty acquiring one or more of these skills – typically alphabetic and higher-level orthographic skills.

In addition to adequate facility in word identification, fluent and meaningful reading depends on vocabulary knowledge, syntactic competence, grade-appropriate knowledge of text structure, general knowledge, domain-specific knowledge, adequate development of comprehension strategies, and the habit of extensive and diverse reading. Deficiencies in one or more of these areas have been found to cause difficulties in reading comprehension, even in children who have adequate word identification skills.

Given the intrinsic and reciprocal relationships between word identification, spelling, and writing, children with significant difficulties acquiring facility in word identification inevitably have problems in spelling and writing. However, some children have reasonably well-developed word identification skills but less well-developed spelling skills. Such children are typically found to be phonetic spellers who 'overregularize' the spellings of words and do not pay sufficient attention to the structural irregularities characteristic of written English. This tendency is often associated with the failure to acquire a flexible set of strategies for acquiring conventional spellings, including rote memorization and extensive practice with irregularly spelled words.

Deficiencies in written expression have been found to be characteristic of children who have limited language and language-based skills, but such deficiencies may also be associated with gaps in general or domain-specific knowledge, perhaps caused to some extent by long-standing reading difficulties.

Ultimate Causes

The search for the ultimate causes of reading difficulties (and related spelling and writing difficulties) has a history that dates back to the latter part of the nineteenth century. Of special interest in this area of inquiry are children suffering from 'specific reading disability' (dyslexia): that is, children who have at least average intelligence, who do not have learning difficulties in other areas, and whose reading difficulties are not caused by sensory deficits, behavior problems, frequent absences from school, or socioeconomic disadvantage. The study of such children has produced a plethora of causal theories over the years, most of which have been discredited by empirical research. Of all of these theories, by far

the most popular and most ubiquitous have been those implicating deficits in the visual system.

The most prominent visual deficit theories propose that reading difficulties are caused by visual perceptual and visual-spatial processing deficits that affect letter orientation and sequencing in both reading and writing. According to such theories, confusing 'b' with 'd' or 'was' with 'saw', or writing them in mirror form – popular stereotypes associated with the term 'dyslexia' – are manifestations of optical reversibility or spatial confusion (i.e. 'seeing' and/or writing them backwards) that impair letter orientation and sequencing. However, there is now abundant evidence that impaired and normally developing readers do not differ significantly on visual processing tasks that do not depend on linguistic coding abilities. There is also evidence that the types of orientation and sequencing errors that spawned the visual perceptual and visual-spatial deficit theories of reading disability, leading to popular stereotypes of the types just exemplified, are actually caused by failure to master the alphabetic code. Consider, for example, the likely difference between children who have learned the sounds associated with the letters 'p', 'o' and 't', and children who are unaware that letters carry sound values, in distinguishing between and 'pot' and 'top' on word identification or writing tasks. Thus, the visual processing deficits implicated in optical reversibility and spatial confusion theories of reading disability are no longer considered viable explanations of difficulties in learning to read and write.

Other visual deficit theories of specific reading disability have been proffered over the years, including those implicating optical-motor deficits that (presumably) impair normal fusion and conversion of retinal images, and visual system deficits characterized by abnormally prolonged 'visual traces' that interfere with the processing of printed words from one eye fixation to the next. However, such theories are controversial, and none of the deficits implicated in these theories has been shown to be causally related to reading difficulties.

In recent years, language deficit theories of specific reading disability have gained in prominence, and there is a good deal of consensus that deficiencies in phonological skills such as phoneme analysis, letter-sound decoding, name retrieval, and verbal memory constitute basic causes of difficulties in learning to read. Correlational support for such relationships is provided by numerous studies finding robust and reliable differences between impaired and normally developing readers on measures of phonological skills such as those just mentioned. However, training and intervention studies have established causal relationships only in the case of phoneme analysis and letter-sound decoding. Some researchers have also suggested that deficiencies in vocabulary knowledge and syntactic competence may contribute significantly to difficulties in learning to read, but a causal relationship has yet to be established.

Specific reading disability has also been attributed to deficiencies in various cognitive abilities that are involved in all learning, not just learning to read: in particular, selective attention, associative learning, intersensory integration, serial-order processing, pattern analysis, and rule learning. Dysfunction in one or another of these basic learning abilities would seem to be logically ruled out as a significant cause of the disorder in a child who has at least average intelligence and who does not have general learning difficulties, given that all of these cognitive abilities are involved in virtually all tests of intelligence, and are most certainly involved in all academic learning. More importantly, however, each of these hypotheses has been discredited as a cause of specific reading disability by empirical research. (*See* **Dyslexia**)

Finally, estimates of the incidence of specific reading disability in school-age children have ranged between 10% and 20%, but results from intervention studies suggest that 1–5% is a more realistic estimate. These studies have shown that early reading difficulties in most children are caused by experiential and instructional deficits rather than basic constitutional deficits. For example, several of these studies have shown that many children who qualified for 'reading disabled' status in first grade, entered kindergarten lacking in foundational literacy skills such as knowledge of print concepts, knowledge of the alphabet, and phoneme awareness, and had been exposed to kindergarten language arts programs that did not facilitate acquisition of these skills. In contrast, children who had been exposed to balanced and comprehensive language arts programs in kindergarten, emphasizing both code-based and meaning-based literacy activities, experienced fewer difficulties in early literacy development. Thus, the key to reducing the incidence of early reading difficulties would seem to be to improve the quality of the language arts programs in the early grades.

CONCLUSION

Early literacy development can be usefully divided into three periods of acquisition: a prealphabetic period, an alphabetic period, and an advanced

alphabetic/orthographic period. During the prealphabetic period, children begin to become sensitized to the similarities and differences in words in spoken language; begin to learn about print concepts and conventions; begin to acquire rudimentary literacy skills such as knowledge of the alphabet and phoneme awareness, and begin to become acquainted with the structural features of written text. During the alphabetic period children expand their knowledge of print concepts and conventions as well as their sight-word vocabulary and text processing skills; most importantly, they acquire phoneme awareness, learn how the alphabet works, and develop proficiency in using letter sounds to aid word identification, spelling, writing, and text reading. They also become increasingly sensitive to frequently occurring and redundant spelling patterns within words, which facilitates initial use of analogy strategies among other generative strategies for word decoding and spelling.

During the advanced alphabetic/orthographic period children consolidate their alphabetic knowledge, become increasingly sensitive to larger letter clusters that have reasonably stable pronunciations across many words ('ight' in 'sight', 'night' and 'right'), increasingly store information about word-general properties of printed words, and learn to make functional use of such knowledge in decoding and spelling multisyllabic words. With more experience with print, children come to store high-quality representations of the unique spellings of words and build a large inventory of sight words that can be identified or written with speed and accuracy.

Difficulties in acquiring early literacy skills have been attributed to deficiencies in reading-related cognitive abilities such as visual perceptual and visual-spatial abilities, language and language-based abilities, and general learning abilities entailed in all learning (e.g. selective attention, associative learning, intersensory integration). However, research to date suggests that visual deficits and general learning deficits are not causally related to impaired literacy acquisition in otherwise normal children, whereas language-based deficits, especially phonological deficits, are so related. Intervention studies provide strong evidence that difficulties in acquiring early literacy skills are, in most cases, caused by experiential and instructional deficits rather than by basic cognitive deficits.

Literacy: Reading (Later Stages)

Introductory article

Michael Pressley, University of Notre Dame, Notre Dame, Indiana, USA

CONTENTS

The later stages of reading are largely concerned with comprehension or the construction of meaning, which requires both conscious and unconscious cognitive activity.

INTRODUCTION

A reader in the later stages of development can comprehend many types of texts. Hence, the topic of reading comprehension has received substantial attention from researchers interested in advanced reading skills. As a result, much is known about how good readers construct meaning as they read; much of this article is concerned with the meaning construction that is skilled comprehension.

Although comprehension begins with processing individual words, it is much more than reading and understanding individual words. It is comprehending those words in relation to one another within sentences, then combining across sentences and paragraphs to construct higher-order meanings. Comprehension is a decidedly cognitive psychological set of activities.

After presenting a descriptive summary of skilled comprehension, there will be coverage of how comprehension can be developed in readers. It may seem backwards to consider development after presenting a conception of the developmental end product, but the components considered important to develop in young readers will make sense once skilled comprehension is understood. That is, the reading experiences and instruction provided to children should be done with an envisionment of the endpoint in mind, with the goal of comprehension development being adult readers who are skilled as described in the next section.

SKILLED COMPREHENSION

First, it is important to emphasize that comprehension is a constructive process. It was once believed that texts contained meaning, and that meaning was constructed by authors as they wrote, rather than by readers as they read. That is, when a writer wrote a text, she or he had a particular meaning in mind, and if the writer was successful, that meaning ended up in the text. According to this perspective, every good reader would find that particular meaning in the text. It is this conception of comprehension that drives many student publications that claim to provide the meaning of challenging texts to students (e.g. student notes for Shakespeare). What became increasingly apparent in the second half of the twentieth century to literary scholars and psychologists interested in comprehension was that the conception of texts having single meanings was not correct.

Readers construct their own understandings of text – albeit, processing the author's words, sentences, and paragraphs, but reacting to and reflecting on the author's input and in doing so, coming to unique understandings of the text. One proof of this comes when several intelligent people come together to discuss the same text. Often two highly intelligent readers can come to very different interpretations of the story, both of which make sense given the information that is in the text. What this situation reflects is that comprehension involves going beyond the information given in the text, with the good reader making inferences during reading. The good reader is very active during reading. Readers are said to respond to text, with responses varying from reader to reader. That is, although the interpretations of two readers can both include many of the same specific ideas and facts stated in a text, the two readers may emerge from the reading with very different conclusions about what was important in the text and how the ideas in this text relate to the world of ideas in general.

During the twentieth century, great progress was made in coming to understand how readers

construct meaning as they read. One research tool, in particular, proved to be very revealing about reading comprehension processes. Readers in a number of studies were asked to think aloud as they read, to report their thinking as they worked through a text. The resulting 'think-alouds' provided a great deal of information about what skilled readers do before they read a text, as they read it, and after reading. There is a complex articulation of a variety of processes as part of comprehending a text.

Before reading, the good reader has a goal about what she or he wants to get out of a text. That is, the good reader knows whether the text is being read for detailed or general understanding. The goal of reading is important, for it will influence greatly just how the reader proceeds to understand the text (e.g. processing will be more complete if the reader is attempting to understand the author's message in detail rather than simply wanting to be entertained by the story). Especially when reading expository texts (i.e. factual texts, in contrast to stories), good readers will often skim a text before reading it in detail. Skimming provides a great deal of information that permits planning of the upcoming reading, including information about the length and structure of the text and sections that might be particularly important or unimportant. As a result of skimming, the reader might decide to read only certain parts of the text carefully. Alternatively, the reader may decide not to read the entire text. If the skim reveals the text to be irrelevant to the reader's goal (e.g. the reader wants to know about the history of track and field sports and this article about the Olympics is only about the winter games), the reader may decide not to read the text. The initial skim can also result in the activation of prior knowledge (e.g. as the reader skims an article about track and field sports, the reader relates ideas encountered in the skim to her or his prior knowledge). Activation of prior knowledge is important, for a reader's construction of meaning very much depends on prior knowledge. Thus, based on an initial skim and reflection on the ideas encountered during the skim, the reader makes predictions about what ideas will be encountered in the text based on what she or he knows about the topic already. As reading proceeds, good readers are alert to whether their predictions and expectations about what might be in the text are confirmed or disconfirmed.

In general, once reading of a text begins, good readers go through that text from front to back, although sometimes they read selectively (i.e. skipping over sections or reading some sections more carefully than others). Good readers are aware of the characteristics of a text (e.g. whether it is difficult or easy to understand) and whether they are understanding what is read (i.e. they monitor their comprehension). If a text is challenging or there are particular points that the reader wants to remember, she or he may reread a relevant section of text or restate the section of text in her or his own words, make notes, or pause to reflect on the text. As reading proceeds, the reader is also alert as to whether expectations are being met, for example, whether predictions made during skimming based on prior knowledge are correct. In addition, as reading proceeds, the reader makes new predictions based on ideas found during reading of the text. This is, expectations and predictions continuously shift during reading, with the hypotheses that arise during reading evaluated as the reader continues going through the text.

Good readers pay attention to essential points in a text more than less essential points. Hence, when reading stories, good readers pay attention to scene-setting information, which is almost always near the beginning of the story. They also pay attention to introductions of main characters, which also occur early in the story. The skilled reader of stories expects that the main characters will encounter one or more problems in the story, with attempts to solve these problems following. One of the attempts will succeed, with this signaling that the story is starting to wind down. When reading an expository text, the reader is attentive to information that is particularly relevant to reading goals (e.g. looking specifically for information about track and field and ignoring information about other sports contained in a text). When processing expository text, the good reader looks for topic paragraphs, topic sentences, and key words. They are particularly attentive to parts of text that they want to remember. Sometimes the good reader will do more than simply pay more psychological attention to important points in a text. Good readers sometimes highlight text, underlining important points or making notes in the margin. Consistent with different readers making different interpretations as they read, readers differ in the portions of text they consider important.

Sometimes a reader's understanding changes dramatically while reading a text. Hence, perhaps in reading a text on track and field, the reader comes to the insight that her or his interest should only be running events. Hence, the reader might change the reading goal, now looking for information only pertaining to track. Perhaps the reader began the text with the belief that the very best

athletes were sprinters. If the author of the text makes a strong case that distance runners are in better condition and have greater natural skills than sprinters, the reader may change her or his mind, leaving the text with a different conception of the relative ability of sprinters and other athletes.

Inferences

Throughout the reading process, the reader participates in the meaning-making process, largely through making inferences. Sometimes these inferences are unconscious, and if they are, there may be little reporting of them as the individual thinks aloud. (Fortunately, there are other procedures for tapping such inferences.) Many inferences, however, are decidedly conscious, with readers readily reporting that they make them. For example, a reader might encounter the following bit of text: 'The ball went over Jack's head into the street. The car swerved to miss Jack.' Many readers would consciously infer that Jack must have run into the street.

What kinds of inferences do readers make as they read? The answer is, many: for example, they infer the referents of pronouns when referents are vague. Thus, if given the sentence 'Laura Bush then introduced the President. He came to the podium', most readers would infer that the 'he' is President Bush. Also, when new vocabulary words are encountered, readers often infer their meaning. Thus, a third-grade student reading the sentence 'There were blue, red, and chartreuse dresses', might infer that chartreuse is a color since the colors blue and red preceded it in the listing within the sentence. Readers also make inferences about connotations made in a text. Thus, if encountering 'Many members of this society believe there are visitors to Earth from other planets. That's pretty likely, isn't it?', many readers would infer from the sentence 'That's pretty likely, isn't it?' that the author did not think it really was likely that Earth is being visited by extraterrestrials.

Much inferencing involves relating ideas encountered in the text to the reader's prior knowledge. Thus, readers sometimes construct explanations for events reported in a text. For example, if a headline states 'New Yorkers Scoop Up World Series Tickets', the avid baseball fan who is just returning to the country from abroad might infer that the New York Yankees have won the American League playoff series. If reading about how certain cars do not live up to their advertised mileage, the Honda owner might infer that the author could not be talking about Hondas, since his Honda gets better fuel consumption than advertised. Alternatively, the reader might relate the author's point to a more general piece of knowledge, thinking to himself: 'The auto makers are engaging in false advertising, and a bad form of it, since fuel-inefficient cars undermine progress on the fossil fuel problem, which is huge.'

One common type of inference is about the author or the author's intention in writing the text being read. Thus, when reading a psychology article about recent important experiments, a reader might infer: 'The author really wants me to believe that psychology is a scientific enterprise.' Alternatively, another reader of the same text might infer: 'This article was written for people with a lot of background in psychology.' Sometimes the reader makes inferences about the author herself, perhaps concluding: 'She must be a psychologist. This could not have been written by a journalist.' In short, good readers have a great deal of prior knowledge based on their experiences in the world and previous reading, and they consistently relate what they know already to ideas encountered in the text, coming to conclusions not explicitly stated in the text.

Integration

Good readers relate across the ideas in a text, attempting to construct the larger messages in that text. Thus, when reading Charles Dickens's *A Christmas Carol*, the reader might reflect on the various scenes to construct the understanding that what happens in later life depends very much on what happens earlier in life, but it is always possible for people to change. The skilled reader of stories will explicitly make certain that she or he knew the setting, the characters, the problems encountered by the characters, and the problem resolution as part of coming to general conclusions about the story. For example, the reader might conclude that '*Christmas Carol* is much like Cinderella in that a life is transformed through the intervention of characters from another world'.

In reading an expository text, the skilled reader will be alert to the introduction of the article and to examples to illustrate general principles. The reader will also be careful to pay attention to logical structures in the text, such as cause-and-effect sequences and compare-and-contrast arguments. Such attention is often in the service of coming to higher-order conclusions, such as: 'This article is about ecological threats to sea-life, with the case being made that many species – from whales to

sharks – are being threatened by man's increasing use of the seas. Although the threats are different for whales and sharks, they are all threats due to humans invading the oceans with more sophisticated technologies.' The construction of such integrative understandings may require a lot of effort, including reviewing points made in the text, rereading sections of text to make certain the ideas were comprehended, and making written notes or outlines as reading proceeds.

Interpretations

The good reader is an interpretive reader, with interpretations obvious in a number of ways. First, good readers do summarize as just described. They also construct mental images reflecting story elements or ideas presented in a text. Thus, as a child reads L. M. Montgomery's *Anne of Green Gables*, she might develop in her mind's eye a detailed envisionment of Prince Edward Island. If a story has a scene in a McDonald's restaurant, the reader might envision that the story took place in the local McDonald's, which is a hangout for teenagers, and thus interpret that the story is about teenage culture. Sometimes the same reader can be multiply interpretive, perhaps trying to imagine alternative interpretations about a text. Thus, if reading a story about the 2000 US presidential election recount in Florida, the reader might reflect on how winning candidate George Bush would interpret the story (e.g. 'It's about public officials making hard but necessary decisions'). In contrast, losing candidate Al Gore might interpret the story differently (e.g. 'It's about how Republicans can twist the facts to fit their view of the world and steal an election in doing so').

Evaluations

Good readers are evaluative as they read. Hence, if ideas presented in a text clash with a reader's prior knowledge, she or he may devalue or dismiss a text (e.g. a patriotic American dismissing an article claiming that the former Soviet Union was the most advanced society in the mid-twentieth century). Alternatively, if the ideas in a text are consistent with a reader's perspective, she or he might be enthusiastic about the book. In addition to being aware of whether arguments in a text are valid or credible from the reader's perspective, good readers are critically aware as they read whether a text is well written (appropriate vocabulary, well-structured sentences and paragraphs, well-developed arguments) or interesting or novel. A reader's evaluations can often be quite pronounced and affective, including surprise, laughter, puzzlement, boredom, frustration, or anxiety (e.g. 'I hope this author isn't concluding that people like me might be at risk for cancer').

Post-reading Cognition

After a good reader has gone through a text, she or he often continues to think about it. Thus, sometimes readers will skim over a text just read as part of constructing the overall meaning of the text. They might be much more thorough, however, rereading parts of the text that seem especially pertinent or perhaps outlining the text. Sometimes they might imagine how the ideas in the text might be used later by them (e.g. thinking about how the ideas about threatened sea-life might make sense in a paper they are writing for a biology course).

Monitoring

Good readers are consciously aware as they read, with such awareness critical in directing their efforts to construct meaning. Such awareness is generally known as 'monitoring', with one specific example of comprehension monitoring provided earlier. More generally, good readers monitor a number of characteristics of a text as they read – whether it is relevant to the current reading goal, difficult or easy to read, written in a biased fashion, related to other texts the reader has read, ambiguous, or presenting ideas consistent or inconsistent with the reader's perspective.

Good readers also monitor their strategies while reading (i.e. whether they are skimming the text or reading it carefully, looking for particular types of information, making predictions and later confirming or disconfirming them, summarizing) and whether the strategies they are using are resulting in the level of comprehension they desire (e.g. whether they are achieving the detailed understanding they want). If the strategies currently being used are not working to produce the understanding the reader desires, the reader may change tactics. That is, as a reader monitors, she or he is especially sensitive to problems being experienced, with the detection of problems leading to actions to solve the problems. So, if the problem the reader detects is that she or he is spending a lot of time reading parts of text that are irrelevant to the reading goal, the reader might decide on a new strategy. The reader might begin to skim each paragraph before reading it, skipping over paragraphs that

do not appear to have much relevant information in them. Alternatively, if the reader monitors that she or he is not remembering some critical details, the decision may be to read much more carefully. If the reader monitors that some parts of a story are much more interesting than others, she or he might elect to read some sections of the story carefully, stopping to reflect on the scenes as developed by the author, and to skim other sections of the story. Thus, a reader who is reading *The Brothers Karamazov* to understand Dostoyevski's orientation to religion might read some sections of the book much more carefully than others. If a reader monitors that an unknown word is really critical to understanding a story, she or he might pay a great deal more attention to the word and the construction of its meaning from context clues than if the word seems less essential to understanding meaning. Thus, a modern child reader of Lewis Carroll's *Through the Looking Glass* might make certain that she or he knew the meaning of 'looking glass', recognizing that if the word is important enough to be in the title, it is important to make absolutely certain that the word is understood. In short, the awareness that is monitoring is a critical determinant of what readers do as they read.

The skilled reading described in this section is observed in some adults but rarely in children, or even high school students. More positively, even very young children can be taught to monitor and use comprehension strategies as they read. Most of the remainder of this article is dedicated to the development through instruction of reading skills that contribute to skilled comprehension.

DEVELOPMENT OF SKILLED COMPREHENSION

Many adult readers do not read as just described. Rather, they pick up a story or an article and begin at the beginning, reading every word, but doing little else. Often, at the end of the reading, little is remembered from the text. Such a reader's understanding of the ideas in the text is not nearly as complete as the understanding of a really skilled reader. One important reason that many people do not become skilled readers is that they are never taught how to read well. Many adults with reading problems can become better readers through the instruction considered in this section. Nonetheless, such instruction should not be put off until adulthood, for the evidence is quite strong that reading comprehension improves reliably when young readers are taught to carry out the processes that are used by good readers. In fact, the evidence is very strong that even struggling child readers (e.g. students with learning disabilities, specifically reading disabilities) benefit from the types of instruction considered in this section.

Word Recognition

One salient characteristic of good readers is that they have no trouble reading individual words. In fact, they are said to recognize words fluently. When word recognition is fluent, it requires hardly any cognitive effort for the reader, which is critical, since cognitive effort consumes short-term memory – short-term cognitive capacity. That is, human beings can do only so many things at once; they have only limited short-term memory capacity. Both word recognition and comprehension processes require cognitive capacity, and hence, compete with one another for the limited capacity that is available. When readers have to exert a lot of effort to recognize words, there is little capacity left over to understand the text being read. Conversely, when word recognition is effortless, there is more capacity left over for comprehension. Thus, it is very important that word recognition skills be developed in readers so that most words can be read fluently – that is, can be read without the reader thinking very hard about them.

In recent years, the research-based consensus is that fluent word recognition is most likely to develop if the beginning reader receives explicit instruction in how to sound out words – that is, explicit instruction in phonics. Although learning how to sound out words does not automatically lead to fluent word recognition, it seems to be a good start. With subsequent practice in reading words, fluency eventually comes for many students. Of course, even the most skilled reader sometimes has to exert effort to recognize a word. For example, when adults who are not physicians read a medical text, there are unfamiliar words that are read only by consciously sounding them out, with their meaning understood only by the reader consciously looking for root words and context clues. Thus, consider the sentence 'Mucous membranes sometimes develop adenocarcinomas'. The skilled nonphysician reader would have to sound out 'adenocarcinoma'. The reader might guess that it is a form of cancer because it contains the word 'carcinoma', which means cancer. In contrast, a cancer doctor would read the same word effortlessly and know what it meant automatically. Good readers eventually can read words they encounter often without effort. Early instruction in

phonics followed by lots of practice reading words can result in fluent reading of the words included in the types of text frequently read by the reader.

Much emphasis has been placed on the development of word recognition skills, almost to the neglect of other skills. Some of those who emphasize teaching of phonics seem to feel that the key skill in reading is word recognition, and that if word recognition is skilled, the young reader will eventually develop into a highly skilled reader. There is no scientific evidence to support such a position. Rather, the evidence is quite consistent that skilled reading more certainly develops from the acquisition of a variety of skills that comprise comprehension, one of which is word recognition. That word recognition skills are critical to skilled comprehension, however, makes clear that the development of readers with advanced reading skills depends on reading education efforts during early schooling. Other evidence also points to this conclusion.

Vocabulary

Skilled readers typically have good vocabulary, which is sensible, given that higher-order meanings in text cannot be constructed without knowing the meanings of individual words. Most vocabulary items are learned by individuals encountering them in context. Thus, young children learn the meanings of many words by hearing them in their worlds. They learn other meanings by encountering words in texts and making guesses about what a word means based on context clues. Even so, teaching students vocabulary that they do not know improves reading comprehension, especially of texts containing the words taught. The conclusion that follows from this set of observations is that encouraging vocabulary development is important as part of developing skilled readers.

There are multiple ways of encouraging vocabulary development. One is to make certain that the child experiences a rich language world, one in which the child interacts verbally with adults and other children. A second is to ensure that the child reads broadly, especially books that contain new vocabulary. A third is to teach vocabulary explicitly. Researchers have produced a variety of data confirming that the development of vocabulary competence has a striking effect on comprehension skills. Again, it is possible even during the early elementary school years to be educating children in ways that are consistent with the skills reflected in really skilled reading.

World Knowledge and Using World Knowledge

In addition to good vocabularies, good readers tend to have substantial and well-organized knowledge about the world. Again, this reflects rich interactions with the world, including a great deal of reading of high quality materials. This extensive world knowledge permits readers to go beyond the information stated in a text, to make appropriate inferences.

That said, a failure documented in recent years is that some readers possess world knowledge that could be used to understand ideas in a text (e.g. knowledge about football that could be used to understand ideas in an article about changes in the rules of football for the upcoming season), but they fail to use it as they read. Thus, there are now efforts to develop instruction that will encourage readers to use the knowledge they already have as they read texts. One powerful approach involves prompting readers to ask themselves why the ideas being presented in a text make sense. Thus, the person reading the article about changes in football rules would be encouraged to think about why the rule changes make sense, based on his knowledge of football.

Another problem involving world knowledge is that some readers will bring to a text world knowledge that seems to be irrelevant to the ideas in the text (e.g. a reader processing the article about football rules recalls how an umpire in a baseball game made a bad call that cost his team the game). Such irrelevant world knowledge can undermine comprehension of text, and hence, researchers are now working to identify ways to reduce the likelihood of readers making such distracting associations.

In summary, eventual skilled comprehension can be fostered by encouraging students to read materials filled with the information that literate people know. Skilled comprehension can be developed further by teaching students to relate the prior knowledge they have acquired through experience (including previous reading) to ideas encountered in texts they are now reading.

Comprehension Strategies

Relating ideas in a text is just one of the comprehension strategies used by good readers. Good readers also predict, ask questions while they read, construct mental images depicting ideas expressed in the text, seek clarification when confused as they read, and summarize the main ideas in the text. Use of such strategies does not develop reliably unless

they are taught. Unfortunately, these comprehension strategies often are not taught in school. More positively, instruction in these strategies can be profitable even during the early elementary grades.

The approach to comprehension strategies instruction that has the most support begins with teacher modeling and explanation of strategies. The strategies can be introduced one at a time, perhaps over a semester. After showing and explaining the strategies to students, the teacher encourages the students to use them when they read. Although the emphasis at first can be on single strategies, the teacher eventually emphasizes coordinated use of the strategies, with the students practicing prediction, questioning, clarification, constructing mental images, and summarizing as they read stories and articles, both in small groups and individually.

The explicit teaching of a repertoire of comprehension strategies through teacher modeling, teacher explanation, and teacher-supported practice is known as transactional strategies instruction. Although a year of *transactional strategies instruction* produces documented effects, several years of such instruction and practice is required for readers to use comprehension strategies automatically and well. In general, the thinking is that comprehension strategies instruction should begin in the early elementary years, with researchers believing that consistent teaching of such strategies is much more likely than traditional reading instruction to produce readers who are active in the ways skilled readers are active, as described in the first section of this article.

Monitoring

Such strategies instruction invariably includes teaching of monitoring as well. Readers are taught to be alert to when they are experiencing difficulties in reading and to respond to difficulties by applying new strategies – for example, looking for context clues, if the meaning of a word is unclear, or rereading, if the meaning of a sentence or paragraph is difficult to grasp. In short, student readers are being taught to be self-regulated readers, with self-regulation involving awareness about when the use of reading strategies is required, followed by the selection and use of appropriate strategies.

Cognitive Capacity Constraints

A reaction to the teaching recommendations in this section could be that young readers are being asked to do too much. In particular, sounding out words, figuring out the meaning of new vocabulary words, relating ideas in a text to world knowledge, using comprehension strategies, and monitoring all involve effortful processing, at least at first. Does the young child have sufficient cognitive capacity to carry out all of these processes? The answer is that the child does not have the capacity to do so consciously when all – or even some – of these processes can be accomplished only with effort. The key is to practice the various processes until they are carried out fluently. That is why word recognition and comprehension strategies instruction, in particular, are thought of as interventions that occur over years rather than over weeks or months. With years of practice, word recognition becomes fluent as does use of comprehension strategies. With increased fluency, there is decreased demand on the child's limited cognitive capacity. If the child is reading excellent material to practice word recognition and comprehension strategies, there are bonuses, with vocabulary and world knowledge expanding. Of course, the more vocabulary the reader knows and the more world knowledge she or he has acquired, the better comprehension is in the future.

MOTIVATION TO READ

Really skilled readers not only can read, but they do read. As they do so, their knowledge increases as do their reading skills, with the result that the richly skilled and knowledgeable get even richer in skills and knowledge. Because extensive reading is so essential to highly skilled reading, much attention has been given in recent years to what can be done to increase student motivation to read.

Schools regularly provide concrete incentives to students for reading extensively (e.g. a pizza gift certificate for reading so many books a month). Permitting students to read in topic areas that are interesting to them motivates reading. What undermines motivation to read, however, is difficulty in reading. Sadly, many students who do experience initial reading difficulties come to hate reading, with this passionate dislike of reading substantially reducing the likelihood that reading will be done voluntarily. Not reading in elementary and secondary school does not augur well with respect to future reading skills. Hence, one of the primary reasons that so much attention is now being given to increasing reading success through early instruction is to prevent students from experiencing the frustrations that undermine long-term commitment to reading. A goal of most reading educators is to develop life-long readers in their students,

since life-long practice of reading is absolutely required to become an effective reader.

BEYOND COMPREHENSION

Before a reading can be comprehended, the reader has to find the material that should be read. Searching for texts that contain particular information and searching for information within a text is a complicated skill. The latter task is understood more completely by psychologists than the former task.

To find material in a text, the reader has to know what she or he is looking for (e.g. information about Olympic track events). Then, the reader has to figure out which parts of a text might have that information (e.g. a chapter on the Olympics, a chapter on track and field). Once the relevant sections to search are identified, the reader has to go through the text sections and recognize the information that is crucial. None of this is easy.

For example, even if a college student knows what she or he wants to find and identifies some particular parts of source texts that might contain the information, there is no guarantee the reader will recognize pertinent information when it is being read. Why is this so? Because a great deal of prior knowledge about a topic is often necessary to be able to pick out sections of text that are directly relevant to a particular topic in the knowledge domain. Without extensive prior knowledge, the reader can read right over information that is exactly the information being sought without recognizing it as such. One of the things that skilled readers can do is to search text effectively, which depends very much on having extensive prior knowledge of the domain being searched.

Beyond finding information in a text, readers often want to use information read in a text for some purpose. A typical student purpose is to write a paper, which is analogous to research writing in general. Unfortunately, we know little about how people carry out research by reading multiple texts in anticipation of writing an article or a book. What we do know is that there is variability in this skill, with some people reading articles and making notes nonreflectively. Others are a bit more reflective, taking note only of ideas or facts in a text that seem true or important. It is a clear minority of college students who read several texts, compare the ideas in them, and attempt to understand the similarities and differences between authors of different articles or books. As far as using what is found by reading several sources, there are also individual differences among college students. Many write papers simply by listing out facts found in readings. It is a minority again that tries to write essays that go beyond the information given in source texts. People high in literacy skills are very reflective as they read multiple texts on a topic, doing much comparison across ideas in the texts, attempting to construct understandings that go beyond the understandings expressed in any one of the texts that have been read.

CONCLUSION

Advanced readers are active readers, constructing understandings of texts, making inferences as they do so, and integrating across ideas in a text to produce summary understandings. They can do so fluently because they have the many component skills of comprehension well honed. They recognize words easily, know the meanings of many words encountered in texts, have expansive world knowledge which they can relate appropriately to ideas encountered in new texts, and know and use comprehension strategies from before reading to during and after reading. All such competencies can be developed through instruction so as to promote comprehension skills. A complete education to develop the advanced reader requires years of instruction in the components of skilled reading as well as much practice doing actual reading. Excellent readers are motivated to read, can find information in texts that is relevant to topics they want to know about, and can combine information across texts to construct new understandings that go beyond the information given in any of the source texts read. When such reading is observed, it is among well-educated adults, individuals with years of reading experience.

CONTENTS

Writing is a self-initiated, self-directed, and self-sustaining activity of composition and inscription that requires the orchestration of a wide array of cognitive processes. Since the mid-1970s the cognitive science framework has dominated the psychological study of these mental operations.

INTRODUCTION

More than 5000 years ago, the Sumerians devised the first known system of writing, called cuneiform, to record goods using a wedge-shaped reed stylus to make impressions on a moist clay tablet. From this modest beginning, the application of writing as well as the means for producing it have undergone an incredible metamorphosis (Graham and Harris, 2000a). The act of producing writing, for instance, has progressed to the point where scientists at Germany's University of Tübingen have developed a machine, called the 'thought translation device', that allows a writer to amplify or dampen brain wave patterns to select letters from a video screen to spell out a message (Begley, 1999). Similarly, writing has evolved from its initial record-keeping debut to being one of humankind's most powerful tools. Among its many functions, it provides a flexible medium for artistic, political, spiritual, and self-expression. Just as important, writing provides an external memory, making it easier to remember, analyze, and share ideas. It can even have therapeutic effects; writing about one's feelings can lower blood pressure, reduce depression, and boost the immune system (Graham and Harris, 2000a).

In contrast, the scientific study of writing has a more recent genesis, totaling no more than 100 years. Since the 1980s, two basic approaches have dominated the scholarly and scientific study of writing (Scardamalia and Bereiter, 1986). One approach has been labeled as 'contextual', and focuses on the meaning that writing has for people in different contexts. The other is referred to as the 'cognitive science' approach. This approach has been particularly powerful in advancing our knowledge about the process of writing and its development. As two influential researchers noted: 'It provides pretty much the "only paradigm in town" for investigating complex mental processes, which all sides agree are of central concern in writing' (Scardamalia and Bereiter, 1986, p. 780).

COGNITIVE MODELS OF WRITING

Although some historians claim that they can identify the exact year (1956) or even date (11 September 1956) that contemporary cognitive psychology was born, such precision is not possible in the study of writing. A watershed event in this area, however, was an interdisciplinary conference at Carnegie Mellon University in 1978 designed to synthesize previous research on writing as well as showcase new research. Papers from this conference were assembled into a book entitled *Cognitive Processes in Writing* (Gregg and Steinberg, 1980). The publication of this book generated considerable interest in the cognitive nature of writing and the application of conceptual and methodological advances from the cognitive sciences.

A particularly influential chapter in this book presented a model of skilled writing (Hayes and Flower, 1980). This model was developed by asking adults to 'think aloud' while composing. Analyses of these verbal protocols provided a window into the cognitive as well as other psychological processes involved in writing. The resulting model comprised three major components.

The first component, *task environment*, included factors that were external to the writer, but influenced the writing task. These included both social factors, such as an assigned writing task, as well as physical ones, such as the text produced so far.

The second component, *cognitive processes*, provided a description of the mental operations involved in writing. This included three basic processes: planning what to say and how to say it, translating plans into written text, and reviewing to improve existing text. Planning, in turn, was composed of three ingredients – setting goals, generating ideas, and organizing ideas into a writing plan, whereas reviewing included reading and editing text. The execution of these cognitive processes was thought to be under the writer's direct control, and it was proposed that virtually any subprocess could interrupt or incorporate any other subprocess. For instance, planning might interrupt translation, if a writer identified the need to develop additional writing goals while producing a first draft. Another writer might combine translation and reviewing, generating a section and then revising it, then generating and revising a second section, and so on.

The third model component, *writer's long-term memory*, included the author's knowledge about the topic, the intended audience, and general plans or formulas for accomplishing various writing tasks.

The Hayes and Flower (1980) model emphasized the recursive nature of the cognitive processes involved in writing. In other words, writing did not necessarily proceed in a linear fashion from planning to translating to revising, as was commonly suggested in the composition textbooks of the time. Rather, skilled writing was viewed as a nonlinear activity, where major cognitive processes and subprocesses were typically interwoven or nested one within another. This property of recursion was a particularly powerful component of the model, because a small number of cognitive processes were now able to account for a diverse set of mental operations during composing. In addition, individual differences among writers could be explained by different specifications of the model. For instance, Scardamalia and Bereiter (1986) developed a description of immature writing, referred to as 'knowledge telling', that was essentially a radically reduced version of the model. Based on their study of school-age children, they proposed that novice or immature writers use a greatly simplified version of the idea-generation process in Hayes and Flower's model. Children converted the writing task into simply telling what one knows about the topic.

The Hayes and Flower (1980) model was also significant because skilled writing was cast as a self-directed activity, involving high levels of self-regulation. Analysis of the verbal protocols from the 'think-alouds' revealed that writing is a goal-directed process. Skilled writers set goals for what they wanted to do and say (e.g. be convincing, funny, and succinct), and frequently established subgoals for meeting their major goals (e.g. use strong arguments and refute counterarguments to convince the reader). Hayes and Flower's analysis further highlighted the cognitive complexity of writing. Skilled writers caught in the act looked very much like busy switchboard operators, trying to juggle simultaneously a number of demands on their attention (e.g. making plans, drawing ideas from memory, developing concepts, creating an image of the reader, testing ideas and text against that image, and so forth).

In 1996, Hayes revised the original model, reorganizing, expanding, and modifying the initial framework so that it captured the ensuing 16 years of writing research. In the new model, the task environment was modified so that it included both a social component (e.g. the audience, other texts read while writing, and collaborators) as well as a physical component (e.g. text read so far and the writing medium, such as a word processor). Hayes's overhaul was not limited to contextual factors, however, as he also reconceptualized internal factors involved in writing. First, he included motivation as a separate component and indicated how affective factors such as goals, predispositions, beliefs, and attitudes influence the writing process. Second, working memory was added to the model. This component provided a limited place for holding information and ideas for writing as well as carrying out cognitive activities that require the writer's conscious attention. Third, the long-term memory component was upgraded to include not only the writer's knowledge of the intended audience, the writing topic, and genre, but also linguistic knowledge as well as schemas for carrying out particular writing tasks, such as revising.

Hayes (1996) further reworked each of the cognitive processes identified in the original model. Planning was subsumed under a more general category, reflection, which encompassed problem-solving, decision-making, and inferencing. In the revised model, writers rely on general problem-solving (including planning) and decision-making skills to devise a sequence of steps to reach one or more writing goals. These reflective processes are abetted by inferencing, as writers make judgments or draw conclusions about their audience, possible writing content, and so forth.

Like planning, translation was also included under a more general category, entitled text production. Hayes (1996) indicated that cues from the

writing plan or the text produced so far guide the retrieval of semantic information, which is held in working memory. This information is then expressed as sentence parts that are produced vocally or subvocally and evaluated by the writer. The resulting production may be deleted, modified, or written down depending upon the subsequent evaluation.

Finally, the process of reviewing or revising was replaced by text interpretation. Hayes (1996) assigned reading a central role in text interpretation, indicating that the writer may read and evaluate text when revising, read source texts to obtain writing content, and read to define the writing task. With each of these tasks, the writer forms an internal representation of the text that can then be acted upon.

Although the original Hayes and Flower (1980) model and the revised model (Hayes, 1996) highlight the cognitive nature of writing, they remain incomplete. For instance, neither model provides an adequate description of all the major aspects of writing. The role of text transcription skills (handwriting, spelling, and so forth), for example, and their possible interaction with other cognitive skills, such as text generation and planning, is not addressed (Graham and Harris, 2000b). Even more importantly, little attention was directed at explaining how writers acquire the cognitive and noncognitive skills underlying skilled writing performance.

The issue of learning was addressed in a model of writing developed by Zimmerman and Risemberg (1997), at least in terms of the self-regulatory aspects of writing. They proposed that writers manage the composing process by bringing into play three general classes of strategies, strategies for controlling: their actions, the writing environment, and their internal thoughts and processes. Writers employ these strategies reciprocally when composing and monitor, evaluate, and react to their use. This allows them to learn from the consequences of their actions. Thus, self-regulatory strategies that are perceived to be successful are more likely to be retained, whereas those that are perceived as unsuccessful are more likely to be abandoned. It was further proposed that the writer's sense of efficacy may be enhanced or diminished depending upon the perceived success of the employed strategies. Self-efficacy, in turn, was hypothesized to influence intrinsic motivation for writing, the use of self-regulatory processes during writing, and eventual literary attainment.

Since the advent of the influential Hayes and Flower (1980) model, increasingly sophisticated descriptions of the mental operations involved in writing have emerged. The subsequent models, including those discussed here, however, are like a painting, where some parts have begun to take definite shape, other parts are being sketched in, and still other parts of the canvas remain blank (Hayes, 1996).

WRITING DEVELOPMENT

Although a great deal remains to be learned about the development of the cognitive aspects of writing, the road from novice to competent to expert writer is paved, at least in part, by changes in writers' strategic behavior (Graham and Harris, 2000b). Take, for instance, the development of planning in writing. As novice writers gain experience, there is an increase in the amount and conceptual complexity of their plans. Bereiter and Scardamalia (1987), for example, found that undergraduate students generated multiple and abbreviated lists of ideas when planning, and that these ideas were often connected by lines or arrows. Conceptual planning notes and evaluative statements (focusing on goals, structuring writing, and overcoming difficulties) were also quite common. In contrast, the planning notes developed by children in grades 4, 6, and 8 in their study showed that younger students simply generated complete sentences that were edited into a final draft when writing, while older students listed content ideas that were later worked into their compositions. Not surprisingly, strategic differences between skilled and novice writers are not limited just to planning, as the revising behavior of these two groups differs as well. For instance, skilled writers revise more for meaning and make more sentence- and theme-related changes than their developing counterparts who take a thesaurus approach to revising, focusing most of their efforts on making word substitutions and correcting mechanical errors (Fitzgerald, 1987).

As novice writers become more competent, their strategic behavior is likely to change in five ways (Alexander *et al.*, 1998). First, they become more *efficient*. Writing tasks that were once novel become more routine, and the strategies used to accomplish them become more practiced, requiring less cognitive energy and time. Second, their strategic behavior becomes more *effective*. This includes developing more powerful and elegant strategies for writing as well as using strategic knowledge more intelligently. Third, they apply strategic knowledge more *flexibly*. This includes modifying a given strategy or combining strategies in novel

ways to meet new purposes. Fourth, they become *less reliant* on strategic solutions for common writing tasks. Solutions for some writing tasks become so automatized for competent writers that they no longer require conscious or effortful processing. Finally, there is a *qualitative shift* in the strategies that writers most commonly rely on. As writers gain more competence, the importance of some strategies declines and the value of others increases.

For those writers who continue on to become experts, another shift in strategic behavior is likely to occur (Alexander *et al*., 1998). Professional writers, such as novelists or essayists, have progressed beyond merely solving writing tasks generated by others (e.g. a teacher) to formulating their own writing problems and tasks. These tasks are often novel or complex enough to require an increase in strategic behavior. Consider, for instance, Irving Wallace's description of writing a novel (Graham and Harris, 1994). He indicated that he used a variety of strategies to help him develop and manage this difficult task. This included making outlines, developing scenes and characters, working out the sequence of the story in his head and then roughly on paper, underlining story problems needing additional work, making many revisions in his plans and outlines, repeatedly rereading and revising his manuscript, constantly monitoring each step of the process, and keeping a detailed record of his progress.

The road from novice to competent to expert writer is also paved by changes in writers' knowledge (Scardamalia and Bereiter, 1986). As novice writers gain experience, their mental representations of writing become more complex and sophisticated. For example, when younger and older students are asked to describe the writing process, older students are more knowledgeable about the factors that constitute good writing, the strategies that writers employ, and the attributes of specific genres (Graham and Harris, 2000b). Advances in knowledge, however, are not just limited to the lore of composition, but involve knowledge of the topics of writing as well. For instance, writers who are more knowledgeable about a topic have to devote less cognitive effort to planning, translating, and revising than their less knowledgeable counterparts (Kellogg, 1987).

Initially, young writers have little knowledge about writing, and what knowledge they do have is fragmented and unorganized (Alexander *et al*., 1998). As they move towards competence, however, their knowledge of writing expands and becomes increasingly ordered. Those who continue on to become experts, such as professional writers, acquire exceptional levels of knowledge, and this knowledge is highly principled and integrated. A more articulated and richly interconnected knowledge base allows writers to behave more strategically and thoughtfully, as they are able to make better decisions about what they need to do to solve routine as well as novel writing problems.

Because writing is goal-directed and effortful, motivation also plays an important role in writing development. As with strategic processing and knowledge, motivational beliefs, such as self-efficacy and attributions for success, change as writers gain experience, and such beliefs are related to writing performance (Shell *et al*., 1995). Motivational factors may be especially important in determining level of effort as well as how a writer solves a particular writing problem. Consider, for instance, Robert, who was asked by his teacher to write a report (Many *et al*., 1996). Although he was familiar with how to conduct a systematic search for information and how to organize it, his search for writing content was driven by his personal interest, and not the topic of his report. As he encountered information that attracted his attention, he added it to his notes, changing the topic of his paper to maintain consistency with the newly added information.

Finally, development of the cognitive aspects of writing is influenced by a variety of contextual factors, especially schooling (Graham and Harris, 1994). Many teachers attempt to influence the course of this development in a relatively straightforward and direct fashion. They may model and explicitly teach the types of strategies and self-control procedures used by more skilled writers (Graham and Harris, 1996), or establish predictable routines where writing processes such as planning and revising are expected and reinforced. Teachers also use less direct methods to promote this development, employing instructional arrangements where children are encouraged to work together on writing projects as well as to rely on each other for input and support. This approach provides students with the opportunity to view and accommodate to other styles of composing, paving the way for each child to incorporate new influences into their own writing.

ASSESSMENT OF COGNITIVE PROCESSES

One general approach for assessing the cognitive aspects of composing is to observe writers directly

and record their behaviors in order to make direct inferences about the mental operations involved in writing. This can involve recording the amount of time that a writer devotes to a particular writing process, such as planning in advance (De La Paz and Graham, 1997). It can also involve using a computer to record the chronology, location, type, or duration of particular writing behaviors. For example, pauses that writers make while composing have been used to assess writers' cognitive planning and decision-making behavior (Matsuhashi, 1987). With this type of analysis, it is assumed that writers pause when they are planning or making decisions, and the location and duration of such pauses provides a window into these processes (e.g. longer pauses generally reflect more important decision episodes). Similarly, a record can be made of the keystrokes that occur when composing at a computer to provide a chronology of a writer's revising behavior (Eklundth and Kolberg, 1996). One advantage of direct observations and recordings is that they are generally nonreactive (i.e. they do not interact with the processes under investigation).

A second general assessment approach is to ask writers to describe what they do and what is happening while they write. For example, with the 'think-aloud' protocol used by Hayes and Flower (1980), writers are directed to say out loud everything they think and everything that occurs to them while completing a specific writing task. Think-alouds can be limited to specific processes, however, such as verbalizing thoughts just about planning. Writers can also be stopped during composing and asked to indicate what they are doing at that point. For instance, they can be stopped at specified intervals and asked to indicate if they are planning, translating, reviewing, or doing something else (Kellogg, 1987). Although these procedures are reactive and may directly influence the mental operations they are meant to assess, they provide a powerful means for accessing the writer's mental landscape during composing.

In addition to asking writers to describe what they do as they compose, they can also be asked to describe these processes retrospectively. One means for doing this is to query writers about their thoughts and actions after they have completed a specific writing task (Fitzgerald, 1987). For instance, a writer might be asked to remember what he or she was doing or thinking at particular points, while viewing a videotape of the writing session. Writers can also be asked simply to describe what they generally do when they write (Graham *et al*., 1993), such as how they go about the process of planning a paper. Although these approaches are not reactive, the resulting data must be interpreted cautiously, as writers may not remember exactly what they thought or did or they may embellish their descriptions.

A third general assessment approach is to examine writing artefacts, such as written plans or the composition itself, to draw conclusions about the mental operations employed by the writer. For example, the content and complexity of written plans can be analyzed, and the resulting written products can be examined to determine how these plans are modified and expanded as writers produce successive drafts of a composition (Bereiter and Scardamalia, 1987). Similarly, first and second drafts of a composition can be compared to ascertain not only the types of revisions made by writers, but their general approach to revising as well (Fitzgerald, 1987). Although analysis of artefacts is nonreactive, identification of intentions and the processes employed by the writers rests solely on inference.

A fourth assessment approach involves theory-embedded experimentation. With this approach, the theoretical contribution of a cognitive process to writing can be tested by explicitly teaching this process to writers who do not typically employ it when composing. For instance, novice writers who do little or no planning can be taught how to plan (De La Paz and Graham, 1997). A positive change in their planning and writing behavior following such instruction would support the contention that this process is an important component of skilled writing.

Simulation by experimentation provides a somewhat similar approach for assessing the role of cognitive processes in writing. With this approach, selected composing strategies or abilities are investigated by structuring writing tasks to simulate these processes. For example, a model of the mental operations underlying revising was tested in one study where researchers examined the effects of a procedure designed to ensure that participants used each of the hypothesized operations (Scardamalia and Bereiter, 1983).

A final approach involves assessing cognitive processing at a more global level. This may include examining performance on more general cognitive measures, such as tests of attention or working memory (Benton *et al*., 1984), or conducting magnetic resonance imaging to map regions of the brain associated with writing performance (Berninger *et al*., 2002).

WRITING DIFFICULTIES

According to data collected as part of the National Assessment of Educational Progress in the United States in 1998, one out of every five high school seniors' writing was so poor that they had not even obtained partial mastery of the writing skills and knowledge needed at that grade level. Although the origins of writing problems are not fully understood, poor writing performance is partially a consequence of difficulties with the cognitive aspects of writing (Graham and Harris, 2000b). This is reflected in findings that good writers are more strategic and knowledgeable than their poor writing counterparts. For example, good writers spend more time planning, and focus more of their attention on text-level concerns, than do struggling writers (Humes, 1983); better writers make more revisions than their less competent peers (Fitzgerald, 1987); and good writers are more knowledgeable than poor writers about the self-regulatory processes involved in composing (Englert *et al*., 1988).

These correlational findings are further buttressed by experimental studies showing that the performance of poor writers can be improved by providing them with procedural support designed to help them regulate specific writing processes. For instance, students with writing disabilities who were directed to use a simple procedure that ensured that each element of the revising process was activated and occurred in an orderly fashion made more and better revisions (De La Paz and Graham, 1997; Graham, 1997). Numerous studies have also demonstrated that the performance of poor writers can be bolstered by explicitly teaching them the types of planning, revising, and other self-regulatory strategies used by more skilled writers (Graham and Harris, 1994, 1996). Thus, an important consideration in preventing or overcoming writing difficulties is helping struggling writers master the cognitive aspects of composing.

Mathematical Processes

Introductory article

Martha W Alibali, University of Wisconsin, Madison, Wisconsin, USA

CONTENTS

Mathematical thinking in the domains of number, arithmetic and algebra involves both core concepts and procedural skills. Understanding how mathematical knowledge is acquired and used can inform the design of mathematics instruction.

INTRODUCTION

Many concepts and skills are involved in mathematical thinking and reasoning. This article reviews a subset of these concepts and skills in the areas of number, arithmetic and algebra, and considers some general issues relating to mathematical thinking and how it develops. In the first section, core concepts and skills in these areas will be introduced and briefly described. The second section will address mathematical problem solving, focusing on arithmetic and algebra. The third section will address the relationships between conceptual knowledge and knowledge of problem-solving procedures. The final section will consider instructional approaches and how they can be informed by knowledge of mathematical processes.

Mathematical reasoning involves many different types of knowledge structures. These knowledge structures have been conceptualized in different ways within different psychological theories. Many theoretical frameworks distinguish between declarative and procedural knowledge. Declarative knowledge is typically defined as knowledge of facts. In mathematics, facts such as '$3+8=11$' or 'a triangle has three sides' are examples of declarative knowledge. Procedural knowledge is typically defined as knowledge of actions and how they relate to goals. In mathematics, procedural knowledge is applied when finding solutions to problems, such as performing long division or constructing a geometrical proof. Some theoretical frameworks also identify conceptual knowledge as a particular type of declarative knowledge. Conceptual knowledge is typically defined as knowledge of principles and knowledge of links among other knowledge structures. For example, a child who is learning to count may understand the principle that each object to be counted must receive a single number tag. A slightly older child might learn the principle of additive commutativity. Some theoretical frameworks also identify schemas, which are larger knowledge structures that involve many interrelated pieces. An example of a schema is understanding of the place value system.

Different individuals may draw on different knowledge structures when performing mathematical reasoning tasks. For example, when performing multi-column subtraction with borrowing, children may rely on their conceptual understanding of place value to guide their performance. They might remember that they can exchange one ten for ten ones, and they might realize that doing so will allow them to perform the necessary subtraction in the ones column. Other children might rely on their procedural knowledge of the steps involved in borrowing. They might recall that the first step in the borrowing procedure is to put a slash through the digit at the top of the tens column. Finally, both sets of children will certainly need to access their declarative knowledge of arithmetic facts (e.g. '$14-6=8$') in order to complete the task.

It is important to understand mathematical processes and how they are applied in problem-solving situations, because this understanding can guide the design of effective instruction.

KEY MATHEMATICAL CONCEPTS AND SKILLS

This section will delineate some of the central concepts and skills in the domains of number, arithmetic and algebra.

Number Concepts and the Number System

Two foundational concepts in mathematical thinking are numerical quantities and the number system. One of the earliest steps towards understanding these concepts is learning the counting string and the counting procedure. Young children often make errors in implementing the counting procedure, such as skipping items and double-counting items. The significance of such errors has been a matter of great debate in the literature on cognitive development.

The debate concerns whether there are innate knowledge structures that guide young children's learning about counting. Some theorists have argued that infants are born with knowledge of core numerical principles (e.g. one-to-one correspondence), and that mathematical development is a process of fleshing out this knowledge. According to this view, young children's counting errors stem from difficulties in performing the counting procedure, and not from lack of understanding of core numerical principles. This view has gained support from recent research on infants' mathematical understanding, which has shown that very young infants can distinguish small numerosities from one another (e.g. 1 versus 2).

Other theorists have argued against the nativist position, claiming that infants and toddlers abstract mathematical knowledge from their experiences with counting and enumeration. According to this view, young children's counting errors indicate that they have not yet acquired the principle of one-to-one correspondence.

Regardless of whether some core of quantitative knowledge is innate, it is clear that social and cultural factors are extremely important in the development of counting skills, as well as in further developments in understanding the number system. The counting string and the structure of the number system are cultural constructions and, as such, they must be learned through experience.

Another early step in mathematical thinking is understanding the principle of cardinality, which is the idea that the final count term in a sequence indicates the quantity of the counted set. With the achievement of cardinality, the number words are no longer simply part of the string of count words, but they are linked to and begin to represent real quantities.

Knowledge of counting and cardinality is an entry point into learning about the number system more generally. During the early school years, children learn about the base-10 system, about fractions and decimals and about negative numbers. Each of these domains presents significant challenges for students' understanding.

There are many factors that influence children's acquisition of these fundamental numerical concepts. Explicit instruction is of course an important factor. However, many other more subtle factors may also be involved. One not-so-obvious source of variation in mathematical development is the way in which numerical concepts are expressed in language. There is evidence that the structure of the words used to name multi-digit numbers in different languages can promote or hinder children's understanding of the base-10 structure of the number system. Children who speak languages such as English that use irregular forms in the teens decade (e.g. 'eleven') have more difficulty learning to count than children who speak languages such as Chinese that use regular forms (e.g. 'ten-one').

Arithmetic Operations

Another fundamental building block of mathematical competence is arithmetic. In the elementary years, children acquire skills in the four basic arithmetic operations of addition, subtraction, multiplication and division. Children first acquire knowledge of addition and subtraction, based on their prior knowledge of counting. Later, they acquire knowledge of multiplication and division, building on their prior knowledge of addition and subtraction.

As with the domain of counting, there has recently been debate in the developmental literature about innate knowledge structures that may guide children's acquisition of knowledge of mathematical operations. Recent studies suggest that even young infants understand that addition makes quantities larger and subtraction makes quantities smaller. Furthermore, some studies suggest that young infants have skills in the exact addition of small quantities. In one experimental paradigm, infant participants watch objects being placed behind a screen. The infants look longer when the screen is lowered to reveal an impossible outcome (e.g. one object plus one object makes one object) than when the screen is lowered to reveal a possible outcome (e.g. one object plus one object makes two objects). Based on such data, some investigators have inferred that infants are capable of arithmetic operations on small numbers.

There is also clear evidence that young children can reason non-verbally about operations such as addition and subtraction before they can perform

such operations on quantities that are represented symbolically. For example, if a 3-year-old child observes an experimenter place two chips and then three more chips under a cover, that child may be able to produce a set of five chips to show the final amount. However, most 3-year-olds cannot yet solve symbolically presented number statements such as '$2+3=?$'.

The bulk of the research on children's knowledge of mathematical operations has focused on procedural aspects of skill in arithmetic computation. Children are often explicitly taught strategies for performing such computations, and they also sometimes invent strategies based on their knowledge of counting and the number system. Recent studies have documented variability in strategy use in arithmetic across ages, within ages and within individual children. For example, when developing skills for single-digit addition, children typically begin by counting fingers for each of the addends. A child using this strategy for the problem $2+5$ might hold up two fingers on one hand and five fingers on the other hand, and count '2, 3, 4, 5, 6, 7'. Eventually children discover that they can solve addition problems by counting from the larger of the two addends, regardless of its position in the problem. A child using this strategy for the problem $2+5$ might simply count '5, 6, 7.' For many children, multiple strategies exist in their repertoires at some points in time, and they apply these strategies adaptively depending on the characteristics of the particular problem that they are attempting to solve.

Skills in complex arithmetical operations are usually learned in school over a period of several years, and these skills involve many specific procedures and notational conventions. Students must learn the carrying procedure, which is applied in multi-digit addition and multiplication, the borrowing procedure, which is used in multi-digit subtraction, and other specialized notations and procedures that are used in multi-digit multiplication and long division. Underpinning all of these skills is the concept of place value, which represents a significant challenge for many students.

Children's difficulties with place value are revealed by their frequent use of so-called 'buggy' procedures in multi-digit arithmetic. For example, in multi-digit addition, students sometimes write two-digit sums beneath each column (e.g. $85+46=1211$). In multi-digit subtraction, students often subtract the smaller number from the larger one within each column, regardless of position (e.g. $230-198=168$). In multi-digit multiplication, students often fail to line up the intermediate products correctly (e.g. $26\times15=130+26=156$). A well-developed understanding of place value can help students to avoid and eliminate such buggy procedures. However, a deep understanding of place value is often elusive, even for older students, and buggy procedures often persist in students' arithmetic for years.

Algebraic Reasoning

Arithmetic operations involve manipulations of numerical quantities. In contrast, algebraic reasoning involves operating on unknown quantities and on general statements, which are often expressed in symbolic form. In a sense, arithmetic operates in the realm of concrete quantities, whereas algebra operates in the realm of abstract quantities.

There are several core concepts that are essential to algebraic reasoning, such as variable, expression, equation and function. Students often have substantial difficulties with these concepts because they cannot straightforwardly generalize their prior knowledge of arithmetic to algebra. In algebra, the operations are not computational as they are in arithmetic. In arithmetic, operations are performed on numbers and yield other numbers, whereas in algebra, operations are performed on algebraic expressions and yield other algebraic expressions. When learning algebra, students must learn to view symbolic expressions (including those that include several terms, such as $2x+3y+14$) as mathematical objects in and of themselves.

Learning algebra largely involves learning a new form of symbolic notation and learning skills for operating on this symbolic notation in order to solve problems. In the view of many students, learning algebra boils down to learning the 'rules' of algebraic manipulation. As will be described in more detail in the section on problem solving, many students have difficulty in applying these rules correctly, and their errors often arise from an incomplete grasp of the symbolic notation used in algebra and a weak or inaccurate conceptual understanding of algebraic manipulations. Students' understanding of algebra often centers on the problem-solving procedures themselves, rather than on understanding what the procedures mean and why they work. Some recent reform efforts in algebra instruction have attempted to address this issue by emphasizing the conceptual underpinnings of the symbolic notation and of algebraic manipulations.

In addition to solving problems, competence in algebra involves the ability to generate, reason with

and translate among different ways of representing mathematical information, including symbolic equations, graphs, tables and words. In order to translate among different representations, students must have skills both for comprehending the given representation and for producing the target representation. For example, in order to generate an equation to represent a story problem, students must be able to comprehend the story sufficiently well to understand the mathematical relationships embodied in it, and they must also be able to produce an equation that represents those mathematical relationships in the symbol system of algebra. These representational skills are also emphasized in some recent reform efforts in algebra instruction.

Briefly, algebraic reasoning involves concepts, skills and notational systems that differ in important ways from those used in arithmetic. A better understanding of the cognitive processes involved in the transition from arithmetic to algebra will help to guide the design of effective instruction.

MATHEMATICAL PROBLEM SOLVING

Mathematical problem solving can be defined as the use of mathematical knowledge to answer questions and reach specific goals. This section will first introduce the distinction between informal and formal problem-solving strategies, and then review research on the development of skills for solving story problems and equations.

Informal and Formal Problem-Solving Strategies

Formal problem-solving strategies are approaches to solving problems that involve operating on mathematical symbols (e.g. numbers, variables, expressions or equations) and using procedures that were historically developed for operating on such symbolic representations (e.g. isolating the variable, factoring). Such strategies are specific to mathematics, and they tend to be learned in school or from other people.

Strategies that do not meet these criteria are termed informal strategies, and there are several different types of strategies that fall into this category. Some informal strategies are based on general approaches to problem solving that can be applied to mathematical content, but that are not specialized for mathematics (e.g. guess and test). Other informal strategies involve operating on representations that are not mathematical symbols (e.g. counting on one's fingers in order to add). Still other informal strategies involve operating on mathematical symbols in non-standard or 'shortcut' ways. Informal strategies often rely on an intuitive understanding of quantities and mathematical relationships. For example, when applying the guess and test strategy, people typically begin by estimating an approximate initial solution, and then iterate from that starting point. Many informal strategies are invented rather than taught in school.

The distinction between formal and informal strategies is not absolute, and blends of informal and formal approaches are often evident in people's attempts to solve mathematical problems.

Solving Story Problems

Both informal and formal strategies are evident in people's approaches to solving story problems. Story problems (sometimes called word problems) are defined as problems that present a story scenario in words and then pose a question about the mathematical content of the story. A simple example of an arithmetic story problem is the following. 'Jack had three cookies, and his mother gave him five more. How many cookies does he have altogether?'. A simple example of an algebraic story problem is the following. 'Margaret is saving her money for a bicycle that costs $400. She has already saved $140, and she can save $20 more each week from the money that she earns on her paper route. For how many more weeks will Margaret need to save before she can buy the bicycle?'. These two example stories will be used to illustrate students' approaches to story problems.

To solve a story problem successfully, the solver must comprehend the presented story and then use the mathematical information provided in the story to obtain a solution to the question that is posed. In the arithmetic example, this involves identifying the initial quantity (3), the quantity to be added (5) and the final or goal quantity (the total), and understanding that Jack's mother giving him cookies involves an additive relationship. In comprehending the problem, the solver may also access previously stored schemas that apply to particular types of story situations. The arithmetic problem presented above is an instance of a 'change' schema, which involves changing a set of objects from an initial state to a final state by applying some kind of transformation (in this case, adding more cookies).

Once the story is understood, a solver might attempt to reach a solution by using an informal strategy, such as counting out three fingers and then five fingers, and then enumerating the entire set of eight fingers. Alternatively, the solver might

attempt to reach the solution by using a more formal approach, namely retrieving the addition fact $3 + 5 = 8$.

In the algebraic example, comprehending the story is considerably more complex. It involves identifying the total quantity ($400), the starting quantity ($140) and the quantity to be added per unit of time ($20). Furthermore, it involves understanding that the total quantity is the sum of the starting quantity and the increments to be added, and understanding that the unknown quantity is the number of increments (i.e. the number of units of time) needed to reach the goal. Depending on the novelty and complexity of the story, the solver may either comprehend the problem with the aid of a previously stored schema, or construct a mental model of the problem situation 'from scratch'.

Once the story is understood, the solver might attempt to reach a solution by using an informal strategy, such as starting from $140 and repeatedly adding $20 until the goal of $400 is reached, while keeping track of the number of increments added. Alternatively, the solver might attempt to reach the solution by using a formal strategy, namely setting up an equation such as $140 + 20x = 400$, and solving for the unknown value x by using algebraic manipulation.

As these examples indicate, problem solvers can encounter difficulties at many different points in the process of solving story problems, and this contributes to the commonly held view that story problems are extremely difficult to solve successfully. Indeed, many people consider story problems to be more difficult to solve than corresponding symbolic problems that involve exactly the same mathematical relationships. For example, the above story problem about Margaret saving for a bicycle is thought by many people to be more difficult than the corresponding equation $140 + 20x = 400$. This is because story problems presumably involve the added difficulty of 'translating' the story scenario into a symbolic representation.

Indeed, if solving a story problem involves all of the same steps as solving the corresponding symbolic problem, plus the additional steps involved in translating to the symbolic representation, then solving the story problem must necessarily be more difficult than solving the corresponding symbolic problem. However, the above discussion should make it clear that solvers do not always solve story problems by translating to a symbolic representation and then using a formal strategy. Instead, people often use informal strategies to solve story problems, and such strategies tend to be highly successful. Story problems can actually be easier to solve than the corresponding equations, because they support the use of effective informal strategies. This is especially true of story problems that involve familiar content, because familiar content allows children to draw on their real-world knowledge of situations like those described in the stories.

Solving Equations

As noted above, students often successfully solve story problems using informal methods before they can solve the corresponding equations. Clearly, then, it is not the mathematical relationships *per se* that are challenging for students, but rather the formal symbol system in which these mathematical relationships are expressed. In particular, students often have great difficulty in generating symbolic expressions to model or represent situations mathematically. Learning the symbol system of mathematics seems to be akin to learning a foreign language and, by this analogy, expressing mathematical relationships in symbolic notation is similar to speaking or writing in a foreign language.

If students have difficulty in generating and understanding symbolic expressions, it should come as no surprise that they also experience difficulty in solving equations. One symbol that poses particular difficulties, both in the early grades and throughout middle school, is the 'equal' (=) sign. Students often interpret the equal sign as meaning 'the total' or 'get the answer', and they do not understand that it expresses a relationship between two quantities. Such students are said to have an 'operational' rather than 'relational' understanding of the equal sign. The roots of this misconception are likely to be in the types of contexts in which students encounter the equal sign during the early elementary years. Students most often see the equal sign in equations such as $7 + 4 = \square$, in which the equal sign comes at the end of the equation and precedes the symbol that is to be filled in with the solution. Hence students infer an inappropriate meaning for the equal sign, and consequently they tend to have difficulty in correctly solving nonstandard problems such as $4 + 8 + 6 = \square + 6$. It is easy to see how such a misconception could be adaptive (or at least not particularly problematic) in arithmetic contexts, but could lead to serious difficulties in the transition to algebra. Indeed, it is difficult if not impossible to integrate the idea of 'do the same things to both sides of the equation' with a conceptualization of the equal sign as meaning 'get the answer'.

A great deal of research has focused on students' acquisition of procedural skills for solving

algebraic equations. These studies have shown that structural features of equations have an important influence on students' performance and learning. Not surprisingly, equations that involve multiple operations (e.g. $4x - 20 = 43$) are more challenging than equations that involve a single operation (e.g. $4x = 63$). In addition, start-unknown equations (e.g. $2x + 30 = 44$) are more challenging than result-unknown equations (e.g. $2 * 7 + 30 = x$).

Students sometimes use rules for algebraic manipulation inappropriately, and they sometimes use incorrect rules. For example, when solving equations such as $3x + 15 = 36$, many students incorrectly apply the rule that states 'do the same thing to both sides' by doing the same thing to both sides of the plus sign. In this example, such a student might (inappropriately) divide both $3x$ and 15 by 3, yielding $x + 5 = 36$. Students also have difficulty with the order of operations rule, and they tend to have special difficulties with problems in formats such as $12 + 3x = 30$, which seem to 'invite' simplification to $15x = 30$. These types of procedural errors are often due to a poor conceptual understanding of the symbol system of algebra and of the meanings of algebraic manipulations. One strand of current research on algebraic reasoning focuses on understanding the conceptual basis for such procedural misapplications.

RELATIONSHIPS BETWEEN CONCEPTUAL AND PROCEDURAL KNOWLEDGE

Mathematical competence involves both conceptual and procedural components, and for optimal performance to be achieved, conceptual knowledge and procedural knowledge need to be well integrated. A great deal of the literature on mathematical development has focused on the relationships between these two types of knowledge. In many domains there has been significant controversy over whether conceptual knowledge precedes and sets the stage for procedural skill, or whether procedural knowledge provides the basis from which conceptual knowledge is induced or abstracted. This section will review the evidence for different temporal and causal relationships between conceptual and procedural knowledge.

Evidence that Procedural Knowledge Precedes Conceptual Knowledge

In some domains there is evidence that students acquire procedural skill before they develop conceptual knowledge. For example, in the domain of counting, several studies have shown that children can count accurately before they understand important principles that govern counting, such as (1) the one–one principle, which holds that each item must receive one and only one number tag, (2) the order-irrelevance principle, which holds that the order in which items are counted does not matter, and (3) the cardinality principle, which holds that the tag that is applied to the final item in a counted set represents the number of items in that set. In several studies, children's understanding of principles has been ascertained by asking them to evaluate the counting performance of a puppet. This technique minimizes performance demands, so that children can reveal the knowledge that they possess, even if they are unable to apply it to their own actions. These studies have shown that 3-year-old children who can execute the counting procedure properly do not always judge the puppet's violations of the one–one and order-irrelevance principles to be incorrect. Thus accurate counting precedes understanding of the one–one and order-irrelevance principles. Furthermore, most 3-year-old children are unable to predict the outcome of counting a row of objects from left to right, even if they have just counted it from right to left. Thus accurate counting also precedes understanding of the cardinality principle. In general, evidence from counting suggests that procedural skill precedes conceptual knowledge.

Students often apply procedural skills from one mathematical domain to solve problems in a related mathematical domain. For example, students often apply their procedural knowledge of whole number multiplication when learning to solve fraction multiplication problems. In such cases, children's procedural skill in the new domain can outstrip their conceptual knowledge in that domain. For this reason, many children can successfully multiply common fractions before they understand key fraction concepts. In general, children tend to display procedural skill before conceptual knowledge whenever they can induce the target procedures from an analogous procedure in a related domain. In such cases, procedural skill provides a basis for the development of conceptual knowledge.

Evidence that Conceptual Knowledge Precedes Procedural Knowledge

In some domains, students possess substantial conceptual knowledge before they acquire procedural skill. This conceptual knowledge is sometimes manifested in correct qualitative reasoning that

precedes the use of accurate problem-solving procedures. For example, there is evidence that young children understand the effects of arithmetic operations in qualitative terms (i.e. addition makes quantities larger and subtraction makes quantities smaller) before they are able to perform arithmetic computations successfully. Similar patterns have been found in older children with regard to proportional reasoning problems (e.g. story problems about mixing containers of water of different temperatures). Children understand the problems in qualitative terms (e.g. the final temperature must change in the direction of the water that was added) before they use correct procedures to actually solve the problems. This qualitative understanding may form the basis for their learning – or discovering – correct procedures.

There is also evidence that children understand certain mathematical principles before they capitalize on these principles in their problem-solving strategies. For example, children have been shown to understand additive commutativity (i.e. addend order does not matter in addition problems, such that $a + b = b + a$) before they reliably use the count-from-larger-addend procedure to solve single-digit addition problems. Some researchers have argued that children's understanding of such principles develops from their interactions with physical objects in the world, and that this understanding is gradually abstracted and applied to mathematical objects. In general, it seems likely that everyday experiences provide a basis for certain intuitive mathematical understandings, and that over historical time these intuitive understandings have been formalized in mathematical notations and procedures. Thus it is not surprising that in individual development, formal procedural skills often build on prior conceptual understanding.

Evidence that Procedural Knowledge and Conceptual Knowledge Develop Iteratively

Of course, the best answer to the question of 'which comes first' seems to be either 'both' or 'it depends'. In some cases, procedural skills are acquired first and form the basis for later achievements in conceptual understanding. In other cases, substantial conceptual knowledge appears to be present before procedural skills are learned. Recent studies have shown that the links between conceptual and procedural knowledge are bidirectional, in the sense that gains in either form of knowledge lead to corresponding gains in the other. Children who learn new problem-solving strategies often display gains in conceptual understanding, and children who learn new concepts often generate new problem-solving strategies. It seems likely that, in most cases, conceptual and procedural knowledge develop in a hand-over-hand fashion, with gains in one type of knowledge leading to gains in the other, which then feed back to influence the first.

It is clear that children's experiences at home and at school have an important role in shaping the developmental relationships between conceptual and procedural knowledge. If children's environments provide frequent experience of relevant concepts, their conceptual knowledge may outstrip their procedural skill. Alternatively, if their environments allow them the opportunity for extensive procedural practice, the reverse pattern may obtain. Among children's mathematical experiences, instruction is an especially powerful influence on mathematical thinking.

INSTRUCTIONAL APPROACHES

Mathematics instruction brings together the psychological study of mathematical thinking and learning (from both developmental and cognitive science perspectives), the study of classroom teaching and the discipline of mathematics itself. This section will briefly consider two broad aspects of mathematics instruction, namely cognitively based approaches to instruction and sociocultural influences on instruction.

Cognitively Based Approaches to Mathematics Instruction

Ideally, approaches to mathematics instruction should be informed by what is known about mathematical thinking and reasoning processes. However, the gap between psychological theories and classroom practices can be difficult to bridge. The scope of psychological analyses is sometimes too narrow and the grain size at which behavior is examined is sometimes too small for psychological findings to have immediate or direct applicability in instructional settings. For example, the study of buggy algorithms in children's multi-digit subtraction has led to a catalogue of common bugs, which can account for a large proportion of students' errors. However, is such information useful for teachers? Is it desirable or even practicable for teachers to attempt to diagnose and repair individual students' buggy procedures? Instruction that is aimed at remediating specific bugs might lead to improved student performance, but such instruction would seem to miss the target of

fostering deep, generalizable mathematical understanding.

It seems clear that a psychological perspective has the potential to inform mathematics instruction. However, for this potential to be realized, the broader implications of the psychological findings must be considered. To take the buggy subtraction example a step further, the detailed analysis of children's buggy procedures points to specific difficulties with the concept of place value that can themselves be addressed explicitly in instruction. Furthermore, if teachers know more about students' thinking, they may be better able to capitalize on students' errors as instructional opportunities. For example, a student's error in borrowing across zero might provide an excellent opportunity for a teacher to reiterate or unpack the concepts of place value and additive composition. In this way, teachers' actions may mediate the way in which knowledge of mathematical processes informs classroom practice.

Cognitive analyses of student thinking can also be a starting point and a source of ideas for curricular innovations. However, one cannot simply assume that the same processes that are involved in mathematical reasoning in experimental settings are also involved in reasoning in the classroom. The classroom is a unique sociocultural environment, and various aspects of the classroom setting may influence performance in unanticipated ways. Thus it is important that new instructional techniques be tested empirically. Evaluation is a key dimension of the process linking research on cognitive processes to mathematics instruction.

Sociocultural Influences on Mathematical Instruction

In recent years, increasing research attention has been focused on the sociocultural context of mathematics learning, both at the level of individual classrooms and at the level of the broader culture within which those classrooms are located.

The culture of each individual classroom has a profound effect on the types of mathematical learning and thinking that take place within it. Many aspects of classroom culture are significant, including the types of activities that are engaged in, the value that is attached to students' informal knowledge and invented strategies, the opportunities for social interaction and communication, and the nature of the mathematical discourse that takes place. These dimensions of classroom culture are in turn shaped by the goals, values and philosophies of the classroom teacher(s) and of the broader social structures within which the classrooms are situated (e.g. departments, schools and school districts). Textbooks also play an important role in shaping classroom culture, in part through their influence on teachers' goals and values.

At a broader level, teaching practices are also shaped by cultural norms. Recent cross-national comparisons of teaching practices have documented important differences in mathematics instruction between Japan, China, Germany and the USA. These differences cut across many aspects of lesson structure and content. For example, American lessons include more seatwork and less whole-class discussion than Japanese and Chinese lessons, and American teachers pose more factual questions and fewer conceptual questions than do Japanese teachers. These broader cultural norms shape the opportunities for learning and thinking that occur in individual classrooms within each culture.

At an even broader level, the presence or absence of a national curriculum in mathematics has an important influence on mathematics instruction. Most industrialized nations have a national curriculum. However, the USA is a notable exception. In countries with a national curriculum, there is relatively little variation across schools and across classrooms in the amount of time spent on mathematics, the specific topics covered and the level of difficulty of the implemented curriculum. In contrast, in countries without a national curriculum, there can be important differences in these dimensions across school districts and even within individual schools.

Mathematics learning is shaped by the sociocultural context at many levels, from the individual interactions of the student and the teacher, to the values and practices that constitute the classroom culture, to the national norms for the content and structure of mathematics instruction. A complete understanding of mathematical processes will require an understanding of how these layers of sociocultural context influence one another, and how they together influence mathematical thinking and learning.

SUMMARY

Understanding mathematical thinking involves identifying core concepts and skills and specifying how they develop and how they are interrelated. This article has focused on central concepts and skills in the domains of number, arithmetic and algebra. Studies of problem solving in these domains have revealed that people do not always solve mathematical problems using formal

mathematical procedures, which are typically learned in school. Instead, people often use informal strategies which rely on their intuitive mathematical knowledge.

Studies have also shown that knowledge of concepts and knowledge of problem-solving strategies can be related in different ways. In some cases, conceptual knowledge is acquired first and forms the basis for later learning of procedural skill. In other cases, procedural knowledge is acquired first, and conceptual knowledge is abstracted from procedures. Specific patterns depend on children's experiences with the relevant concepts and procedures, both at home and at school.

Instruction is a powerful force for shaping mathematical knowledge. The links between instructional practices and research on mathematical thinking are not always direct or obvious. However, there are many ways in which studies of mathematical thinking can inform the design of mathematics instruction for classroom settings.

CONTENTS

Memory can be defined as the mental storage of information and the processes involved in the acquisition, retention, and retrieval of that information.

INTRODUCTION

There are few things as pivotal to cognition as memory. Memory serves as the center stage around which both more elementary (e.g. encoding, categorization) and more elaborate (e.g. reasoning, problem-solving) forms of cognition revolve. Any application of cognitive science research to education must entail an examination of memory. This is particularly true when dealing with the education of children, who vary considerably in their memory abilities, depending on their developmental level. This article first provides a brief overview of several aspects of children's memory development. Second, it focuses on the role of two key components of memory development: strategies (middle section) and knowledge (final section). In the discussion of knowledge, we refer to how (1) expertise in a particular domain (knowledge base), and (2) a knowledge of the workings of one's own memory (metamemory) affect children's memory performance. However, as we will see, children's memory is influenced by a host of interacting factors and will vary depending on the context and the purpose to which 'memorizing' is put. (*See* **Memory, Development of**)

DEVELOPMENT

It's a fair question to ask 'When does memory begin?' Human infants at birth (and even before) are able to learn simple associations, indicating the presence of a functioning memory system (see DeCasper and Spence, 1986). By six months of age, babies can experience an event (the face of an unfamiliar person, for example), and remember that event later, as determined by the amount of time they look at that face versus a completely novel one (Fagan, 1974). Such memory performance increases over infancy, but is this the type of memory that typifies older children's cognition, especially in a school-related context? As we will see in the next section, memory is not a unified phenomenon. Rather, different types of memory or memory systems have been proposed that follow different developmental paths, and it seems that the type of memory displayed by infants is qualitatively different from that displayed by older children. One very basic, and primary, distinction in types of memory is that between implicit and explicit memory. (*See* **Memory: Implicit versus Explicit**)

The Development of Implicit and Explicit Memory

Cognitive scientists typically make a distinction between *implicit*, or *procedural memory* (sometimes known as *nondeclarative memory*) and *explicit*, or *declarative memory*. Implicit memory refers to memory without awareness, and is reflected in memory for routinized skills (i.e. procedural memory), priming, and classical and operant conditioning. Explicit memory refers to memory with awareness, or the conscious recollection of events. Explicit memory is composed of two different types of interacting systems, *episodic* and *semantic* memory. Episodic memory corresponds to a person's record of past experiences, specifically recollections that can be situated at a particular place or time. In contrast, semantic memory refers to our world knowledge, that is, knowledge of language, rules, and concepts (Tulving, 1985).

We believe that a majority of researchers would agree that the type of memory displayed by infants in conditioning and visual recognition tasks

involves implicit, and not explicit, processes. However, there is evidence for *deferred imitation* in infants and toddlers and a suggestion that this requires the long-term retention of explicit (self-aware) memories (Meltzoff, 1995). In these studies, infants watch as an experimenter demonstrates some novel behavior with an unfamiliar toy. At some later time, the infants are given the toy. If they display the novel behavior more than a control group of infants who had not previously been shown the toy, it implies they formed a long-term memory for the action they had only observed. The results of recent research reveal deferred imitation for simple actions in infants as young as nine months of age, with babies retaining these memories for as long as one year (Bauer and Wewerka, 1995). (*See* **Infant Cognition**)

But is such memory necessarily explicit? One source of evidence suggesting that it is comes from neuropsychological research examining deferred imitation in a sample of brain-damaged adults who were unable to acquire new explicit memories but could form new implicit memories (McDonough *et al*., 1995). McDonough and her colleagues (1995) administered declarative memory tasks and deferred-imitation tasks, similar to those passed by one-year-old toddlers, to a group of amnesics. The brain-damaged adults failed both sets of problems, suggesting that the same type of memory system that underlies explicit memory, as reflected by free recall and recognition memory tasks, also underlies deferred imitation and is functioning, at least in rudimentary form, by the beginning of the second year of life. (However, it should be noted that some researchers have argued that implicit and explicit memory do not actually represent different memory systems and are both available in the first year of life: see Howe, 2000; Rovee-Collier *et al*., 2001).

Although the explicit memory system may be functioning early in life, it goes through substantial development over the course of childhood. For example, three- and four-year-old children are able to recall many specific details of daily events, but they generally recall less information and require more prompts to do so than older children (Fivush, 1997). This is in contrast to implicit memory, which shows smaller age-related changes over time (e.g. Perez *et al*., 1998). For instance, in some studies children are asked to identify fragmented pictures (e.g. an umbrella). This is initially very difficult, but it becomes increasingly easier as more of the picture is provided. After completing a series of such picture-identification tasks, children are shown fragmented pictures of both previously seen and unseen objects. The typical finding is that children identify fragmented pictures of previously seen objects significantly faster than fragmented pictures of previously unseen objects, despite the fact that they may not remember (explicitly) seeing those pictures before (e.g. Hayes and Hennessy, 1996). Moreover, age differences on these tasks, and other implicit tasks (e.g. Anooshian, 1997), are typically small or nonexistent. That is, young children display memory without awareness that is superior to their explicit memory, with little age difference in levels of performance. (*See* **Working Memory**)

The Development of Working Memory

When we use the term 'memory' we often do so to refer to the long-term retention of information or to the recall of 'memories' from the distant past. But 'memory' can also refer to the relatively brief retention of small amounts of information, and developmental and individual differences in this ability, referred to as *working memory*, can greatly influence people's performance on a wide range of cognitive tasks. More specifically, working memory refers to the resource-limited mental space where active thinking occurs. In some tests of working memory, participants remember a series of items in exact order, but they are embedded in an additional task in which they must transform the target information. For instance, children may be given a set of sentences for which they must add the final word (e.g. 'In the winter it is very _____'). After hearing a series of such sentences, they are asked to recall the final word from each sentence in the order they were presented (Siegel and Ryan, 1989). In general, working-memory tasks show regular improvements with age. A similar pattern is also found for *memory span* tasks, in which children are asked only to recall in exact order a list of items without the additional cognitive 'work'. Performance on the less mentally arduous memory span tasks is typically about two items greater than on comparable working-memory span tasks.

Although these results give the impression of an increase in the absolute capacity of working memory with age, there is evidence that how much children know and how quickly they can access and articulate the stimuli plays a role in tests of working memory (Gathercole, 1998). For example, children who are experts at chess show greater memory for positions on a chess board than do nonexpert adults, despite the fact that adults have greater memory spans for digits (e.g. Chi, 1978). This and other research (e.g. Dempster, 1985) suggests that one reason for older children's

greater working memories relative to younger children's is their greater knowledge base – they know more than younger children do about most topics, which permits them to retain more information in working memory. This is critical, in that performance on working-memory span tasks is related to performance on a host of more complex cognitive tasks, including reading, mathematics, and IQ (e.g. Siegel and Ryan, 1989).

The speed with which children can articulate the words they must remember also influences memory span, with younger children generally requiring more time to articulate the stimulus words than older children, and as a result, having shorter memory spans (e.g. Hitch and Towse, 1995). One interesting implication of this is that digit words (e.g. 'one', 'two', 'three', and so on) in different languages are articulated at different rates, which contributes to cultural differences in digit span. For instance, digit words in Chinese can be articulated more rapidly than the corresponding words in English and this difference, which is found as early as four years of age, accounts for the greater digit spans of Chinese relative to American children (Geary *et al*., 1993). This suggests that one reason for the superior mathematics performance shown by young Chinese relative to American children may be the faster rate that number words can be articulated in the Chinese language.

Although factors such as knowledge base and speed of processing may influence performance on memory span tasks, there is evidence that age differences in how much children and adults can apprehend during a brief period serve as the foundation for performance on these tasks. For example, Cowan *et al*. (1999) evaluated age differences in the *span of apprehension*, which refers to the amount of information that people can attend to at a single time or the number of items that people can keep in mind at any one time. Span of apprehension can be assessed only when factors such as focused attention, knowledge of the target items, and encoding strategies are eliminated. Cowan and his colleagues (1999) had seven- and 10-year-old children and adults play a computer game while they heard a series of digits presented through earphones but which they were told to ignore. Participants were occasionally and without warning asked to recall, in exact order, the most recently presented set of digits they had heard. Because participants were not attending to the digits, it is unlikely they were using any strategies to remember them, making the task an appropriate one for assessing span of apprehension. Cowan and his colleagues reported that the average span of apprehension increased significantly with age, and they interpreted these results as reflecting a true developmental difference in the capacity of the short-term store. (*See* **Memory Mnemonics**)

STRATEGIES

Despite the limits of our working memory, people, including children, frequently retain large amounts of information for long periods of time. To do this often requires 'higher-order' cognitive processes, among them the use of memory strategies. *Strategies* refer to deliberate mental operations that are aimed at solving problems. The development of intentional cognitive control is an important question, both theoretically and practically, and the development of memory strategies lies at the center of this key issue in cognitive development.

Children are rarely fully strategic before six years of age. Although preschool children will behave strategically in some contexts (Bjorklund and Douglas, 1997), their strategies are rarely as complicated and effective as those used by older children. Effective memory strategies typically begin to develop between seven and 13 years of age, often under the tutelage of parents, teachers, or older peers. Rehearsal is an early-used strategy, although children usually adopt a 'passive' style (i.e. repeating one word at a time), and only later use the more 'active' and effective cumulative style of rehearsal (i.e. rehearsing several different words at one time: Ornstein *et al*., 1975). Young children can be easily induced to use a simple organizational strategy (e.g. to recall categorically related items together), but typically do not do so on their own until eight or nine years of age or older (Bjorklund and Douglas, 1997).

Mediational, Production, and Utilization Deficiencies

Strategies, unlike other aspects of memory development, do not always develop 'spontaneously', but sometimes require explicit instruction. The extent to which children can and do benefit from strategy instruction led to the discovery of two types of 'deficiencies': (1) *mediational deficiency*, in which children are not able to use a strategy even when one is demonstrated to them, and (2) *production deficiency*, in which children who do not use a strategy spontaneously do so when instructed and display improved task performance as a result. Most strategy development research through the 1980s was concerned with production deficiencies (mediational deficiencies have actually received

relatively little research attention), with the *training study* being the workhorse of researchers. Basically, the logic went, if we can train children to use and benefit from a strategy, we not only demonstrate that children have the underlying conceptual ability to execute the strategy, but we can learn important things about development by carefully controlling the factors we manipulate in training.

A third type of deficiency has only recently been identified (Miller, 1990). A *utilization deficiency* occurs when children use a strategy but garner little or no benefit from it. The existence of utilization deficiencies questioned the canonical interpretation of the strategy development literature – that strategy use was directly responsible for increasing memory performance. And utilization deficiencies were not rare occurrences: Miller and Seier (1994), in a review of 30 years of research, reported strong or partial evidence of utilization deficiencies in more than 90 percent of all experiments examining children's spontaneous use of memory strategies; evidence of utilization deficiencies was similarly found in more than 50 percent of memory training studies conducted over a 30-year period (Bjorklund *et al*., 1997).

Explanations for utilization deficiencies center around the fact that implementing strategies consumes too much of children's limited mental capacity, and, as a result, they do not have sufficient resources remaining to devote to the actual retrieval of items from memory. Other possible reasons for utilization deficiencies are that children are not aware that the strategies are not improving their performance, and that new strategies are used for the sake of novelty, without consideration for their consequences. The end result may be adaptive. As the novelty wears off, the strategy becomes less effortful to execute (as a result of repeated use), resulting in eventual memory benefits (Miller and Seier, 1994).

Multiple and Variable Strategy Use

Despite the presence of the various strategy deficiencies, children's memory strategies do increase in frequency and effectiveness with age. However, recent research has shown that children do not necessarily replace simple and inefficient strategies with more complicated and efficient ones in a stage-like fashion. Rather, children of all ages have a variety of different strategies available to them, with these strategies 'competing' for use (Siegler, 1996). Over time, children's modal strategies increase in sophistication, but they exist alongside less sophisticated strategies that are occasionally used when the more advanced strategy doesn't quite do the job. From this perspective, there is much variability in a child's strategy use, with this variability representing an important component of strategy development and not simply random 'noise'.

Children's multiple and variable strategy use has been demonstrated for a wide variety of tasks (see Siegler, 1996, for a review), including memory. For example, Coyle and Bjorklund (1997) gave second-, third-, and fourth-grade children a series of five sort–recall trials, using different sets of categorically related words on each trial. Children were allowed to study the words during a two-minute study period prior to each trial, during which several study strategies were observed: sorting cards into groups, category naming, and rehearsing. Above-chance levels of clustering (remembering categorically related words together) during recall were also assessed as a fourth strategy. Coyle and Bjorklund reported that children of all ages used multiple strategies on most trials, although mean number of strategies used per trial increased with age. Within an age level, children who used more strategies on a trial generally recalled more words. Children of all ages also showed substantial (and comparable) variability in strategy use, frequently switching strategies between trials. When looking at the relation between variability and recall, no consistent pattern was noted for the second- and third-grade children. However, fourth graders showed significant, although moderate, negative correlations between recall and strategy variability. That is, the more stable the fourth-grade children were in their strategy use, the higher their levels of recall tended to be. In related research, gifted second- through fourth-grade children were found to use multiple strategies as frequently as nongifted children, but recalled more words per trial and displayed lower levels of strategy variability than their nongifted peers (Coyle *et al*., 1999). Moreover, strategy variability was more consistently (and negatively) related to recall for the gifted than the nongifted children. This research points to consistent relations between multiple strategy use, strategy variability, and memory performance, making it clear that variability on cognitive tasks is more than just 'noise'.

KNOWLEDGE

Domain Knowledge and Expertise

Since the late 1970s, there has been increasing evidence for the striking effects of domain knowledge on performance in many memory tasks.

For example, several researchers have proposed that age and individual differences in children's *knowledge base* account for more of the variance in strategic memory performance than any other factor (e.g. Hasselhorn, 1995). Bjorklund (1987) proposed that having an elaborated knowledge base can affect memory in at least three ways: (1) by increasing the accessibility of specific items; (2) by making relatively effortless the activation of relations among sets of items; and (3) by facilitating the use of deliberate strategies. For example, in one line of research children were asked to recall the current members of their school class (Bjorklund and Zeman, 1982). Levels of recall were high and most children recalled their classmates' names systematically by seating arrangement, reading groups, or sex of child. Yet, there was little relation between degree of strategy use and how much children remembered. And in a later experiment when children were required to recall their classmates by a specified category (sex of child or seating arrangement), six-, eight-, and 10-year-old children did so almost perfectly, but recalled no more names than children who organized their recall less well (Bjorklund and Bjorklund, 1985). For these children, it seems, most of their elevated level of recall was attributed to nonstrategic factors associated with an elaborated knowledge base. (*See* **Knowledge Representation, Psychology of**)

The effects of knowledge on memory performance are perhaps best illustrated when children are 'experts' in a given domain such as sports, music, or science (for a review, see Schneider, 2001). For instance, Schneider, Körkel, and Weinert (1989) presented about 500 third-, fifth-, and seventh-grade children with a story about a soccer game, with the participants classified as soccer experts or novices. The expected differences between experts and novices were especially evident in the recall and comprehension of the soccer-related passage. A reversal of the typical developmental trend was observed in that third-grade experts recalled significantly more text units than both fifth- and seventh-grade novices. Moreover, there were also qualitative differences in the way experts and novices recalled the text. Whereas experts of all ages recalled more important than unimportant aspects, the soccer novices recalled as much important as unimportant text information, regardless of age. Thus performance differences between experts and novices can be attributed to both quantitative and qualitative differences in information processing. (*See* **Expertise**)

Interestingly, rich domain knowledge further compensated for low overall aptitude: when the samples of experts and novices were further subdivided into subgroups of high- and low-aptitude children, there were no significant effects found for psychometric intelligence. This finding is in accord with basic assumptions of the 'deliberate practice' model of expertise acquisition developed by Ericsson and colleagues (e.g. Ericsson, 1996). According to this model, the extent and intensity of practice during childhood and adolescence determines the level of expertise eventually reached later in adulthood. Thus levels of expertise seem to depend more on noncognitive factors such as motivation and endurance than on cognitive variables such as IQ.

The developmental studies on expertise discussed above have all demonstrated the rapid development of domain-specific knowledge in child experts and its close relationship to performance in the domain of interest. Domain knowledge also contributes to the development of other competencies that have been proposed as sources of memory development, such as basic capacities, memory strategies, and metacognitive knowledge (Schneider, 2001). Accordingly, it seems evident that changes in domain knowledge play a large role in memory development.

Metacognitive Knowledge

Although differences in content knowledge, such as those that distinguish experts and novices within a particular domain, account for substantial differences in memory performance, so also does knowledge of the workings of one's memory. Memory research using a variety of materials (e.g. categorized words, texts) has consistently demonstrated that frequent experience with tasks and materials increases children's knowledge about how to proceed in order to be effective. For instance, when children are repeatedly asked to do the kind of sort–recall task described earlier, they slowly develop an understanding of the importance of strategies such as sorting, rehearsal, and self-testing for successful performance (Bjorklund and Douglas, 1997). Children's knowledge about memory has been labeled *metamemory* (Flavell and Wellman, 1977). There are two general types of metamemory, *declarative* and *procedural*. Declarative metamemory refers to the explicit, conscious, and factual knowledge concerning person and task characteristics and memory strategies. Procedural metamemory refers to *memory monitoring* and *self-regulation* of memory behavior during ongoing memory activities. For instance, realizing that one does not learn a list of items fast enough to

reach the goal of perfect recall within a reasonable time limit constitutes an example of memory monitoring. Replacing a suboptimal learning strategy by a more effective one could be a self-regulation measure well suited to solving this problem. (*See* **Metacognition**)

Empirical research exploring the development of declarative metamemory has shown that children's knowledge of facts about memory increases considerably over the primary-grade years but is not complete by the end of childhood. Improvements in declarative metamemory are typically correlated with age-related increases in memory behavior (see Schneider, 1999, for a recent review). The average correlation between metamemory and memory performance is of moderate size (about 0.4) and increases with age.

On the other hand, developmental trends in procedural metamemory are not similarly clear. Although findings are not consistent, there is evidence that basic monitoring skills are already well developed in kindergarteners and young schoolchildren and do not improve much later on. It appears that developmental trends in procedural metamemory are mainly due to age-related increases in the interplay between monitoring and self-regulation skills. That is, whereas young schoolchildren may well be able to monitor a memory problem during a given task, only the older schoolchildren act accordingly and use self-regulation strategies in order to overcome the problem. For instance, when the task is to learn easy and difficult word pairs, both younger and older schoolchildren are able to identify the difficult pairs. However, only the older children will use this information to allocate their study time accordingly; that is, to devote more time to the study of difficult items (cf. Schneider, 1998).

CONCLUSION

Memory is not a single phenomenon, but reflects a host of related mechanisms that develop over time and are used to navigate the social and physical worlds humans inhabit. Memory is at the center of cognition for all people in all cultures. But an understanding of memory and its development becomes especially important in technological societies, where formal school requires the retention of information and techniques of remembering that would be foreign to our ancient ancestors.

Scientific Thinking

Intermediate article

Rosemary A Rosser, University of Arizona, Tucson, Arizona, USA

CONTENTS

Scientific thinking – both domain-general and domain-specific aspects of it – is a model of rationality, everyday thinking, and cognitive development.

INTRODUCTION

Why would cognitive scientists be interested in studying scientific thinking? For a number of reasons, some of them more obvious than others.

First, the reasoning behind the scientific enterprise represents an impressively high level of complexity, involving discovery, innovation, problem-solving, and intellectual creativity. Additionally, the products of scientific thought have had such great value to humankind that the cognitive processes responsible for those products are important as well as inherently interesting (Klahr, 2000). In fact, scientific thinking has become the standard for rational thought, and seeking to understand rationality is what cognitive scientists do (Stanovich, 1999).

Second, perhaps less intuitively, the processes that underlie scientific thinking may resemble those responsible for everyday thinking, the sort on which human beings ordinarily rely to understand their environments. If scientific thinking and everyday thinking is the same sort of mental 'stuff', then investigations of the former offer the promise of elucidating the phenomenon of thought more generally.

And yet a third reason: one goal of those who study cognitive development is to explain the origins of mind (Spelke, 1994; Spelke *et al*., 1992). In pursuit of that goal, they have sometimes adopted the 'child-as-scientist' metaphor for the developing intellect (Rosser, 1994), equating the naive child facing the task of figuring out the world with the scientist on a quest of discovery. The child, from this perspective, is also a 'discoverer' – acquiring data, accumulating knowledge, and constructing theories. The study of scientific thinking, then, provides information about the culmination of the developmental process, a standard with which to compare the evolving mind, and a model to represent children's thought.

In short, we study scientific thinking in order to discover: (1) the nature of a form of innovative, complex reasoning so fundamental to the Western intellectual tradition, (2) the nature of the everyday reasoning that characterizes our species, and (3) the emerging nature of the child's ability to think. In this article, research spurred by each of these pursuits will be evaluated for what it contributes to our understanding of scientific thought.

THE NATURE OF SCIENTIFIC THINKING

The scientific enterprise entails adopting a theoretical position and even-handedly evaluating evidence *vis-à-vis* the position taken. Scientific training, regardless of discipline, is about learning the procedures required to (1) gather that evidence, data, or observations – i.e. accumulate knowledge, and (2) provide coherent explanations of the knowledge accumulated. Thus, there are two critical aspects of doing science. There is the *empirical* side of science, which is tied to experimentation, observation, and data collection; and there is the *theoretical* side of science, which goes beyond empirical observation to supposition about the underlying nature of things. Rather than being mere summaries of facts, theories are *explanatory systems*, constructions from the facts that present hypotheses about causal mechanisms to account for those facts. To hold a theory of some phenomenon is to have an explanation for how the phenomenon works. Data serve as the raw material and inform theory; theory interprets data and points the way to new observations. Thus, empirical and theoretical knowledge have an important relationship with one another. The former is the sum of the descriptions, facts, and data acquired through experimentation and observation; the latter explains empirical

knowledge, augments it where facts are scarce, predicts what new facts may yet be found, and provides a cohesive, interpretive structure within which the facts make sense.

When a theory can account for the accumulating facts, there is synchrony between empirical and theoretical knowledge. In one account of the history of science (T. Kuhn, 1962), these are periods of *normal science*. During such a period, a single theory or *paradigm* predominates. Sometimes, however, incoming facts will be at odds with the theoretical account. As contradictory data accumulate, there comes pressure to re-evaluate the theory in relation to the changing data base. Theoretical reformulations that serve to bring theory into alignment with observation represent *paradigm shifts*. Scientific development can be envisioned as a succession of dominant paradigms, each prevailing for a time until empirical pressure mounts, a new replacement system evolves, and equilibrium is returned to the balance between fact and the framework for fact. Paradigm shifts entail *conceptual change* (Carey and Spelke, 1994, 1996), as new concepts better able to account for new facts are added to a theory, old concepts are adjusted, and the relations among those theoretical concepts are altered.

The scientist's first task is to collect facts and make inferences from those facts. Scientists adopt an *objective* perspective towards the task of observation and data collection: objectivity means that the procedure for recording observations and obtaining facts is conducted in such a way that the products are independent of the individual doing the observing and collecting. Generalization of principles from observations of phenomena are judged to be only as sound and supportable as the care with which scientific procedure is followed. Method and the rules of reasoning associated with that method are the *hows* of science, independent of the subject matter investigated. These 'hows' are *domain-general*, meaning that the same thinking, the same rationality, would apply to any phenomenon in any domain.

The scientist's second task is to explain the facts collected. Principles of observation and explanation may be domain-general, but the outcome of scientific endeavors, the *whats* of science, are not. Observations collected are *about* something in particular, not something in general; and the sum of the observations accumulated constitute a body of facts characterizing some specific thing(s) or event(s). The accompanying theory that proposes an explanatory 'story' for a phenomenon is also *about* something. The products of science are *domain-specific*. There are biological facts and biological theories, physical facts and physical theories, psychological facts and psychological theories. Principles from one theoretical domain, such as biology, are not used to explain phenomena from another domain, such as physics. When we examine how scientists might think, we differentiate domain-general thinking from the domain-specific variety.

DOMAIN-GENERAL THINKING

Domain-general reasoning abilities are those abstract intellectual capacities that the individual can recruit in a variety of contexts, including contexts the scientist would face when designing and conducting experiments, drawing inferences from data, and evaluating the validity of conclusions. This type of cognitive activity is typically what we construe as rationality and is a broadly applicable, consciously deployed, cognitive resource. While we might contend that this kind of intellectual activity is characteristic of what scientists do, it is characteristic of everyday thinking too (Kuhn, 1993).

In experiments intended to tap domain-general thinking, the individual is presented with a problem and given time to apply a formal solution strategy, algorithm, or rule in order to achieve a correct solution. This sort of reasoning is conscious, deliberate, demanding of cognitive resources, and context- and task-independent. That means, the mental operation deployed is a generalized abstraction applicable across tasks and circumstances. To judge the validity of an argument or solve a presented problem, the specifics of the premises or the specifics of the problem context are of less interest than the cognitive procedures and operations recruited.

Investigators whose research is focused on domain-general thinking describe these cognitive activities in terms of *strategies, heuristics, algorithms*, or *logical structures*, all of which are abstract solution devices or programs applicable across a wide variety of situations. Problems well suited for the study of this aspect of cognition include deductive reasoning tasks, analogical reasoning tasks, and problems from intelligence tests. Puzzles present an appropriate problem-solving context too, as do problems that specifically elicit scientific reasoning (Chi *et al*., 1982; Kuhn, 1989). Common features of these tasks are: the premises of the problem are specified, the way it is framed can be manipulated, and the correct solution is known. Investigators can observe how the solution is achieved; and the cognitive operations inferred from protocols may permit formal modeling.

Domain-general Thinking and Cognitive Development

The 'child-as-scientist' metaphor is a popular one for cognitive development. References to children *discovering* the workings of the world, *testing hypotheses* about that operation, and *formulating principles* of explanation link children's thinking with the scientific enterprise. Jean Piaget (Inhelder and Piaget, 1958) represents one who adopted this metaphor in a domain-general sense. He depicted the infant as an experimenter deciphering the physical laws governing the behavior of objects. He extended the metaphor to the toddler and the child acting upon the environment in order to construct representations of how things work, as scientists do. And he envisioned the important achievement of the adolescent as the ability to test hypotheses in a systematic and exhaustive manner, again much as a scientist would. The hallmark of mature thinking for Piaget was the construction of highly generalized abstractions as tools for thinking. And he envisioned development as the progressive movement towards a greater and greater *objective* understanding of the workings of the universe. The formal operational thinker behaves much like a scientist, *forming* hypotheses, *deducing* conclusions, *predicting* outcomes, and *evaluating* data. This kind of thinking is deliberate, intentional, conscious, and explicit, whether engaged in by the formally tutored scientist or by the adolescent who has reached the formal operational stage of development. Like the ideal scientist, the formal operational thinker should systematically examine all possibilities, consider the empirical evidence, and objectively evaluate each particular hypothesis in accord with that evidence.

Piaget's theory is one of the major treatments of the development of domain-general reasoning and logical thinking. Individuals' abilities to generalize cognitive routines across contexts, content, and situations was what most interested him. He construed cognitive structures as highly abstract, symbolic formalisms, and depicted development as the sequential evolution of thought from very situation-bound forms, the thought of the infant and toddler, to the symbolic forms displayed by the adolescent and adult. Essentially, Piaget argued that development involved a succession of increasingly powerful logical systems, where *powerful* is a synonym for *generality* of application. The formal reasoner can access these systems and apply a mental logic that is fully abstract, efficient, and disembedded from specific content. As a consequence, they are able to conceive of possibilities, to engage in hypothetical-deductive reasoning, and to speculate about a myriad empirical outcomes (i.e. evidence), including those not yet encountered (i.e. contradictory evidence). In short, the model for the culmination of cognitive development is scientific thinking.

How Well Do Individuals Do?

Deliberate, conscious, broadly applicable thinking routines are not likely to surface early in development. Such accomplishments require an understanding of mental operations, a cognitive sophistication not expected of the young child. Deliberate use of mental operations presumes explicit control of those operations. Again, this is unlikely with young children. And the ability to apply a strategy, rule, or algorithm across contexts is related to experiences in application; amount of experience is developmentally constrained as well. Intentional reasoning that the individual can reflect upon and explicitly describe is *not* characteristic of early emerging mental abilities. In fact, preadolescent children rarely do well on the sorts of tasks Piaget used to assess formal reasoning (Rosser, 1994). The young child does not look like a scientific thinker in the domain-general sense.

But another question is whether older individuals demonstrate the capacity to reason as a scientist would. Some evidence supports the existence of these abilities in adults, but the evidence is mixed (Johnson-Laird, 1993). For example, consider this conditional reasoning problem: 'if p then q; not q therefore not p'. With a task like this one, investigators determine whether a subject will evaluate the validity of a proposition by seeking falsifying counterexamples or *disconfirmation*. Both adolescents and adults will experience difficulty. Most subjects will ignore the possibility of counterexamples and just restrict their evaluation to the *confirmation* of 'if p, then q'. In science, one must seek to disconfirm contentions rather than confirm them; that is why the ability to search for counterexamples is so important for scientific thinking. But it is not characteristic of everyday thinking.

The factors that affect success rates on reasoning problems are related to the specific content of a problem. Indeed, psychologically realistic reasoning is often better captured by models based on the *semantics* of the problem presented (i.e. what the problem is about) than on the underlying logical *syntax* of that problem (i.e. the abstract form) (Bell and Johnson-Laird, 1998). So, even adults do not exhibit generalized domain-specific thinking all of the time.

One way of explaining this discrepancy between formal models of reasoning and what people actually do is to differentiate between *competence* and *performance*. Competence is the ideal, what the human mind is capable of doing; it is the *potential* for employing abstract reasoning strategies. Performance is what people tend to do on actual problems presented to them; it varies from the ideal as it is affected by the vagaries of the situation, by randomly occurring departures from rationality. Characterizing performance may bring us closer to modeling actual thinking. Discrepancies from the ideal are often systematic (Stanovich, 1999). For example, when individuals must evaluate evidence, they often display *bias*, as opposed to scientific objectivity (Klaczynski, 2000). One kind of bias comes from personal beliefs about content. People tend to evaluate evidence consistent with their beliefs differently than they would evidence inconsistent with those beliefs (Klaczynski and Narasimham, 1998). In fact, they are more apt to bring the cognitive resources of formal reasoning and logic to bear when evaluating inconsistent evidence, while taking logical short cuts when evaluating consistent evidence, which they are predisposed to accept anyway. Objectivity, then, is situational.

In short, belief-relevant evidence is interpreted, evaluated, and judged as a function of existing belief rather than uniformly evaluated with domain-general cognitive schemes. Scientific thinking of the modal sort is a possible cognitive achievement we use some of the time, but it may not be a probable stance we generally assume all of the time.

DOMAIN-SPECIFIC THINKING

There is another way, however, that everyday thinking may overlap with scientific thinking. Scientists collect data and also construct theories. Their theories account for the empirical phenomena. Not just scientists, but people generally may consult theories of a similar sort for a similar reason – to make sense of what is experienced and observed in the world. Like scientists, all of us need frameworks to provide conceptual glue for the bits and pieces of knowledge we accumulate. These bits and pieces form domain-specific knowledge systems (Keil, 1991), systems better characterized as *intuitive*, rather than rational; *constrained* to specific problems, rather than generally applicable; *effortless* and easily accessed, rather than demanding of cognitive resources and energy; and *pre-conscious*, rather than conscious (Klaczynski, 2000). The connection between this kind of knowledge and formal science is that untutored, domain-specific knowledge may also be organized into naive 'theories' (Gopnik and Meltzoff, 1997). A 'theory' of this sort serves as a causal explanatory system for entities which fall into a common category. So, for example, to have a naive theory of biology means one can (1) identify a set of entities that qualify as biological, (2) group those entities into a shared conceptual category, (3) apply unique causal principles to that set, and as a consequence, (4) draw inferences, make predictions, and explain outcomes, specific to biological phenomena. For both the trained biologist and her common-sense counterpart, the theory would apply only to biological phenomena, not phenomena in general. But the naive version is rooted in fundamental ways we as human beings construe the world, rather than in formal training.

What are some of these naive theories? Research attests to the existence of three commonly held, naive theories parallel to those of a scientist: (1) a physics, (2) a biology, and (3) a theory of mind, or intuitive psychology (Gopnik and Meltzoff, 1997; Keil, 1992; Spelke, 1988). These common-sense systems are like formal theories in that they (1) explain existing facts, (2) help us interpret new facts, (3) predict what facts may yet be forthcoming, and (4) change in response to the accumulation of knowledge.

Domain-specific Thinking and Development

Like its domain-general cousin, domain-specific cognition reveals both individual and developmental variation (Rosser, 1994). Expertise and maturity in one domain can be independent of another and not predictable from general indicators of intellectual functioning. Thus, a person could display precocious knowledge and reasoning in one domain but not necessarily in others, partly as a consequence of the survival relevance of a domain. The basic contention is: some information is so relevant to our survival that specialized mechanisms have evolved to help us deal with that information in very efficient ways. The prediction is: abilities mediated by such mechanisms will surface early in development.

A case in point is our understanding of other people as a special category of objects whose behavior is uniquely motivated by mental events such as intentions, beliefs, and desires. Predicting the behavior of other people by consulting a 'theory of mind' has survival relevance for a social animal. And, indeed, evidence indicates that such intuitions are available to the child early in

development (Wellman, 1990). Infants distinguish people from other objects and respond differently to people, suggesting that the domain of human behavior is construed as special. By their second year of life toddlers understand deceit, pretense, desire, and the role desire plays in motivating behavior. By their third year, preschoolers distinguish appearance from reality, reason about belief and intention, and differentiate their own perceptions and cognitions from those of other people. In short, early in development, when domain-general rationality is still limited, children are able to deal quite effectively with psychological 'stuff' (Rosser, 1994).

A second domain-specific knowledge system is associated with understanding biology (Keil, 1992). Again, children can access an intuitive theory, a 'folk biology' that is dissociable from other sorts of thinking (Hatano and Inagaki, 1994). This biology can support causal reasoning about such varied phenomena as kinship, inheritance, and biological origins, concepts of life and death, mind–body relationships, and the causes of disease and contamination. Early emerging biological notions overlap somewhat with adult conceptions, but the two versions are not identical. Common-sense biological knowledge continues to modify with increased exposure to biological information and the accumulation of facts.

As for an intuitive physics: rudimentary knowledge of physical objects, their properties, and their behavior is displayed very early in life (Baillargeon, 1994; Spelke, 1994). Infants reveal an appreciation of the constraints which operate in the physical world when they behave as if they expect objects to react to forces applied to them, move on connected paths, follow a continuous trajectory between locations, and not pass through spaces occupied by other objects (Carey and Spelke, 1996; Spelke, 1988). From this beginning, naive conceptions of physics build on core knowledge (Spelke *et al*., 1992) as children come to appreciate more subtle object properties and to understand the nature of more influences on object behavior (e.g. gravity). But the origins of a naive physics, like the basics of an intuitive biology and theory of mind, emerge very early in development.

How Well Do Individuals Do?

With such an early start to scientific thinking, can we expect the cognitively mature to exhibit sophisticated, domain-specific reasoning and problem-solving? To some extent they do, but demonstrations of expertise are primarily restricted to everyday contexts. In addition, naive theories lack the explicit conceptual richness of the formal versions. For example, the untutored can draw on a semblance of 'germ-theory' that permits them to avoid contagion, but few understand what a virus is. They can employ a 'physics' that facilitates the successful management of object-filled space and a 'psychology' that enables complex social negotiation; but these naive theories do not match formal science either. In fact, there is ample evidence, particularly in the case of physics, for pervasive misconception.

One relevant literature attests to the problem that high school and college students exhibit when faced with acquiring principles in physics (Chi, 1992; Halloun and Hestenes, 1985). Both adults and older children demonstrate misconceptions about the natural motions of objects and make erroneous predictions about trajectories (Kaiser *et al*., 1986; Proffitt *et al*., 1990). They also err, systematically not randomly, when anticipating the expected collision of a moving object and a target (Rosser and Chandler, 1995); and they misconstrue certain kinds of physical concepts, such as sound and light, and reason about them as if they were matter (Chi, 1992; Chi and Slotta, 1993). Why might they make such errors? McCloskey (1983) contends that naive theories of physics exhibit characteristics of pre-Newtonian impetus theory, a predominate paradigm during medieval times. In impetus theory the object is the center of the explanatory system, rather than the forces acting on objects. Our intuition leads us to the *bias* to be 'object-centric', and as a consequence of that bias, we perceive physical information differently from how the scientist would. Hence, our informal solutions will be incorrect some of the time. In short, naive theories, while providing us with *sufficient* explanatory systems for everyday life, do not match the conceptual systems scientists have so far devised to explain natural phenomena.

What might the source of the mismatch be? For one, informal reasoning and formal reasoning may differ in how problems are represented. In physics, for example, scientists rely on mathematical representations of events. In everyday reasoning, perception-informed representations are a more likely mediator. Also, formal problem-solving occurs in circumstances where there is time to manipulate the mathematical representations in rule-governed ways: not so for everyday problem-solving. There is rarely sufficient time, and such attempts would be much too demanding of cognitive resources. Instead, when reasoning 'online', we fall back on heuristics that are less cognitively

demanding, less effortful, but provide solutions close enough to still be adaptive (Rosser and Chandler, 1995). When a person is driving a car in traffic and approaches another car which has stopped, there is insufficient time to calibrate mathematically the dynamics of the impending collision. Intuitive reasoning, supported by perceptual representations, results in reasonable action anyway. Our intuition provides us with obligatory cognitive 'short cuts' that suffice.

A second reason intuitive and formal theories diverge has to do with differences in conceptual structure. Formal theories contain concepts absent from the informal versions. The rich data base scientists have gathered in a domain will have fueled a conceptual elaboration that need not occur in folk systems. Everyday theory accounts for everyday data (e.g. the behavior of medium-sized objects in a friction-filled environment), not all possible data (e.g. the behavior of particles in a vacuum, in space, within an atom) as a formal system must. Thus the two 'sciences' will differ conceptually. The intuitive scientist will not share the knowledge structure of the formally trained one and may not have a conceptual 'place' to put novel entities. How we categorize an entity affects what properties we assume that entity possesses and what causal explanations we will use to account for its characteristics. When the naive encounter ontologically ambiguous entities, such as sound, or light, or a virus, they may very well misassign them. So, for example, the child lacking a category for sound might assign it to the MATTER category and infer accordingly that sound takes up space, travels quickest through a vacuum, cannot pass through space occupied by other matter, and so forth. Everyday domain-specific reasoning of both children and adults shares some of the features of scientific thinking. But naive systems, though still 'theoretical', are not as informationally rich nor as conceptually elaborate.

CONCLUSIONS: SCIENTIFIC THINKING REVISITED

Scientific thinking is an inherently interesting cognitive phenomenon as a model of rationality and possibly as a model of everyday thinking. We have seen that there are two aspects of it: (1) a *domain-general* style of reasoning equally applicable to all phenomena, and (2) a *domain-specific* style, constrained to particular phenomena. We have also seen that the scientist must assume two roles: (1) the *empirical role* of objective data-collector, the accumulator of fact, and (2) the *theoretical role*, the constructor of explanatory systems to account for fact. The trained scientist understands the relationship between those roles, understands the connection between data and theory, and appreciates how evidence must be taken into account when evaluating the adequacy of theoretical contention.

The performances of individuals, including children, reveal both similarities and differences compared to the scientific model. In everyday reasoning, we collect facts and evaluate evidence too, but the objectivity we adopt will vary as a function of development, individual skill, the particulars of the task, and existing belief. Generally, ideal versions of domain-general rationality are not achievable until cognitive maturity, but even then they are not uniformly applied. While adults may be able to achieve the ideal in some circumstances, they will also exhibit systematic bias as well as random departures from rationality. Modal domain-general reasoning is cognitively effortful; apparently human beings have acquired cognitive 'short cuts' that are adaptive, conserve cognitive resources, and suffice most of the time.

Both adults and children are also naive theorists consulting intuitive explanatory knowledge systems to account for experience and observation. Unlike domain-general aspects of thought, domain-specific knowledge emerges early in development. These rudimentary systems enrich with development and the accumulation of information. Naive theories serve the same function as formal ones, but they are less elaborate, less sophisticated, less adequate, and account for fewer phenomena than the formal versions. In sum, we can reason in everyday life in ways similar to the trained scientist some of the time. We often do not; and we are simply not as good at it all of the time.

Self-regulated Learning

Intermediate article

Gregory Schraw, University of Nevada, Las Vegas, Nevada, USA
Douglas F Kauffman, University of Oklahoma, Norman, Oklahoma, USA
Stephen Lehman, Utah State University, Logan, Utah, USA

CONTENTS

Self-regulated learning relates to our ability to understand and control our learning environments.

DEFINITIONS AND BACKGROUND

Self-regulated learning refers to our ability to understand and control our learning environments. To do so, we must set goals, select strategies that help us achieve those goals, implement those strategies, and monitor our progress towards our goals (Schunk, 1996). Few students are fully self-regulated; however, those with better self-regulatory skills typically learn more with less effort and report higher levels of academic satisfaction (Pintrich, 2000; Zimmerman, 2000).

Self-regulated learning theory is a relatively recent development in cognitive psychology, with its origins dating back to the social-cognitive learning theory of Albert Bandura (1997). At the heart of Bandura's theory is the idea of *reciprocal determinism*, which suggests that learning is the result of personal, environmental, and behavioral factors. Personal factors include a learner's beliefs and attitudes that affect learning and behavior. Environmental factors include things such as the quality of instruction, teacher feedback, access to information, and help from peers and parents. Behavioral factors include the effects of prior performance. Reciprocal determinism states that each of these three factors affects the other two factors.

Since the 1980s, researchers have applied Bandura's (1997) social-cognitive theory to many settings, including school learning. These attempts led to the development of self-regulated learning theory, which states that learning is governed by a variety of interacting cognitive, meta-cognitive, and motivational components (Butler and Winne, 1995; Zimmerman, 2000). Social-cognitive approaches to self-regulated learning postulate that individuals learn to become self-regulated by advancing through four levels of development, including observational, imitative, self-controlled, and self-regulated levels (Schunk, 1996; Zimmerman, 2000). Learning at the observational level focuses on modeling, whereas learning at the imitative level focuses on social guidance and feedback. Both of these levels emphasize a reliance on external social factors. In contrast, as students develop, they rely more and more on internal, self-regulatory skills. Thus, at the self-controlled level, students construct internal standards for acceptable performance and become self-reinforcing via positive self-talk and feedback. At the self-regulatory level, individuals possess strong self-efficacy beliefs, as well as a large repertoire of cognitive strategies, that enable them to self-regulate their learning.

Contemporary self-regulated learning theory differs in two important ways from Bandura's social-cognitive learning theory. One is the emphasis that self-regulated learning theory places on the construction and management of cognitive strategies to control one's academic learning, otherwise known as meta-cognitive control. A second change is the inclusion of broad motivational constructs, such as causal attributions, goal orientations, and intrinsic motivation, that extend far beyond the boundaries of social-cognitive motivational constructs such as self-efficacy.

The remainder of this article is divided into five sections. The first of these describes three main components of self-regulated learning, including cognitive, meta-cognitive, and motivational components. Section two summarizes three different process models of self-regulated learning based on the work of Michael Pressley, Philip Winne, and Barry Zimmerman. Section three summarizes recent research on strategy instruction and

provides a seven-step guide to implementing strategy instruction. Section four reviews recent research on comprehension monitoring. Section five summarizes our main themes.

COMPONENTS OF SELF-REGULATED LEARNING

Experts agree that self-regulated learning includes three main components, including *cognition*, *meta-cognition*, and *motivation*. Cognition includes skills necessary to encode, memorize, and recall information. Meta-cognition includes skills that enable learners to understand and monitor cognitive processes. Motivation includes beliefs and attitudes that affect the use and development of cognitive and meta-cognitive skills. Each of these three main components is necessary for self-regulation. Those who possess cognitive skills, but are unmotivated to use them, for example, do not achieve at the same level of performance as individuals who possess skills and are motivated to use them (Zimmerman, 2000). Similarly, those who are motivated, but do not possess the necessary cognitive and meta-cognitive skills, often fail to achieve high levels of self-regulation.

The three main components of self-regulation can be further subdivided into the subcomponents shown in Figure 1. We describe each of these components below, as well as several finer-grained subcomponents.

Cognition

The cognitive component includes *encoding*, *organization*, *elaboration*, and *inferencing* subcomponents.

Encoding refers to our ability to process information currently in working memory in order to store it in long-term memory. Working memory is thought to be temporary and limited in capacity, whereas long-term memory is thought to be permanent and unlimited in capacity (Neath, 1998).

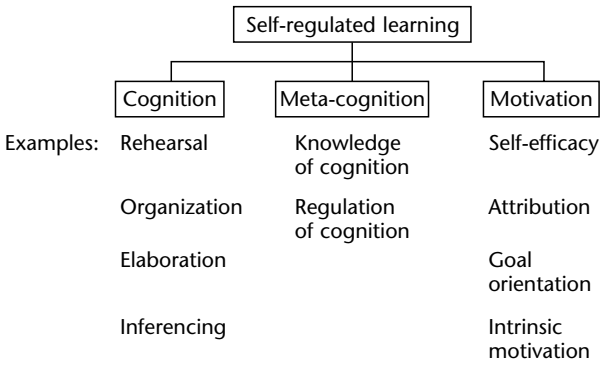

Figure 1. Components of self-regulated learning.

Organization refers to how information is sorted and arranged in long-term memory. Most experts agree that information in long-term memory is organized into knowledge structures called *schemata* and *scripts* (Neath, 1998). A schema is an organized body of declarative knowledge (i.e. stateable factual or conceptual knowledge). One example is a politics schema in which government is divided into three branches (i.e. executive, judicial, and legislative) headed by the President, Supreme Court, and Congress respectively. Schemata are crucial to self-regulated learning because they enable us to organize, store, and recall large amounts of information very quickly. Indeed, without schemata, the automated processing on which expertise depends would be impossible. Similarly, a script is an organized body of procedural knowledge that enables us to perform a task or skill automatically. Examples include scripts for getting dressed, ordering food at restaurants, riding a bicycle, and most other routine procedural activities. Collectively, schemata and scripts enable us to organize and access huge amounts of information in memory quickly.

Elaboration refers to our ability to embellish new information by linking it to information in long-term memory. Elaboration can occur at a shallow or deep level. Shallow elaboration is often referred to as *maintenance rehearsal*. For example, students may memorize the great lakes by repeating them over and over. In contrast, students could engage in several types of *elaborative rehearsal* such as creating an acronym (e.g. HOMES: Huron, Ontario, Michigan, Erie, and Superior), or constructing a mental image based on a map. Students could encode this information even more deeply by associating different lakes with different colors. For example, Lake Ontario could be remembered as orange, while Lake Michigan is remembered as magenta.

Inferencing refers to our ability to infer new information from existing knowledge and information. Inferencing is crucial to self-regulated learning because it enables us to go beyond what we know, constructing what we need to know to perform at a higher level of proficiency. The role of inference generation has been studied extensively by cognitive psychologists, particularly as it pertains to reading. Researchers know that self-regulated readers combine the facts and main ideas in a text into themes that are never stated explicitly, but are essential for comprehension.

Meta-cognition

Meta-cognition includes two main subcomponents generally referred to as *knowledge of cognition* and *regulation of cognition* (Schraw and Moshman, 1995).

Knowledge of cognition refers to what we know about our cognition, and usually includes three subcomponents. The first, *declarative knowledge*, includes knowledge about ourselves as learners and what factors influence our performance. For example, most adult learners know the limitations of their memory system and can plan accordingly based on this knowledge. *Procedural knowledge*, in contrast, refers to knowledge about strategies and other procedures. For instance, most adults possess a basic repertoire of useful strategies such as note-taking, slowing down for important information, skimming unimportant information, using mnemonics, summarizing main ideas, and periodic self-testing. Finally, *conditional knowledge* includes knowledge of why and when to use a particular strategy. Individuals with a high degree of conditional knowledge are better able to assess the demands of a specific learning situation and, in turn, select strategies that are most appropriate for that situation.

Research suggests that knowledge of cognition is late developing and explicit (Alexander *et al*., 1995). Adults tend to have more knowledge about their own cognition and are better able to describe that knowledge than children and adolescents. However, many adults cannot explain their expert knowledge and performance, and often fail to spontaneously transfer domain-specific knowledge to a new setting. This suggests that meta-cognitive knowledge need not be explicit to be useful and, in fact, may be implicit in some situations (Butler and Winne, 1995).

Regulation of cognition typically includes at least three components, planning, monitoring, and evaluation (Schraw and Moshman, 1995). *Planning* involves the selection of appropriate strategies and the allocation of resources. Planning includes goal setting, activating relevant background knowledge, and budgeting time. Previous research suggests that experts are more self-regulated compared to novices largely due to effective planning, particularly global planning that occurs prior to beginning a task. *Monitoring* includes self-testing skills necessary to control learning. Research indicates that adults monitor at both the local (i.e. an individual test item) and global levels (i.e. all items on a test). Research also suggests that even skilled adult learners are poor monitors under certain conditions (Pressley and Ghatala, 1990). *Evaluation* refers to appraising the products and regulatory processes of one's learning. Typical examples include re-evaluating one's goals, revising predictions, and consolidating intellectual gains.

Experts believe that self-regulatory processes, including planning, monitoring, and evaluation, may not be conscious or explicit in many learning situations. One reason is that many of these processes are highly automated, at least among adults. A second reason is that some of these processes may develop without any conscious reflection and therefore are difficult to report to others.

Motivation

The motivation component shown in Figure 1 includes four important subcomponents, consisting of *self-efficacy*, *attributions*, *goal orientations*, and *intrinsic motivation*.

Self-efficacy: refers to the degree to which an individual is confident that he or she can perform a specific task or accomplish a specific goal (Bandura, 1997). Self-efficacy is extremely important for self-regulated learning because it affects the extent to which learners engage and persist at challenging tasks. Previous research indicates that students with higher self-efficacy are more likely to engage in a difficult task and more likely to persist at a task even in the face of initial failures compared to low-efficacy students (Pajares, 1996). Higher levels of self-efficacy are related positively to school achievement and self-esteem. The trends observed with respect to student self-efficacy also generalize to teachers and even schools. Teachers with higher levels of teaching self-efficacy, for example, set higher goals and standards, give more autonomy to students, and help students reach higher levels of achievement than do teachers with lower levels of self-efficacy (Goddard *et al*., 2000).

Self-efficacy is affected by a number of variables, but especially vicarious learning and modeling. *Vicarious learning* occurs when individuals learn by observing others perform a skill or discuss a topic. Vicarious learning is advantageous to learners because they are not expected to perform the task, and therefore experience less anxiety, and can also focus all of their resources on observing experts. *Modeling* occurs when learners learn intentionally from other individuals such as teachers and students. Modeling typically includes the teacher breaking a complex task into manageable parts and asking students to demonstrate each part separately in sequence. Bandura (1997) proposed that modeling is effective because it raises

expectations that a new skill can be acquired, in addition to providing a great deal of knowledge about the skill. Peer models are usually the most effective because they are most similar to the learner. Indeed, students are most likely to increases their own self-efficacy when observing a model of similar ability level perform the skill (Schunk, 1996).

There are two main ways to increase students' self-efficacy. One is to use both expert (e.g. teacher) and non-expert (e.g. student peers) models. Research demonstrates that models improve cognitive skills and self-efficacy. The second is to provide as much informational feedback to students as possible. Feedback should indicate not only whether the skill was performed acceptably, but provide as much information as possible about how to improve subsequent performance. Given detailed informational feedback, performance and self-efficacy can increase even after students experience initial difficulty performing a skill.

Attributions: refer to causal explanations of events that happen in our lives. For example, two students may do poorly on a test. One student may attribute her poor performance to bad luck, while the other student attributes her poor performance to lack of effort. These attributions provide very different explanations of the same event. Attribution theory states that it is not an event *per se* that affects us, but our interpretation of that event (Graham and Weiner, 1996; Weiner, 1986).

Weiner (1986) proposed that attributions vary along three dimensions. The first is *locus of control*, which defines the cause of an outcome as either internal or external to the individual. Mood and emotions are examples of internal causes, whereas teachers are external causes. A second dimension is *stability*, which pertains to whether an attributional cause is permanent or temporary. Ability is stable, whereas effort tends to be less stable. A third dimension is *controllability*, which refers to whether an event is under the student's control or is uncontrollable. Controllable causes of academic success include effort and strategy use, whereas uncontrollable causes include luck and task difficulty.

Researchers have considered the separate effects of locus of control, stability, and controllability; however, of greater importance is how the three dimensions contribute simultaneously. Internal, controllable, stable causes such as effort promote positive academic responses, whereas external, uncontrollable, unstable causes such as luck produce frustration or undermine academic confidence. Weiner (1986) reported that internal, controllable causes, such as strategy use, promote positive affective responses, whereas internal, uncontrollable causes such as ability may create negative emotions such as shame and guilt.

Fortunately, students may be helped to change negative attributional responses through observation and training. A review of the attributional retraining literature found that the majority of attribution retraining programs are successful. Successful programs included the following three components: (1) individuals are taught to identify desirable behaviors such as effort and strategy use, (2) attributions that support positive behaviors are evaluated, (3) favorable attributional responses are rewarded. Overall, the attributional retraining literature provides evidence that individuals can learn to make more adaptive attributional responses that improve motivation and achievement-related behaviors such as effort, help seeking, and persistence.

Goal orientations: refer to beliefs about ability and how those beliefs affect learning. Dweck and Leggett (1988) proposed that learners adopt either *performance goals* or *learning goals* based on personal beliefs about the stability of intelligence. Students who believe that intelligence is fixed and unchangeable adopt performance goals, in which they seek to *prove* their competence in academic settings. Those who believe that intelligence is malleable and changeable adopt learning goals, in which they seek to *improve* their competence. A number of studies suggest that students who adopt learning goals are more adaptive and satisfied than students who adopt performance goals. Learning-oriented students typically achieve more because they seek challenge, persist, use strategies, attribute success to effort, and demonstrate positive responses to periodic failure. In contrast, performance-oriented students often adopt maladaptive response patterns characterized by avoidance of challenge, quitting after initial failure, use of inappropriate strategies, helplessness, and attributing success to uncontrollable causes such as ability and luck (Ames and Archer, 1988).

Learning- and performance-oriented students differ with respect to academic self-efficacy and self-regulated learning (Midgley *et al.*, 1995). Schunk (1996) reported that students with learning goals report higher levels of self-efficacy which, in turn, is related to higher levels of academic achievement. Bouffard *et al*. (1995) found that college students who reported strong learning goals also attained the highest level of academic self-regulation.

Learning-oriented students also appear to have better relationships with their teachers. In fact, in a study by Ames and Archer (1988),

learning-oriented students considered teachers to be more important than effort, ability, or strategy use. Surprisingly, however, learning-oriented students did not attribute their failure to teachers, whereas performance-oriented students did!

Bruning *et al*. (1999) have suggested a number of ways to foster adaptive goals. One is to promote a flexible attitude about the role of ability. Students should be encouraged to make the most of their existing ability rather than focus on how much ability they have compared to other students. Second, teachers and parents should concentrate on rewarding effort. Third, teachers should stress that mistakes are a normal part of learning and are best dealt with by persistence, help seeking, and strategy use.

Intrinsic motivation: refers to behaviors that are engaged in for their own sake (Deci and Ryan, 2000). When an individual is intrinsically motivated, tasks are performed for internal reasons such as joy and satisfaction, rather than for external reasons such as rewards, obligation, or threat. Extrinsic motivation refers to behaviors that are performed to achieve some externally prized consequence, not out of interest or personal desire for mastery. Studies reveal that performing a task because of intrinsic motivation results in satisfaction and a desire to perform the task again. In contrast, performing a task due to extrinsic motivation may lead to indifference or displeasure, and may decrease the desire to perform the task again.

Summary

Self-regulated learning refers to learners' abilities to understand and control their learning environments. Self-regulated learning involves a combination of cognitive strategy use, meta-cognitive processing, and motivational beliefs. Cognitive strategies take the form of encoding, organization, elaboration, and inference-making. Meta-cognitive processing refers to knowledge and control of cognitive skills, and usually involves planning, monitoring, and evaluating. Finally, the motivational component refers to students' beliefs in their capacity to learn. Motivation takes many forms including self-efficacy, attributions, goal orientation, and intrinsic motivation.

PROCESSES AND MODELS

Self-regulated learning is a relatively new field of study in cognitive psychology. Different theorists view self-regulated learning in different ways. Most experts agree that self-regulated learning includes the three main components described above (i.e. cognition, meta-cognition, and motivation). However, experts differ in terms of the relative contribution of each of these three components. In this section, we describe three overlapping yet distinct models of self-regulated learning. The first model is based on the work of Michael Pressley and colleagues and is known as the *Good Information Processor* model (Pressley *et al*., 1989). This model places special emphasis on the role of cognitive strategies. The second model is based on the work of Philip Winne and colleagues and is known as the *Self-regulated Learning* model. This model emphasizes the interactive relationships among cognitive, meta-cognitive, and motivational components, although it differs from the good information processor model in that it more strongly emphasizes the role of meta-cognition, and especially the role of monitoring and feedback. The third model is based on the work of Barry Zimmerman and is often referred to as the *Phases of Self-regulation* model. Though quite similar to Winne's self-regulated learning model, the phases of self-regulation model differs in that it has fewer phases and emphasizes the role of personal volition.

Pressley's Good Information Processor Model

The good information processor model was developed initially to explain effective strategy use. The model includes five main characteristics: (1) a broad repertoire of strategies, (2) meta-cognitive knowledge about why, when, and where to use strategies, (3) a broad knowledge base that is relevant to the task at hand, (4) the ability to eliminate unwanted distractions, (5) automaticity in the four components mentioned previously.

Regarding the first of these characteristics, Pressley *et al*. (1989) distinguished between two different types of strategies. The first of these include domain-specific strategies that are appropriate only for a specific task such as solving a quadratic equation. The second type is a higher-order strategy, which is used to control other lower-level strategies. One example of a higher-order strategy is sequencing the use of several domain-specific strategies while reading; tactics such as skimming before reading, drawing conclusions, then reviewing. Using higher-order strategies to orchestrate lower-level strategies is crucial to one's ability to self-regulate.

The second characteristic corresponds closely to what experts call conditional knowledge; that is,

knowledge about when, why, and where to use strategies in an optimal fashion. Conditional knowledge is important because knowing how to do something is of little practical use unless one also knows when to do it. For example, one can study the correct information for a test but do so quite poorly. Knowing how to study is at least as important as knowing what to study.

The third characteristic is a broad knowledge base. Researchers agree that learning is extremely difficult and time-consuming without supporting knowledge already in long-term memory. Indeed, a number of studies report that average-ability students with high levels of knowledge about a topic generally outperform higher-ability students with low levels of background knowledge (Bruning *et al*., 1999). In addition, background knowledge is related to the effective use of memory resources and the ability to construct integrated internal representations of a task.

The fourth characteristic is the ability to eliminate unwanted distractions. Pressley *et al*. (1989) refer to this as *action control*. Students with action control are able to motivate themselves in several ways. One is to allocate effort to the task and persist when the task is difficult. A second is to attribute their success to controllable causes such as effort and strategy use. A third is to tune out unwanted distractions.

The fifth characteristic is automaticity of the four previous characteristics. *Automaticity* refers to being able to perform a task or retrieve information from memory with little conscious effort. Automaticity is important for two interrelated reasons. First, automating lower-level cognitive skills conserves our resources for higher-level cognitive tasks that are less likely to be fully automated. Second, because fewer resources are consumed, students have more resources available to engage in complex information processing. Automaticity is one of the key components of self-regulation because our effort can be devoted to planning and monitoring the outcome of our performance, rather than performing the task.

Collectively, the five skills characteristics of good information processors enable students to self-regulate learning with a great deal of efficiency. Needless to say, each of the five components is necessary and must work in synchrony with the others. For this reason, Pressley and colleagues (Pressley and Wharton-McDonald, 1997) suggest teaching the five components described above in an integrated fashion in which all components are addressed simultaneously.

Winne's Self-Regulated Learning Model

Winne's Self-Regulated Learning model makes three broad assumptions about self-regulated learning. First, unlike the Good Information Processor model, it emphasizes the sequence of self-regulated learning over the five individual components described by Pressley and colleagues. Second, Winne conceptualizes self-regulated learning as the ability to bridge the gap between setting and achieving learning goals (Winne and Perry, 2000). Third, he highlights the importance of self-generated feedback as a mechanism that supports self-regulated learning. Winne and colleagues emphasize four stages in the self-regulated learning process, including (1) defining the task, (2) planning and goal setting, (3) enacting tactics, (4) adapting meta-cognition (Butler and Winne, 1995; Winne and Perry, 2000).

Phase one of the self-regulated learning model consists of defining the task. This phase can be broken down into two major subcomponents, task conditions and cognitive conditions that support self-regulated learning. *Task conditions* refer to factors external to the learner such as time, instructional cues, and availability of resources that affect the learner's ability to perform a task successfully. *Cognitive conditions* refer to factors internal to the learner that affect performance. Examples include personal beliefs such as self-efficacy and attributions, domain knowledge, knowledge of the task, conditional knowledge, and personal motivational factors such as goals and intrinsic motivation. According to Winne, both task and cognitive conditions conjointly influence the learner's ability to evaluate the task and formulate outcome expectations. After defining the task, the self-regulated learner must plan and set goals.

Phase two consists of planning and goal setting. In this phase, learners evaluate task and cognitive conditions information in order to establish their main goals. Learners may have multiple goals, each with its own standard for performance. Learners set these standards based on their knowledge about the task domain, automaticity performing the task, and an assessment of how well they can monitor their performance.

Phase three consists of selecting and coordinating a wide variety of cognitive learning strategies based on the goals and standards that have been set previously. These include information search strategies such as retrieving information from long-term memory, information management strategies such as identifying important information and

summarizing, and help-seeking strategies such as working in groups or asking peers or teachers for help. The purpose of enacting strategies is to produce cognitive products such as organized information in memory or written reports. In turn, products can be evaluated against the goals and standards set in phase two.

Phase four consists of using meta-cognitive knowledge, particularly monitoring, to evaluate one's performance. Winne and Perry (2000) distinguished between meta-cognitive knowledge and meta-cognitive monitoring. Meta-cognitive knowledge includes conditional knowledge about cognitive strategies, knowledge about the task, knowledge about one's current knowledge base, and one's own interests. Meta-cognitive monitoring includes judgments of one's available resources, assessing the relative difficulty of the task, evaluating current performance, and generating feedback to correct comprehension errors. Meta-cognitive knowledge and monitoring are used to assess the fit between students' initial goals and final performance. The extent to which a disparity exists necessitates a return to phase one of the cycle to eliminate this disparity. This self-regulated learning process continues until performance matches one's learning goals.

Zimmerman's Phases of Self-Regulation Model

Zimmerman and colleagues proposed a cyclical model of self-regulated learning that consists of three distinct phases: (1) forethought, (2) performance control, (3) self-reflection (Zimmerman and Kitsantas, 1999; Zimmerman, 2000). Zimmerman's model is similar to Winne's sequential self-regulated learning model in many respects, yet differs in three ways. First, motivational factors such as self-efficacy play a more influential role during the forethought phase. Second, self-affect plays a more influential role during the self-reflection phase. Third monitoring plays a smaller role in Zimmerman's model than in the Pressley and Winne models.

The forethought phase of Zimmerman's model includes two main components consisting of *task analysis* and *motivational beliefs*. Task analysis variables are similar to those described by Winne and Perry (2000), and include planning and goal setting. However, Zimmerman includes more motivational variables, emphasizing the role of self-efficacy, goal orientations, and intrinsic motivation.

The performance phase likewise includes two components consisting of *self-control* and *self-observation*. Self-control includes attention focusing strategies that enable students to tune out unwanted distractions. This component also includes the use of a wide variety of study strategies to control learning. In addition, students may also use what Zimmerman refers to as *self-instruction*, in which individuals vocalize instructions to themselves explaining how to perform a task or monitor their comprehension. The self-observation component includes a variety of record keeping activities in which learners keep track of their cognitive progress and emotional reactions.

The self-reflection phase includes both *self-judgments* and *self-reactions*. Self-judgments include monitoring one's cognitive performance, evaluating affective reactions to performance, and making appropriate causal attributions. During this phase, learners monitor whether they have met their previously established learning goals. Progress is evaluated on a number of dimensions, including whether basic goals have been mastered, how well they have performed relative to others, and how well they have performed compared to their previous performance. Self-reactions pertain mainly to judgments of their affective engagement. Zimmerman (2000) argues that task satisfaction depends on one's ability to meet previously established goals and standards.

Summary

The three models of self-regulation described above agree on the need for cognitive, meta-cognitive and motivational components. They differ in the extent to which these main components interact. Pressley's Good Information Processor Model focuses more on the componential makeup of self-regulated learning, while the other models emphasize the sequential (Winne) or the cyclical (Zimmerman) nature of the self-regulated learning process. In Winne's model, the process of bridging the gap between setting and achieving goals, as well as the importance of self-generated feedback is crucial. In contrast to Winne, Zimmerman emphasizes the importance of motivational variables, such as self-efficacy as well as suggesting that self-reactions play an integral part in the learner's continued regulatory processes.

SELF-REGULATION AND STRATEGIES

Research on Strategy Instruction

Research on strategy instruction has boomed since the early 1980s. Unfortunately, implementing a

strategy training program is time-consuming and expensive; thus, most interventions have focused on the effectiveness of only one or two strategies. Researchers have conducted *meta-analyses* to better understand the effectiveness of strategy instruction. A meta-analysis is a procedure that aggregates similar studies to determine their overall effectiveness. Two analyses by Hattie *et al*. (1996) and Rosenshine *et al*. (1996) supported the following four claims:

1. Strategy instruction typically is moderately to highly successful.
2. Strategy instruction appears to be most helpful for younger and under-achieving students.
3. Programs that combine several interrelated strategies are more effective than those that include only one strategy. An interrelated repertoire of four or five strategies seems optimal (Pressley and Wharton-McDonald, 1997).
4. Strategy interventions are more effective when they teach conditional knowledge.

Strategy research has also addressed whether strategy instruction is more effective in teacher-centered versus student-centered classrooms. Neither type of setting appears to increase the effectiveness of interventions, although it should be noted that few studies have compared different instructional approaches directly.

Another important question addressed by strategy instruction research is what strategies should be taught to students. Experts generally agree that a limited number of general strategies are most effective (e.g. 4–8). Based on their analysis, Hattie *et al*. (1996) suggested the following set of strategies: self-checking, creating a good study environment, planning and goal setting, reviewing, summarizing, and seeking teacher and peer assistance. Similarly, in a comprehensive review of the strategy instruction literature, Dole *et al*. (1991) recommended a similar set of five core learning strategies that included determining what is important to learn, summarizing, drawing inferences, generating questions before and during studying, and monitoring one's comprehension.

How to Teach Strategies

Strategy instruction should be an integral part of every class (Pressley and Wharton-McDonald, 1997). Prior to strategy instruction, teachers should help students understand the value of strategies and decide which strategies to teach their students. Most experts recommend an instructional sequence that stretches from 10 to 20 weeks in which strategies are introduced, modeled, practiced, and finally automated. The following seven-step sequence is typical of effective strategy instruction programs:

1. Discuss and explain the value of strategies. Strategies increase efficiency, save time, and enhance deeper processing.
2. Introduce a limited number of strategies. Most programs recommend four or five general strategies such as summarizing and comprehension monitoring.
3. Practice each strategy over an extended period of time until it becomes automated.
4. Model strategies extensively so students acquire not only the strategy, but conditional knowledge about how, when, and where to use the strategy.
5. Provide feedback to students about strategy use. This information helps them evaluate the effectiveness of strategies and monitor their comprehension more effectively.
6. Promote transfer by encouraging students to use strategies in new settings or by adapting them to new tasks. Previous research suggests that strategies learned in one setting do not transfer unless students are instructed to use them in different settings.
7. Encourage reflection on strategy use. Students who reflect on strategy use acquire more meta-cognitive knowledge and are more apt to use strategies in a flexible way to self-regulate. One way students can self-reflect is through journals. A second way is by comparing the advantages and disadvantages of different strategies with peers.

Overall, research suggests that effective strategy use is critical for self-regulated learning. Effective strategy use is accomplished most efficiently through the extended instruction, modeling and practice of a small repertoire of general strategies such as planning, inferencing, and monitoring. In addition to a repertoire of strategies, increasing self-regulated learning is dependent on the learner's ability to monitor comprehension.

COMPREHENSION MONITORING

Comprehension monitoring refers to evaluating the ongoing state of one's understanding. Monitoring takes place during or after a learning activity and provides information about the effectiveness of that activity. Monitoring is important because it provides self-generated feedback to the learner. Without accurate monitoring, efficient control of one's performance is impossible.

Monitoring studies typically require individuals to make subjective judgments of learning or test performance during or after an initial study phase. Four types of judgments have been used in the adult monitoring literature, including *ease of learning* (i.e. judgments of encoding difficulty),

judgments of learning (i.e. the degree to which information was learned during the study phase), *feeling of knowing* (i.e. the degree to which one has access to previously learned information in memory), and *performance judgments* (i.e. assessments of performance accuracy).

Studies measuring these four types of judgments indicate that adults monitor their learning and performance with a moderate degree of success, although results vary from study to study. Surprisingly, monitoring proficiency does not appear to be related strongly to relevant domain knowledge or academic achievement (Pressley and Ghatala, 1990). These conclusions have been supported in the children's monitoring literature as well, although there is considerable debate regarding whether children monitor as accurately as adults (Alexander *et al*., 1995).

These studies indicate that there are three specific factors that affect monitoring proficiency. First, situational constraints affect estimates of monitoring proficiency. One constraint is the point in the learning-test sequence in which monitoring judgments are made. A number of studies indicate that calibration of comprehension (i.e. the correlation between pre-test judgments and actual test performance) is often quite poor, with most studies reporting correlations in the 0.00 to 0.25 range (Pressley and Ghatala, 1990). In contrast, calibration of performance (i.e. the correlation between post-test judgments and actual test performance) appears to be much better in both children and adults, often ranging from 0.30 to 0.50 (Pressley and Ghatala, 1990).

Second, specific testing conditions affect monitoring proficiency. For example, calibration of comprehension can be improved under the following circumstances: (1) when adjunct questions similar to post-test questions are provided during study, (2) when periodic feedback is provided to test takers, (3) when expert knowledge about the to-be-learned material is *minimized*, (4) when test takers generated missing text information. Surprisingly, calibration of comprehension does not appear to improve when learners are specifically requested to monitor their comprehension or when they are given the opportunity to re-study the to-be-learned materials, or when they are given practice questions prior to study.

Like calibration of comprehension, calibration of performance improved under a number of testing conditions, especially when adjunct questions were provided during the study phase, when test takers received external incentives to improve monitoring accuracy, and when test takers received recall rather than recognition tests. Calibration of performance was also related to level of test performance. In addition, individuals monitored with less bias when judging their performance on easy rather than more difficult items.

Third, feedback, incentives, practice, and training positively affect monitoring proficiency. Schraw (1994) reported that pre-experimental estimates of monitoring proficiency were related to both local (i.e. the accuracy of item-specific performance judgments made during testing) and global (i.e. judgments of overall performance made after testing) monitoring accuracy. The accuracy of local monitoring was correlated positively to the accuracy of global monitoring. In addition, the change in monitoring accuracy between local and global monitoring improved significantly among good monitors, but did not improve among poor monitors.

Monitoring training also improves performance. Delclos and Harrington (1991) examined fifth- and sixth-graders' ability to solve computer problems after assignment to one of three conditions. The first group received specific problem-solving training, the second received problem-solving plus self-monitoring training and practice, while the third received no training. The monitored problem-solving group solved more of the difficult problems than either of the remaining groups and took less time to do so. The group receiving problem-solving and monitoring training also solved complex problems faster than the control group.

The monitoring research summarized above leads to a number of conclusions. Overall, adults monitor their performance with a moderate degree of accuracy. Monitoring accuracy improves as tests become easier and more factual. Second, monitoring proficiency appears to be independent of intellectual ability (Alexander *et al*., 1995) and academic achievement (Pressley and Ghatala, 1990). Third, monitoring proficiency may be independent or even negatively related to domain knowledge, independent of ease of comprehension judgments, but correlated with other types of meta-cognitive knowledge. Fourth, one's ability to monitor one's performance may improve with practice (Delclos and Harrington, 1991).

SUMMARY

Self-regulated learning theory evolved from Bandura's (1997) social-cognitive learning theory. In 2002 self-regulated learning theory focuses on the transition from social to self-directed learning processes. Several main themes emerge from this

research. The first is that self-regulated learners rely on an integrated repertoire of cognitive, meta-cognitive, and motivational skills. Second, self-regulated learners use these skills to plan, set goals, implement and monitor strategy use, and evaluate their learning goals. Third, self-regulated learners use a wide variety of strategies in flexible ways, augmenting these strategies with a variety of adaptive motivational beliefs such as high self-efficacy, attributions to internal controllable causes of academic success, learning goals, and intrinsic motivation.

A review of the strategy instruction literature suggests that a repertoire of four or five general strategies such as summarizing and comprehension monitoring skills can be taught to students of all ages. Strategy instruction is most effective when it extends over a 10- to 20-week period, includes extensive modeling and feedback, teaches conditional knowledge necessary for effective strategy use, and helps students recognize the cognitive and motivational benefits of strategy use. In addition to strategies, self-regulated learners monitor their comprehension and debug learning problems when they occur. Research suggests that monitoring is unrelated to ability and improves with practice.

Overall, there is strong agreement that self-regulated learning is necessary for academic success and is attributable to meta-cognitive knowledge and a repertoire of learning strategies, rather than ability *per se*. These skills are learned through observation and modeling, feedback from others, and consistent practice. Models also provide important motivational support.

Thinking Skills

Intermediate article

Diane F Halpern, Claremont McKenna College, Claremont, California, USA

CONTENTS

There are many different types of thinking skills and frameworks for categorizing them. Good or clear thinking is called 'critical thinking'. Critical thinking skills are those skills that increase the probability of a desirable outcome, and are essential to problem-solving and decision-making.

INTRODUCTION

Thinking is commonly regarded as the highest form of human activity. It is a universal, private activity, inferred from behavior. Thinking is a multivariate construct, and people vary widely in the skill and ease with which they think. Some psychologists define 'thinking' as the mental manipulation of symbolic representations of objects and of relations among objects. Consider, for example, a chess player who is contemplating the next move; in deciding which move to make, she needs to mentally envision or rehearse a limited subset of all possible moves and countermoves by her opponent. Skillful chess players use strategies or plans for deciding how to move. Similarly, an architect who is designing a building will mentally manipulate a symbolic representation of the building that is being planned in deciding how to design the structure. 'Thinking skills' are the plans, strategies, or tactics for good or clear thinking. The terms used to define thinking skills – plans, strategies, tactics – are also used in military science to refer to military maneuvers designed to achieve an objective, which is an apt analogy for the abstract concept of skilled thinking. Good thinkers use higher-order cognitive skills, and, consequently, have better outcomes than poor thinkers.

There has been a growing interest in understanding and enhancing thinking skills because contemporary society is more complex than that at any previous time in history. Advances in technology have created an information glut, and workplace skills are increasingly technical at all but the very lowest levels of employment. As a result of these changes, a greater proportion of the general population needs more advanced thinking skills. Thus, there is increased concern about the identification, development, and transfer of those skills that characterize clear, precise, purposeful thinking.

Good or clear thinking is called 'critical thinking'. 'Critical thinking is the use of those cognitive skills or strategies that increase the probability of a desirable outcome. It is used to describe thinking that is purposeful, reasoned, and goal directed – the kind of thinking involved in solving problems, formulating inferences, calculating likelihoods, and making decisions' (Halpern, 2003). Critical thinkers are predisposed to use these skills; they are willing to engage in the hard work of critical thinking. Thus, any consideration of thinking skills needs to be considered along with the disposition or willingness to use those skills.

A Taxonomy of Thinking Skills

There are several schemes for categorizing critical thinking skills (Halpern, 1998). A five-part taxonomy that encompasses many of the skills that have been identified in reviews of the literature (e.g. Jones *et al.*, 1995) uses the following organizing categories: (a) *Verbal reasoning skills*: the skills listed under this rubric include those that are needed to comprehend and defend against the persuasive techniques that are embedded in everyday language (also known as natural language). (b) *Argument analysis skills*: an argument is a set of statements with at least one conclusion and one reason that supports the conclusion. Argument analysis requires the skills of identifying conclusions, rating the quality of reasons, and determining the overall strength of an argument. (c) *Skills in thinking as hypothesis testing*: the rationale for this category is that much of our day-to-day thinking is like the scientific method of hypothesis-testing. In many

of their everyday interactions, people function like intuitive scientists in order to explain, predict, and control the events in their lives. (d) *Using likelihood and uncertainty*: because very few events in life can be known with certainty, the correct use of probability and likelihood plays a critical role in almost every decision. (e) *Decision-making and problem-solving skills*: in some sense, all of the critical thinking skills are used to make decisions and solve problems, but the ones that are included here involve the use of multiple problem statements to define the problem and identify possible goals, the generation and selection of alternatives, and judging among the alternatives.

Taken together, these five categories define an organizational rubric for a 'thinking skills' approach to critical thinking. They have face validity and can be easily communicated to the general public and to students, and offer one possible answer to the question of what to teach when the educational goal is improvement in thinking. Thinking skills are often difficult to articulate because thinking is an abstract concept. Some common distinctions among types of thinking are presented in the following sections.

REASONING

Reasoning skills are one category of thinking skills. The formal discipline of reasoning is closely tied to logic, the branch of philosophy that explicitly states the rules for deriving valid conclusions. According to logic, a conclusion is valid if it necessarily follows from premises or statements that we accept as though they were true. A conclusion that does not follow from its premises is illogical. A distinction is often made between deductive and inductive reasoning.

Deduction and Induction

Deductive reasoning applies to a class of thinking tasks in which the thinking process begins with statements that are known or believed to be true. The task is to determine if a conclusion is valid. There are several types of deductive reasoning tasks, each characterized by the nature of the relationship among the premises. Linear reasoning tasks include concepts that vary along a single dimension, such as height (e.g. 'A is taller than B, and B is taller than C,' therefore A is taller than C'); spatial location (e.g. 'A is to the left of B, B is to the left of C'), and intelligence (e.g. 'A is smarter than B, B is smarter than C'). Syllogistic reasoning tasks include concepts that are related by the inclusiveness of their group membership (e.g. 'All A are B, some B are C'). Conditional reasoning tasks include 'if–then' relationships (e.g. 'If A, then B. B occurred'). In all deductive reasoning tasks, conclusions are always valid if they must be true given that the premises are true.

By contrast, inductive reasoning applies to tasks where observations are collected and generalized to suggest conclusions about the population from which the observations were drawn. For example, if every secretary you have ever met was female, you might inductively conclude that all secretaries are female. Unlike conclusions from deductive reasoning tasks, conclusions from inductive reasoning tasks can never be proven to be true because, in this example, it would take only one secretary who is not female for the conclusion to be false, and unless you have observed every secretary in the population, you cannot be sure that an unobserved secretary would not make the conclusion invalid. Hypothesis-testing skills are conceptually similar to inductive reasoning skills. Conclusions are always probabilistic with inductive reasoning; better conclusions will result from large and representative samples of the population, but as long as the conclusion is based on a sample, there is always some probability that it will be incorrect.

Although it is common to differentiate between deductive and inductive reasoning tasks, the distinction may not be a particularly useful description of how people reason in real life. In everyday contexts, most people switch back and forth from inductive to deductive reasoning in the course of thinking. Our hypotheses and beliefs guide the observations we make, while our observations, in turn, modify our hypotheses and beliefs. Often, this process will involve a continuous interplay of inductive and deductive reasoning. Thinking in real-world contexts almost always involves the use of multiple types of thinking skills.

Are Humans Logical?

When people use the formal rules of logic in formulating and testing conclusions, we label their thinking 'rational'. Do most people use these rules, or are we (mostly) irrational (Stanovich, 1999)? This question can be addressed from both an experimental and a philosophical perspective.

On the one hand, there is an abundance of data that shows that under most everyday circumstances, few people use the rules of formal logic. It seems that in the everyday use of reasoning, few people determine whether a conclusion is valid

solely on the basis of the statements that are given. Instead, they alter the statements according to personal beliefs and then decide whether a conclusion follows from the altered statements. People function under a kind of personal logic in which they utilize their personal beliefs about the world to formulate conclusions about related issues. People tend to use *pragmatic* reasoning rather than the rules of logic: the word 'pragmatic' refers to anything that is practical. In real life, people have a *reason for reasoning*, and sometimes the laws of logic are at odds with the setting, consequences, and commonly agreed upon reasons and rules for deriving conclusions. For example, according to the rules of logic, the sentence 'If you wash the dishes, I will give you $5' also implies that I may give you $5 even if you do not wash the dishes. In most everyday settings, 'If you wash the dishes, I will give you $5' means '*if and only if* you wash the dishes, I will give you $5'. Thus, people use everyday or pragmatic logic, which is not the same as the formal laws of logic.

In real-world settings, most people fail to accept the logical task. In other words, even when they are told to base their conclusions on the premises that are given, they use their prior knowledge and personal belief systems instead of reasoning from only the given premises. In most real-life settings, we would expect that people would use their beliefs and knowledge about the world when reasoning. Often, people are able to use the rules of formal logic, but reject these rules as irrelevant in most real-life settings. Thus, there is a distinction between the ability to reason logically and the practice of reasoning logically.

PROBLEM-SOLVING

Components and Stages

For many psychologists and other scientists, the term 'problem-solving' is synonymous with thinking. A problem exists whenever there is a gap between where problem-solvers are and where they want to be. In understanding how people solve problems, it is useful to think of all problems as composed of different parts – a start state, a goal state, solution paths that lead from the start state to the goal state, blind paths that may appear to connect the start and goal states but, in reality, do not, and the entire problem space, which encompasses all of these parts. The goal of any problem-solving task is to move from the start state to the goal state in an efficient manner. Problems occur in virtually every aspect of life – making one's money last until the next pay check, completing a crossword puzzle, discovering a cure for a dread disease, negotiating a peace settlement, finding a mate, etc. With a thinking skills approach, guidelines or heuristics that apply to the type of problem being solved are tried out as a means of achieving the goal.

Problem-solving often proceeds in a series of stages. In the first stage, the problem-solver becomes familiar with the nature of the problem – understanding the start and goal states and the constraints on reaching the goal. In the second stage, the problem-solver produces several possible solutions. Finally, there is a judgment or evaluation stage when the various solutions are assessed in order to select the best one. Sometimes, when there do not seem to be any readily evident solutions, there is an incubation stage. During this time, the problem-solver seems to forget about the problem and goes on to other activities. The term 'incubation' suggests the image of a mother hen sitting on eggs that will hatch into chicks; similarly, good ideas can 'hatch' from an incubation stage, during which the problem is not being actively considered. There is a large literature of anecdotal evidence suggesting that time away from a difficult problem can sometimes lead to good solutions, perhaps because a 'time out' allows for ineffective mental sets to dissipate. It is difficult to demonstrate incubation effects in the laboratory, which necessarily weakens causal statements about the validity of incubation.

Well-defined and Ill-defined Problems

In real life, most problems are ill-defined. Ill-defined problems have multiple possible goals and the problem itself has to be recognized in the hectic array of the natural environment. For example, someone with a 'money problem' would need to recognize that there is not enough money to pay all the bills and then would have to decide which of many possible goals should be pursued – for example, ask for a raise, get a second job, find a less expensive apartment, move in with a friend, rob a bank, etc. Some of these solutions would cause other problems (e.g. jail time for bank robbery), so each possible solution and goal state needs to be assessed in terms of the new problems that would arise in solving the money-shortage problem. One thinking skill for ill-defined problems is to restate the problem and several different goal states as a way of generating multiple possible solutions. Redefinitions of the desired goals should suggest additional solutions for the problem.

By contrast, the problems that are typically used in formal learning environments and in textbooks are well-defined. Students are given all the information they need to solve the problem, and it is easy to determine whether the problem has been solved. Usually there is only one correct answer. For example, problems in mathematics classes and physics classes are usually well-defined. Well-defined problems are often artificial and have been criticized for giving students a false picture of how problems are identified and solved in out-of-school settings.

MENTAL MODELS

How do we understand complex, abstract topics such as human nutrition, the national debt, or how electricity works? The information that we have about topics like these is organized into interconnected knowledge structures that specify causal, predictive, and covariate relationships, hierarchies of categories, and other relationships that allow us to understand these topics. For example, we may believe that eating vegetables and fruit will make someone healthy (causal relationship) and that a healthy person has energy (covariate relationship) and will live a long life (predictive relationship).

An interconnected web of concepts that we use to make sense of the world is called a *mental model*. We use the mental models that we create to make decisions and to assess claims. Mental models are altered when we encounter new information that has to fit into an existing model (e.g. eggs are part of a healthy diet), and the model has to change when new information exposes an error in the existing model (e.g. the amount of protein eaten needs to be limited). Individuals with expertise in these areas have extensive and accurate mental models. The mental models for complex topics are for most people incomplete, a mix of solid, factual information, some half-truths, and some incorrect information. When we make decisions about what and how much to eat, whether it is safe to eat vegetables that have been irradiated, or whether it is worth the additional cost to buy produce that has been grown without pesticides, we rely on the unique model of human nutrition that we built from our partly solid, partly incomplete, and partly wrong information.

It might seem that mental models would continually be improving as we encounter additional relevant information, but, in fact, beliefs about the world that make sense to the individual are highly resistant to change. Instead, we tend to interpret new information in ways that make the new information fit into our existing models, and to reject information that runs counter to our beliefs. This is why it is so difficult to get people to reassess their positions on controversial topics, such as capital punishment or gun control. We tend to concentrate on information that is consistent with prior beliefs and downplay or ignore contradictory data (Nickerson, 1998).

ANALOGICAL PROCESSES

Analogies are pervasive in human thought. Whenever we focus on the similarity between two objects or ideas or other phenomena, we are using an analogical process. Analogies are always imperfect because they focus on the similarity between objects and events that are not identical. Analogies are frequently used in problem-solving by noticing the way in which two problems that differ in surface features (e.g. radiating a tumor and capturing a fortress) are similar in their deep structure or underlying features (use multiple lines of attack when radiating a tumor or capturing a fortress). When using analogical processes in thinking, we are mapping attributes from a known domain onto a novel domain. Research has shown that the spontaneous use of analogical processes in problem-solving depends on the thinker's ability to recognize when two seemingly dissimilar topics are similar in their underlying structure.

Unlike the sciences, where the rules of evidence require causal experimental designs (with random assignment of participants to groups), the legal profession relies most heavily on analogies to persuade a judge and jury that the conclusion the lawyers favor is the best one. The basic premise of a case law system is that each situation is unique, so no general statements of law can be counted on to settle complex individual cases. Instead, similarities are noted between a case being tried and the facts and circumstances of earlier cases. Thus, lawyers and others in the legal system base their arguments on the degree to which two or more cases can be thought of as similar. Of course, the opposing side in a legal case will attempt to argue that the dissimilarities are more important than the similarities when the earlier case had an outcome that was not desired by the opposing lawyers.

Creativity and Analogies

Creative thinking is a type of thinking in which the outcome is unusual and appropriate (or meaningful or especially good; Halpern, 2003). Creative

outcomes often involve 'noticing' the similarities between two different domains and then borrowing a concept from one domain to apply in the other. For example, in an analysis of the creative genius of Alexander Calder (1898–1976), one author noted that Calder combined the bright colors and abstract art of Piet Mondrian with the jewelry-making skills he learned from his mother to create colorful mobiles that hang from wire, much like a very large earring (Weisberg, 1993). Similarly, a new method for bonding dental material onto teeth was based on an analogy from another wet environment: the suction used by barnacles to attach themselves to piers served as the inspiration for suction-based attachments for teeth. These are two of a very large number of creative outcomes that can be traced directly to a situation that is highly dissimilar in surface information, but essentially similar in its deep structure.

When solving a problem, one heuristic is to think of a problem in nature that is essentially similar to the one you are solving. The underlying idea of this technique is that there are many ingenious solutions in nature that we can use for other, more mundane problems. The idea for Velcro, those two-sided sticky closure tabs that can be found on shoes and many clothing items for children and the disabled, is analogous in design to the way the sticky balls that drop from trees adhere to shoes and clothing when we walk through a forest. The closing for many bottles of glue is similar to a flap-like mechanism that closes the human bowel. When these common natural solutions are applied to problems with similar underlying structure, they are often judged to be creative.

THINK-ALOUD PROTOCOLS

How do we study something as unobservable and illusive as thought? Thought leaves no directly observable traces and can be known or suspected only by inference. One way that researchers study thinking skills is by having thinkers 'think aloud', which means that thinkers are asked to say out loud everything they are thinking as they work through a problem or comprehend a text or oral message. The idea of think-aloud protocols is that they make private activities overt so that thinking can be studied and modified. Unfortunately, it turns out to be very difficult to articulate the thought process. It is as though the act of speaking aloud about the thinking process alters that process. By directing attention to something we usually do without any conscious thought, we change the very activity that we want to study. Very often people cannot say what they are doing when they are thinking.

Verbatim records of think-aloud protocols have shown that many people use images when they think, especially when they are thinking about concrete nouns, which are easy to image. When think-aloud protocols are analyzed, each portion is broken into separate segments and scored as to content, relationship to earlier and later segments, number of hypotheses considered, and the order in which thoughts occur. There has been some attempt to use the protocols of experts as a way of training novices how to think about topics in the expert's domain of knowledge. By making individuals think aloud, they are being forced to evaluate their thinking strategies, with the goal of enhancing communication about the thinking process. Think-aloud protocols are also used in the design of artificial intelligence programs that mimic the strategies used by real humans.

CONCLUSION

There are many varieties of thinking skills, ranging from the formal rules of logic used to assess the validity of a conclusion to the heuristics that are designed to increase the probability of a creative response. There is much interest in understanding and teaching the skills of critical thinking because enhanced thinking skills are needed in our increasingly complex world. Studies have shown that often people can use the rules of formal logic, but choose not to because it would require that they disregard everything they know about the world. Thinking can be studied by having people verbalize everything they are doing when they are working on a problem. Although results obtained with this technique of 'think-aloud protocols' have provided a glimpse into some of the processes used in thinking, it cannot capture the full complexity of human thought.

Cooperation and Conflict, Large-scale Human

Advanced article

Francisco J Gil-White, University of Pennsylvania, Philadelphia, Pennsylvania, USA
Peter J Richerson, University of California, Davis, California, USA

CONTENTS

Along with a few other animals such as bees, termites, ants and wasps, humans live in societies that cooperate for a common goal. Serving the greater good seems to go against basic Darwinian theory, so the question is, how and why have complex, cooperative societies developed in some species? In spite of so much cooperation, why do human societies remain so conflict ridden?

INTRODUCTION

Suppose you stroll to the corner restaurant for breakfast: eggs, bacon, and a glass of orange juice. A simple activity? No. Mind-numbing complexity is more like it. A farmer in Virginia produced your egg, another in Florida your orange juice, and yet another in the Midwest your bacon. Different truckers brought each of these to a supermarket. The restaurateur then bought them there and had them prepared for you. Seven people are involved in your 'simple' activity? Well, no. This is a caricature. Just for starters, the egg farmer/capitalist hires several workers to operate considerable equipment, all of which was purchased from other companies, made up of capitalists and workers, who in turn bought their parts from yet other companies, which…(the mind reels). Your day has barely begun, and a few dollars' worth of breakfast has already brought an army of considerable size to your service.

Only a select few animal species have societies with extensive cooperation, fine coordination, and massive division of labor: the social insects (bees, termites, ants, and wasps), possibly naked mole rats (but their level of complexity is far below that of the advanced social insects, as is the scale of their societies) and us. This form of social organization is clearly evolutionarily successful; social insects are diverse and abundant, especially in the tropics, and human populations grow so fast that our rapid and energy-expensive expansion into every conceivable niche is a considerable threat to other species and the climate. Given this, one might be naturally inclined to ask: why is this adaptation not more common among the species of the world? After all, beneficial adaptations should proliferate, shouldn't they?

Actually, for modern students of evolutionary theory – trained as they are in the framework of what has been called the 'modern synthesis' and 'neo-Darwinism' – the puzzle is rather different. Modern biologists are trained to be surprised not by the rarity of this dramatic adaptation but by the fact that it is possible at all. How could something this strange evolve? Darwin himself worried that the self-sacrificial altruism of the social insects might be fatal to his theory. To see the problem his way, we must briefly develop the theoretical instincts of a modern evolutionary theorist.

DIFFICULTIES ACCOUNTING FOR HUMAN ULTRA-SOCIALITY IN DARWINIAN TERMS

Individuals attempt to reproduce before they die, and some do better than others. If the features of an individual are passed on to the offspring, then good reproducers will beget good reproducers, who in turn will beget good reproducers once again. And so on. Each time, good reproducers leave more descendants than other types, so after a number of generations the entire population will become of the type that reproduces best (with the

exception of frequency-dependent effects, when selection will maintain several types at equilibrium). This is the basic Darwinian insight of 'natural selection'.

The mechanism responsible for stable similarities between parent and offspring is genetic inheritance. Mere individuals live and die, but genes can potentially keep going forever. Modern Darwinism focuses on changing genes in order to understand the processes responsible for historical change in organic populations.

The analytical focus of a modern Darwinian is the 'gene's eye view' heuristic, which relegates individual organisms to the status of temporary 'vehicles' conveying the potentially immortal genes from one generation to the next. Genes that have a better chance of proliferating are those that increase the reproductive success of their vehicles in competition with other vehicles. Finding 'unselfish' genes that cause their vehicles to suffer sacrifices to benefit another vehicle's reproduction is thus a major puzzle. But nothing in these arguments really depends upon there being a single gene for altruism; this is just a convenient way to strip the problem to its bare essentials. Darwin was right to worry.

This brings us to the social insects. Massive division of labor is impressive, but the reason it is possible in the first place is the truly big puzzle. Although many ants in a colony will famously give up their lives protecting it, for example, this is only because they have already given up their reproduction. The latter is, to a Darwinian, the really dramatic fact. How could they give up their reproduction? In human ultra-sociality, on the other hand, defense is the most dramatic puzzle because those who risk and often give their lives to defend their society are indeed capable of reproducing and by fighting give up some or all of this capacity.

For non-human altruism, twentieth-century evolutionary theory has provided two elegant and very successful explanations: kin selection and reciprocity. Before examining them, notice that the fundamental issue for any explanation in this domain is the problem of assortment. The gene's eye view allows us to state the obvious: since the gene is trapped inside its vehicle, the vehicle must reproduce if the gene is to proliferate. So how can a gene proliferate more than competing genes if it makes its vehicle transfer reproductively useful resources to other vehicles? At first glance this would seem impossible, and for most kinds of resource transfers it will be. But if the vehicle is making resource transfers to other vehicles also containing copies of that same gene, then the gene promotes its own proliferation at one remove.

The question therefore is: what could cause vehicles with altruistic genes to assort with one another?

KIN SELECTION

Green Beards

Imagine a gene – 'G' – producing two effects: (1) it gives you a green beard, and (2) it makes you help those with green beards (Dawkins, 1989, pp. 88–89). G's twin effects solve the problem of assortment: if you help those with green beards, then, because those individuals also have G (hence their beard), G is making you help other copies of itself. Copies of G can 'find each other' thanks to the beards, and therefore when G causes its vehicle to transfer resources to other vehicles it is nevertheless promoting the spread of G.

It is virtually impossible that the same gene will cause a discriminatorily altruistic behavior and also the cue used to discriminate, unless altruism itself is the cue. Theoretical considerations suggest that it is also highly improbably that "green beard" genes can arise as a result of two tightly linked loci where the gene at one locus would code for the green beard, and the gene at the other for the altruistic behavior. But the thought experiment brings the problem of assortment into sharp focus: if an 'altruistic' gene is to prosper, its vehicle must confer benefits disproportionately on other vehicles containing copies of the same gene. Something like a green beard must facilitate this nonrandom assortment for altruistic genes to evolve.

In one proposal (Hirshleifer, 1987; Frank, 1988), if altruism is mediated by emotions, and if emotions result inevitably in facial expressions and other bodily manifestations, and if such manifestations are hard to fake, then altruists can assort with each other by examining each other's expressions of emotion. In other words, those who 'look' altruistic probably are, so altruists can find and prefer each other for mutual benefit. Genes coding for altruistic emotion/displays will be favored.

But the problem with this kind of 'green beard' argument is that, once the signal is common, selection will favor selfish individuals who pretend to be altruists but don't help. Actors and confidence artists can fake emotions well enough to fool us. Darwinians indeed expect that the evolution of clever, green-beard-exploiting sociopaths will undermine the evolution of emotional signals. This theoretical embarrassment to the green beard

argument is accompanied by an empirical one: emotions that appear very similar to ours occur in other mammals (as Darwin himself wrote in his book *The Expression of Emotions in Animals and Man*). Thus, if nonhumans can produce emotions and signal them, why can't they use this to assort for altruism and build ultra-social communities? Human emotions are no doubt involved in motivating and signaling cooperation in humans, but this is likely to be a secondary effect of other evolutionary processes, not something that can be shaped directly by natural selection to favor the original emergence of altruism. If it could, many nonhuman mammals should have it.

Kinship as a 'Green Beard' Substitute

If not emotional green beards, then what? Suppose that if you have the altruistic gene, then you can use an observable cue X to guess with some probability p that somebody else also has the gene. If so, then the altruistic gene – call it gene 'K' – will be helping itself so long as it specifies 'to individuals with cue X give a benefit size b, where b satisfies the following:

$$bp > c,$$

where c is the cost to the altruist of transferring the benefit. In other words, out of a large population of individuals bearing cue X and therefore receiving my help, only a proportion p will actually carry gene K. Thus – on average – the benefit that K's vehicle (me) confers on other copies of K is not b but the scaled down benefit bp. If this weighted payoff is greater than what it costs me to help, then K is giving itself a net benefit.

In 1964 William Hamilton argued persuasively that kinship can play the role of cue X. Consider two siblings, Higley and Bob. Bob carries a gene K that makes him an altruist. What is the probability that Higley also has gene K? Well, Bob's father passed down half of his genes to each sibling, who get the other half from their mother. These samples are subject to independent random assortment, so that Bob and Higley share a quarter of their father's genes and a quarter of their mother's. Thus, the probability that Bob and Higley share gene K is at least $p = \frac{1}{2}$. The probability may be higher if the gene is common in the population, but the critical value is the chance that siblings share the identical gene by common descent. This is the same as the probability of sharing the gene when it is rare. So suppose that K specifies a behavior that makes Bob give 5 units of benefit to siblings like Higley, for a cost to the actor of 2 units. Will K spread? Yes.

$$\frac{5}{2} = 2.5 > 2$$

On the other hand, if at the cost of 2 units K confers only 3 units of benefit to these recipients, then K will not spread.

What have we shown? That if a gene makes its vehicle assist its close kin, then it has found a way for its vehicle to assort (a fair amount of the time) with other vehicles carrying copies of the same gene. This assortment is what makes it possible for altruistic genes – within benefit/cost limitations – to evolve. This is, of course, far short of the perfect assortment that green beards would make possible, but it is what nature uses because green beards or their equivalents are usually impossible. This 'kin selection' argument explains the widespread observation of nepotistic altruism in humans and many other species. In particular, it explains the ultra-sociality of the social insects, for in, say, an ant colony, everybody is a close relative due to the fact that everybody is a child of the queen.

Washburn's Fallacy

The above insight is usually expressed as Hamilton's famous rule: $br > c$. Here r replaces p, and stands for 'coefficient of relatedness': the probability that two individuals have identical copies of the same gene, descended from the same, recent ancestor gene. Thus, recall that for Higley we calculated the probability that he has an identical gene to Bob's that is in fact descended from their father's or mother's copy.

The r in Hamilton's rule is often misinterpreted as 'the probability or proportion of genes shared in common between two individuals'. This is commonly referred to as 'Washburn's fallacy' because the anthropologist Sherwood Washburn used to argue – in critical fashion – that Hamilton's rule would imply altruism towards everybody and only slightly more altruism towards kin. Why? Because any of us shares about 80 percent of our genetic alleles with any other randomly chosen member of the human species, and 80 percent is a lot. If true, this argument would appear to solve the puzzle of human ultra-sociality, but it would create an even bigger puzzle: why aren't many more species ultra-social?

But Washburn's argument follows only if the r is interpreted as the proportion of genes shared in common, rather than as the probability of sharing identical copies of a gene descended from the same, recent ancestor.

Why is Washburn wrong? Even if 80 percent of the people in the population have the altruistic gene (and the others have a selfish alternative), since Washburn's altruistic gene says 'help anybody', having an altruistic gene will not make a vehicle disproportionately likely to get help. The 20 percent of people not sharing the altruistic gene will get the same benefit as the 80 percent that do, and since they don't pay the costs of helping others, they have higher fitness. Selfish genes will increase in frequency and drive out the altruistic genes. An altruistic gene that said 'help close kin', on the other hand, would make altruistic genes disproportionately likely to get help. Individuals with the altruistic gene are more likely than randomly chosen members of the population to have close relatives with copies of this gene, and are therefore more likely to get helped, than individuals with the selfish gene.

Washburn could have avoided his fallacy simply by imagining how his 'help anybody' gene could have become common in the first place. Here things become crystal clear: unless a gene codes for a behavior promoting its spread when it is a new and therefore rare mutation, the gene will wink out of existence as quickly as it appeared. When the 'help anybody' gene first appears virtually no other vehicles have copies of it, so 'helping anybody' confers no benefits on the gene's spread and the gene quickly goes extinct. A new mutant gene is, by definition, rare, and thus only close kin of its vehicle are likely to carry copies. An altruistic gene therefore has a chance of spreading from low frequency only if it discriminates in favor of close kin. Why not distant relatives? When the gene is rare, distant relatives are about as unlikely to have copies of the gene as a randomly chosen member of the population – in fact, at the limit, these are the same, because all members of a population are (very) distant relatives.

Kin selection can explain nepotism in many species, most spectacularly in the case of eusocial ants, bees, and termites, where huge numbers of close relatives cooperate. But in human social systems, even at their most simple, average r is so low that we may well say members are not, in fact, related. As Campbell (1983) rightly observed, human societies, unlike the social insects, exhibit cooperation among reproductive competitors. If kin selection can cause ultra-sociality with human levels of average r, then many more animal species should have such complex societies. Humans are probably a special case requiring a special explanation.

RECIPROCITY

In the logic of reciprocity (first explored by Robert Trivers (1971)) an 'actor' suffers a cost to benefit a 'recipient', expecting a return benefit at some other time (I'll scratch your back if you scratch mine). The time delay distinguishes this from 'trade' as commonly understood, for trade lacks the risk of no payback. Perhaps this explains the unfortunate popularity of Trivers's coinage 'reciprocal altruism', which has caused much confusion. If we stick to the gene's eye view, however, the terminological tangles quickly evaporate. When will a gene specify a transfer of reproductively relevant resources from its own to other vehicles? Kin selection can lead to this, as we have seen. Reciprocity can too, but it differs from kin selection in that, so long as the recipient pays back the favor, it matters little whether the recipient's motivation arises from a gene identical by recent descent (or indeed from some entirely different gene). Reciprocity may even occur between species, as in mutualisms. What matters is that there be some reasonable probability that the favor will be returned and a method for assessing this probability. If favors are made when they are relatively cheap for the actor but beneficial for the recipient, and if they are returned, then a gene making its vehicle do such favors will prosper.

How well will a rare reciprocity gene do? When it is rare, a vehicle carrying the gene is very unlikely to meet another such vehicle that will reciprocate its good turns. Thus, the evolution of reciprocity requires some initial assistance from kin selection. For example, since the individuals carrying a new and rare mutation will be close relatives, vehicles carrying the reciprocity gene will be likely to meet other such vehicles – even when rare – if individuals are organized in local kin groups. Once the gene for reciprocity becomes a little more common, such kin-biased population structure is unnecessary for the success of the reciprocity gene.

Even when reciprocators are common, it is important to ensure assortment to prevent 'cooperators' from being exploited by 'defectors', and this brings us to the question of the cognitive mechanisms involved. Theoretical considerations suggest that nice-but-not-gullible strategies like 'tit for tat' (if you cooperated with me last time, I will cooperate this time; if you didn't, I won't) are at the heart of our reciprocating psychology (Axelrod and Hamilton, 1981; Axelrod, 1984), but the actual mechanisms are complex and subtle.

The logic of reciprocity can easily explain cooperation in very small groups, especially dyads. However, reciprocity cannot so easily explain cooperation in larger groups (Boyd and Richerson, 1988). In a dyad, my help is a private benefit directed to one individual; if the partner does not reciprocate, I can ignore this individual in the future and direct my help towards another who *will* pay back my assistance. But when my benefit is consumed not by one partner but by two or more simultaneously (say, for example, that I build a wall which protects everybody who lives inside of it), the structure of the problem changes. (Notice, by definition, if the benefit is being consumed by a group, this means I cannot selectively withdraw the benefit from nonreciprocators, and am therefore producing a 'public good'. If I can discriminate, then we don't really have a 'group', but are back to dyadic interactions.) When everybody in the group returns my favor we all benefit, but if some don't return my favor, they create a dilemma for me: either (1) I can cooperate, and reward the defector (who gets the benefit without paying the cost of returning my favor); or (2) I can defect, giving up the benefits of reciprocity with those in the group who *are* reciprocators. The larger a group is, the less likely that just by chance it will have disproportionately large numbers of cooperators, so genes supporting (2) will do better with increasing group sizes. In particular, when the gene for reciprocity is new and therefore rare, the chances of having many reciprocators in a large group are vanishingly small. As groups get larger, then, kin selection is less and less effective at helping group-based reciprocity get started. For groups as small as 10, the potential to get group-based reciprocity off the ground becomes very small.

Some have considered the indirect benefits of reciprocity as a possible explanation for human ultra-sociality that sidesteps the public goods problem. Trivers (1971) speculated that given widespread dyadic reciprocity, selection would favor a strategy that used altruism towards third parties as a gauge of trustworthiness. Richard Alexander (1987) argued that the resulting structured webs could solve the problem of reciprocity in large groups. The argument is that humans are smart enough that each individual can keep track of who reciprocates with third parties; a strategy that prefers such reciprocators as partners will do well because it is better at picking low-risk partners. The resulting large webs of 'indirect reciprocity' can build much more complex societies of nonrelatives than in other species.

More recent models (Nowak and Sigmund, 1998a, b) challenge Boyd and Richerson's (1988) conclusion that large-group reciprocity cannot evolve. However, as Leimar and Hammerstein (2001) argue, the Nowak and Sigmund model makes a very unrealistic assumption: interactants never make mistakes. (see also Panchanathan, 2001). They show that when mistakes are allowed to occur, indirect reciprocity does not easily evolve because one needs information about people's intentions, not just their behavior (e.g., did Bob not reciprocate because he was punishing a nonreciprocator or because he himself is a nonreciprocator?). Indeed this is true even of dyadic reciprocity: if people make mistakes, we need to distinguish between honest mistakes and defections, and for that we need a gauge of people's intentions (Sugden, 1986; Boyd, 1989; Boerlijst *et al*., 1997). Panchanathan (2001) concludes that language (in the form of gossip) can furnish people with very good information about the reputations of others, where reputation (based on the person's known record of interactions) works as a gauge of someone's probability of defection. Indirect reciprocity may thus help explain why a language-endowed social mammal was capable of organization on the scale of hunter–gatherer bands, which are larger and considerably more complex than other mammalian societies but small enough that people can keep track of reputation through gossip. Whether indirect reciprocity is a sufficient explanation for organization on the level of tribes, chiefdoms, and states is unclear.

Undoubtedly, dyadic and indirect reciprocity are importantly involved in the evolution of cognitive mechanisms such as guilt and shame, and their associated signals. For example, Fessler (1999) provides a detailed analysis of the situations that elicit shame. The purpose of the emotion/display is apparently to signal one's recognition of having made a 'mistake', with the implication that one is not really challenging the social norms. The importance of signaling contrition is evidence that people care about intentions, not merely behaviors.

Signaling

If large-scale organization does depend on generating public goods altruism, perhaps such behaviors can emerge through signaling. If I benefit from advertising my qualities to others, I will want a signal that cannot be faked by lower-quality competitors. This may explain the provision of expensive public goods as a form of signaling the quality

of one's genes (Smith and Bliege-Bird, 2000). Male hunters, for example, may share difficult to catch prey items with everybody because they index the hunter's skill. Attention-getting sharing thus might ensure a strong broadcast of the 'hunting quality' signal. The benefits to such hunters would be things such as being preferred in the market for mates and greater political leverage.

The first benefit is obvious, as those who make themselves known as good hunters will be perceived, on average, as better providers, and their popularity in the marriage market will allow them to choose the most desirable (e.g., rich, healthy, hardworking, fertile) partners. This translates into healthier and more abundant progeny. The second benefit requires that there be a reason for other people to defer to the political interests of the hunter (and thus entails a form of trade or reciprocity, even if not a straightforward one). Since the prey is being shared collectively, one will not get more meat by deferring to the hunter, so why do it? Hawkes (1990) argues: in order to keep the hunter in the group (although she refers to the benefit that the hunter gets as 'social attention'). But this explanation does not solve the problem of selfishness, it merely places it elsewhere, as Smith and Bliege-Bird (2000) argue. Henrich and Gil-White (2001) suggest a reciprocal altruism hypothesis to explain deference to good hunters: sycophants who defer to the political interests of a hunter are buying access in order better to acquire the very skills the hunter has advertised.

The signaling hypothesis probably explains some altruism. However, it suffers from the same general problems as 'green beard' explanations. Why can't the selfish use the signals of altruists as a cue for whom to exploit selfishly? Why doesn't the signaling of qualities support complex societies in other species? Costly displays of good genes occur in many species, yet in no other species is aid to the group used to signal value as a mate. Emotional commitments to an altruistic moral order no doubt are a proximate explanation for such behaviors, but such emotions in turn have to be explained. The real puzzle is explaining how we came to be equipped with such emotional attachments to norms, and for that we probably need an explanation in terms of group selection generating the emergence of punishment for deviance, as argued below.

CULTURAL GROUP SELECTION

The Problem of Genetic Group Selection

Suppose we have two groups of the same species, one full of individuals with generalized altruism genes, and the other full of individuals with selfish genes. Which gene will do better evolutionarily? The fitness of a gene is equal to the average fitness of the vehicles carrying it, so here an average altruistic vehicle has higher fitness because it is surrounded by other such vehicles (which results in profitable mutual assistance). A selfish vehicle, on the other hand, has relatively lower fitness because it is surrounded by other selfish vehicles.

So the altruistic gene will win? The problem is maintaining sufficient variation between groups for group selection to be a potent force. Two forces erode variation in altruism between groups: the relative success of selfish individuals within groups and the migration of selfish individuals from group to group. Group selection can favor altruistic genes so long as (1) migration is sufficiently low; and (2) the fitness benefits of being in a group of mostly altruists is so large that new groups of altruists which competitively displace selfish groups are generated at a pace fast enough to more than compensate for the dilution of altruists by within-group processes and the arrival of selfish migrants.

Some students of altruism (Sober and Wilson, 1998) like to think of kin selection as a form of group selection in which relatedness creates sufficient variation between groups for group selection to operate. Terminological disputes aside, the kin selection view of groups illustrates the problem with large-scale group selection; if kin groups are reasonably outbred, relatedness falls dramatically with genealogical distance and the evolution of altruism is restricted to close kin. Outbreeding is equivalent to migration into the kin group. Observed rates of migration are generally too large to allow relatedness to build up in large groups, hence making group selection in them implausible. Ever since Williams's (1966) criticism of early attempts to explain adaptations as group selected, many evolutionists reject group selection as a plausible explanation almost as a matter of principle.

A Cultural Solution

Despite the problems with large-scale group selection explanations in outbred organisms, many, starting with Darwin, have speculated that some form of group selection is important in the special case of humans (Sober and Wilson, 1998). Humans certainly do compete as groups, and organized warfare is a spectacular example. But our groups are so porous (e.g., successful groups often induce a flow of mates from less successful ones) that one is brought back to the problem of migration. If some process could minimize the effects of migration – something quintessentially human – this would give us an elegant explanation simultaneously accounting for human ultra-sociality and also for the fact that other animal societies are restricted to forms of altruism derived from kin selection. That something might be culture, defined here as the intergenerationally stable, high fidelity, social transmission of information (socially transmissible packets of information are often referred to as 'memes', after Dawkins (1989, chap. 11)).

Theoretical models show that, given a capacity for acquiring information directly from others (which appears to be uniquely hypertrophied in humans), a bias for conformity will evolve. Conformity is adaptive because it helps individuals pick up useful memes that others have already converged upon (Boyd and Richerson, 1985; Henrich and Boyd, 1998). It is also advantageous to the degree that human societies often involve games of coordination in which direct advantages stem from doing what others do, such as driving on the agreed-upon side of the road (Gil-White, 2001). When in Rome, do as the Romans do. Many psychological studies have documented this cognitive bias (Miller and McFarland, 1991; Kuran, 1995; Asch, 1956, 1963). Conformity reduces the problem of migration (Boyd and Richerson, 1985; Henrich and Boyd, 1998) because when migrants absorb the memes in their host community they tend not to affect the local equilibrium. Rather the local equilibrium tends to convert *them*. Thus, selfish migrants arriving in an altruistic group will – if they are conformists – absorb the local altruistic norms even as their own are discriminated against, thus preserving rather than diluting the altruistic character of the group. This allows cultural group selection to generate new altruistic groups fast enough to overcome the rate at which spontaneous (cultural) mutations of individuals from altruistic to selfish erode altruism within groups (cf. Soltis, Boyd, Richerson, 1995). If cultural group selection operated over sufficiently long periods of time in the late Pleistocene, gene-culture coevolution might have resulted in the evolution of innate predispositions and skills adapted to participation in group selected social units (Richerson and Boyd, 2001).

WITHIN-GROUP COOPERATION AND BETWEEN-GROUP CONFLICTS

A complementary explanation maintains that if a norm for punishing deviations is adhered to by most members of a group, it can stabilize anything, including a norm for altruism (Boyd and Richerson, 1992). If much group competition is active rather than passive (e.g., violent combat for land), then within-group altruistic norms maintained by punishment will confer dramatic advantages. This could make the production of new altruistic groups faster than the processes which dilute altruism within the group (Boyd *et al*., unpublished). The result would be a panhuman selection pressure for cognitive adaptations reducing the likelihood of 'mistakes' in order to avoid costly punishment (prosocial emotions such as duty, patriotism, moral outrage, etc. that commit us to predominant social norms even in the absence of coercion). These could easily form the basis for large-scale ultra-social organization, including dramatic cultural adaptations for collective defense. Such emotions could help explain why humans often engage in altruistic acts even in the absence of monitoring or reputational benefits and why they die anonymously in battlefields.

Clearly, the other side of the coin of group cooperation is group conflict. Groups that develop norms that channel their within-group cooperation towards outward bellicosity will force other groups to develop the same (or better) or become extinct. This process selects for ever stronger forms of within-group cooperation and outward aggression and is likely to be an important force responsible for the creation of ever larger and more complex social human groups.

IDEOLOGY, SYMBOLS, AND INGROUP MARKING

No society can exist without the acquiescence of its members to the roles they must play in the maintenance and reproduction of the social whole. Historically, anthropology and sociology were both centrally interested in the question of the functional organization of individuals into such roles (both disciplines owe much to the pioneering sociology

of Emile Durkheim and pioneering anthropology of Bronislaw Malinowski), but these days the topic itself has fallen out of favor with the rise of 'methodological individualism' and 'rational choice' perspectives that insist on a picture of human nature as driven by selfish, individualistic considerations. Rational choice theorists, however, can account for high-cost altruism, such as soldiers being willing to die in battle, only by including in the concept of self-interest rewards and punishments that are in turn hard to explain on individual selection grounds. A soldier may not fight out of altruistic feelings (though at least a few undoubtedly do). But whatever the personal motives (glory, duty, shame, need for recognition from others, blind respect for authority), his behavior is more likely the result of adhering to a particular ideology, and the emotions which are inculcated as part of it, than a narrow calculation of the relative material costs and benefits to himself in the evolutionist's reproductive fitness sense. (The reader should note that group selected altruism is not saintly self-sacrifice. When the final tally is completed, altruists must do better at reproducing their genes or their culture than those adopting the selfish alternatives. One target of group selection may be systems of reward and punishment, especially culturally transmitted social institutions in the human case, that indeed motivate even the highly self-interested individual to cooperate. A relatively low frequency of altruistic moralistic punishers may be all that is necessary to keep reluctant cooperators cooperating.) If so, this means we must understand the cognitive processes by means of which ideas are acquired through social learning and emotions are attached to them. We must also understand why and how rendering ideas in the forms of reified symbols makes these ideas so attractive. Such work has barely begun.

In the domain of ethnic-group cognition, some first steps are being taken. It appears that the human brain is predisposed to essentialize ethnic and racial groups. One approach argues that essentialized 'human kinds' can be created out of any social category (Hirschfeld, 1996), depending on local cultural and historical circumstances.

Another approach argues that only those categories – such as, say, ethnic groups and castes – that superficially resemble biological species will tend to be essentialized (Gil-White, 2001). The salient resemblances to species categories are (1) normative endogamy; (2) descent-based membership; (3) characteristic marking (in ethnic groups this is outward marking in the form of dress, scarification, etc.); (4) a distinctive local social adaptation (in ethnic groups this is a local norm equilibrium). These surface resemblances fool the brain into thinking that it is looking at a species category, and the essentialism normally applied to biological kinds is activated. Features 1 and 2 are caused by 4 because interaction – especially in marriage – with outsiders who have different coordination norms is costly. A recent model shows that feature 3 also follows from 4 (McElreath *et al.*, in press). The model shows that everybody benefits from broadcasting the community of origin – if such communities differ in their norms – because in this way costly interactions between partners who will likely fail to coordinate properly will be avoided.

It is important to note that the above is insufficient for an explanation of, say, racial conflict. For most of history the antagonistic political units have often not been maximal ethnic units but smaller (e.g., subethnic tribes, clans) or larger (e.g., multiethnic chiefdoms, empires) units. Only with the recent advent of ethnonationalism – an ideology maintaining that political and ethnic boundaries should coincide – do we get a proliferation of conflicts where the antagonistic units are maximal ethnic groups. These conflicts appear especially difficult to contain and negotiate precisely because the groups in conflict perceive themselves as unalterably 'natural' groups. Smaller groups often recognize their 'inherent' similarities with coethnics, and larger ones usually find it impractical to motivate emotional adherence based on belonging to the same imperial system. We are still very far from understanding how and why ideologies such as ethnonationalism spread and remain stable and why they are so easily exportable into vastly different cultures. An understanding of the cognitive processes that make certain ideologies attractive in particular circumstances (i.e., become cultural selection pressures), and which commit us emotionally to such ideologies, is sorely needed.

CONCLUSION

Explanations that don't go beyond the mechanisms responsible for cooperation in nonhuman species fail to account in a satisfactory manner for the vast aggregations of cooperating nonrelatives that constitute human societies. Kin selection and reciprocity arguably need to be complemented by cultural group selection as the main driving force. While some work has been done to elucidate the formal properties of cultural group selection, the task of understanding the cognitive mechanisms that such processes have shaped, and their

interactions, have only begun. As a result, we don't yet have a good theoretical handle on how the social brain creates selection pressures that affect the distribution and maintenance of ideologies central to large-scale human cooperation and conflict. However, we can now at least begin to ask the questions in a Darwinian framework, applied to culture as a system of inheritance in its own right.

Cultural Processes: The Latest Major Transition in Evolution

Introductory article

Eörs Szathmáry, Collegium Budapest (Institute for Advanced Study), Budapest, Hungary

CONTENTS

The origin of humans and human society is linked to the appearance of a unique mechanism for cultural inheritance, namely language. Earlier major evolutionary transitions can shed light on the latest transition.

A REVIEW OF THE MAJOR TRANSITIONS IN EVOLUTION

What Are the Major Transitions?

Table 1 lists what have recently been termed the 'major transitions in evolution'. A few remarkable features can be seen. Some major transitions in evolution (e.g., the origin of multicellular organisms or that of social animals) occurred a number of times, whereas others (e.g., the origin of the genetic code, or language) appear to have been unique events. However, one must be cautious about using the word 'unique'. Owing to the lack of 'true' phylogeny of all extinct and extant organisms, one can give it only an operational definition. If all of the extant and fossil species which possess traits arising from a particular transition share a last common ancestor after that transition, then the transition is said to be unique. Obviously it is quite possible that there had been independent 'trials', as it were, but we do not have comparative or fossil evidence for them.

Important Common Features

There are a number of sufficiently common features of the major transitions for them to require special attention, namely the emergence of an evolutionary unit at a higher level from lower-level ones, an increase in complexity, the appearance of a novel inheritance system, and the 'freezing in' of the transition (often there is no way back). The means whereby these features are achieved include local interaction, synergy, contingent irreversibility, and central control. We will look at each of these in turn, but will first briefly consider evolutionary units.

Units of Evolution

A unit of evolution must be capable of *multiplication*, *heredity*, and *variation* (Figure 1). If some hereditary traits influence the likelihood of survival and/or reproduction of the unit, then in *a population* of such units, evolution by natural selection can take place. Note that this definition does not refer to living systems. Many consider that viruses are not alive (e.g., they lack metabolism), but they do evolve. Some computer programs evolve in the electronic environment, and they are not regarded as alive either. In addition, there are items of culture, which are passed on from individual to individual, that also behave as evolutionary units (referred to as 'memes', by analogy with genes; see below). It is important to bear the generality of this definition in mind, as it enables us to apply Darwinian reasoning to nontrivial cases as well. The reference to population is also crucial, as individuals metabolize, reproduce, run, behave, etc., but they do not evolve. Evolution takes place in populations through the generations of evolutionary units.

Emergence of higher-level evolutionary units

The origin of the eukaryotic cell is a good example. Eukaryotic cells are much more complex than bacteria. Humans are also built of such cells. Mitochondria are the cell organelles that serve as the power plant of the cell. They are very simple, tiny structures that look like bacteria. It turns out that this resemblance is not casual, as they are indeed descended from once free-living bacteria. They became captured by an ancestor of our cells

Table 1. The major transitions in evolution

Before	*After*
Replicating molecules	Populations of molecules in protocells
Independently replicating genes	Chromosomes
RNA as gene and enzyme	DNA genes, protein enzymes
Bacterial cells (prokaryotes)	Cells with nuclei and organelles (eukaryotes)
Asexual clones	Sexual populations
Single-celled organisms	Animals, plants, and fungi
Solitary individuals	Colonies with non-reproductive castes
Prelinguistic societies	Human societies with language

Reproduced from Maynard Smith J and Szathmáry E (1999) *The Origins of Life. From the Birth of Life to the Origin of Language*. Oxford: Oxford University Press.

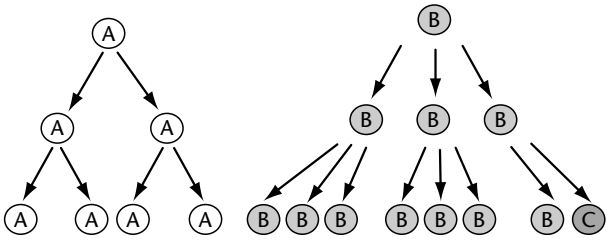

Figure 1. Units of evolution. A and B are reproducing entities of different types. Their average fecundity is shown to be different. Heredity is not exact (there is variability), as one B gives rise to a novel type C. Such units are not necessarily alive.

(around 2 billion years ago) and became enslaved for the production of ATP (the energy-storage molecule of all cells). Obviously, before this transition, the proto-eukaryote and the proto-mitochondrion were two types of unrelated, independently reproducing cell, but now they are integrated into one functional unit.

If such a transition is successful, then *adaptations*, which are discernible at the higher-level unit, evolve that suppress the competitive tendencies of the integrated lower-level units. Essentially, viewed from the lower level, a 'super-organism' is created. However, viewed from the higher level, it is just an organism.

Increase in complexity

Although natural selection does not guarantee that organisms will increase in complexity as they evolve, it is apparent that complexity along certain lineages, such as the one leading to humans, has increased during evolution. Is the number of genes in an organism's genome an appropriate measure of biological complexity? The recent flurry of completed genome sequences, including our own, suggests that this is not necessarily the case. There must be more sensible genomic measures of complexity than the mere number of genes. It is the *regulatory gene interactions* that seem to play a crucial role. In fact, *Drosophila* has more regulatory interactions than *Caenorhabditis elegans*, although mere gene numbers give the reverse order.

Figure 2 illustrates the ways in which genetic complexity can increase in evolution.

Novel inheritance systems

DNA is commonly referred to as the genetic material, with ample justification. However, there are other hereditary mechanisms. A good example is epigenetic inheritance in the cells of multicellular organisms. It is easy to see that something like that must operate in our bodies. Most animals start their lives as a fertilized egg. Cells divide and undergo differentiation in embryogenesis, so muscle, liver, nerve cells, etc. arise that look different and function differently. Some of them remain capable of proliferation. When a healthy liver cell divides, it gives rise to two liver cells – 'liver-cell-ness', as it were, is passed on. Note that the state of being a liver cell was not present in the fertilized egg, but rather it is generated in development. Thus it seems that a characteristic has been acquired and can be inherited at the level of the cell. Just so – this is a Lamarckian dimension of multicellular organisms. However, it extends very rarely from organism to organism during reproduction. To conclude, if a dual inheritance system were not active in us, we simply would not exist.

Obviously language, which is so central to our concern, is also a radically new method of information storage and retrieval. As we shall see, it has a Lamarckian component.

Local interactions

Whenever one develops a theory for a certain transition, one finds that some type of local interaction in the dynamics of the population is important. This can take several forms, and all of them are known to be important for the evolution of *cooperation*. *Reciprocal altruism* can lead to cooperation between unrelated individuals. Because of limited dispersal, cooperating individuals may remain close to each other, or they may remember past interactions with particular individuals. *Kin selection* is a mechanism in which genetic relatedness

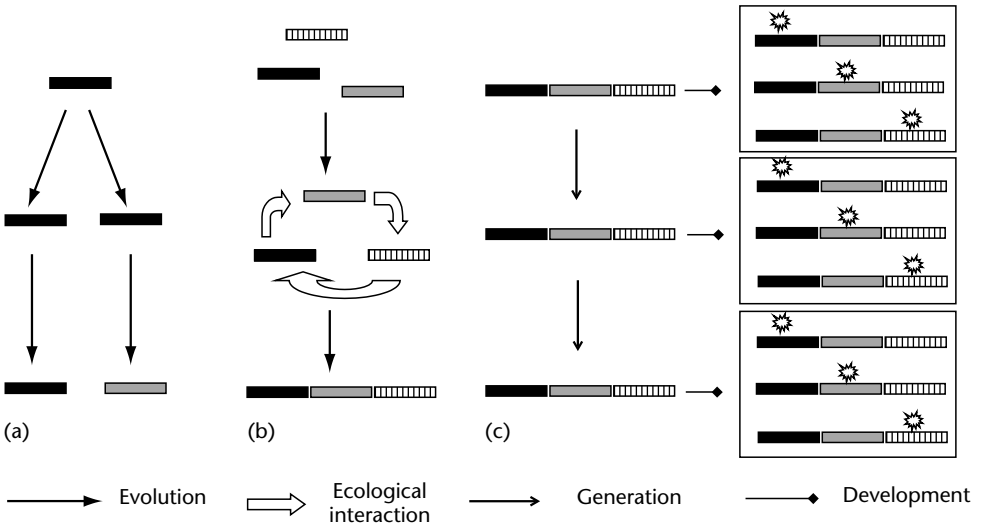

Figure 2. Means of increasing genomic complexity. (a) Duplication and divergence. (b) Symbiosis. First, independently reproducing units engage in an ecological interaction. Finally, the units cannot reproduce alone, and a new evolutionary unit has been formed. (c) Epigenesis. The genes remain the same, but they are differentially activated in the different cells. Modified from Maynard Smith J and Szathmáry E (1995) *The Major Transitions in Evolution*. Oxford: Freeman.

plays a crucial role. Hamilton's rule states that it pays to be an altruist if $br > c$, where b is the benefit received by the helped relative, c is the cost paid for by the helper, and r is the degree of genetic relatedness between them. Finally, *group selection* is a mechanism that applies when not only the individuals, but also groups formed of them, multiply and have heredity and variability. This criterion is readily satisfied when (1) the number of groups is much higher than the number of individuals per group, (2) each group is formed from one parental group only, and (3) there is no migration between groups.

The relative importance of the above mechanisms in accounting for the transitions varies from one case to another, but there is little doubt that all of them have been influential.

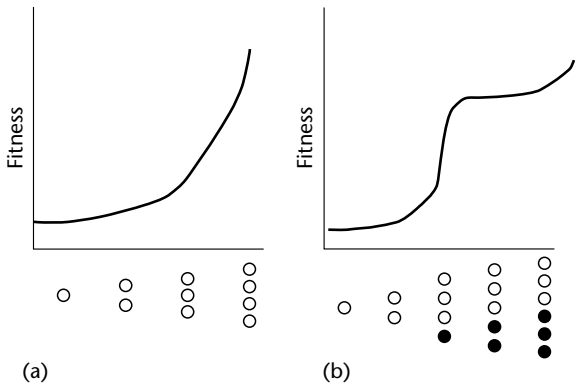

Figure 3. Types of synergy. (a) Quantitative synergy. (b) Qualitative synergy. In the latter case, combination of functions causes a very steep rise in performance, and hence fitness.

Synergy

Synergy can be both quantitative and qualitative (Figure 3). In both cases the performance (efficiency) of the interacting units increases non-linearly. In evolution, this translates into non-additive fitness interactions. In the case of qualitative synergy there are at least two types of interacting unit – they cannot substitute for each other. Cooperative guarding of the young is a good example of quantitative synergy. The interaction between different cell organelles, such as the mitochondrion and the plastid in a plant cell, is an example of qualitative synergy. *Economy of scale* and *combination of functions* are other terms used to refer to quantitative and qualitative synergy, respectively.

Contingent irreversibility

In many cases, once a transition has occurred there seems to be no way back. However, there are exceptions. For example, there are insects whose solitary state is secondary – all of their living relatives are highly social. Yet, in contrast, there is no mitochondrial cancer. This can be understood, given the fact that most mitochondrial genes had been lost in evolution, a fraction had been moved to the cell

nucleus, and very few genes remain in the organelle. Emphatically, all of the genes that are necessary for the division of this organelle have moved to the nucleus, and therefore the latter is in complete control of mitochondrial division. We can thus appreciate contingent irreversibility as a key mechanism for 'locking in' the result of a transition. It is not the case that a reversal would be *logically* impossible, rather it is just far too demanding on the side of the requisite heritable variation – the number of simultaneous, chance genetic changes enabling the reversal is so large (and their joint probability is so small) that *for all practical purposes* we can assume that they will not occur.

Comparative 'Transitionology'

It is a striking feature that some transitions involved related individuals, whereas others involved unrelated ones (Table 2). This gives rise to the important distinction between 'fraternal' and 'egalitarian' types of transition. Kin selection does not work for the latter, but local interactions are crucial.

THE ORIGINS OF ANIMAL SOCIETIES

Animal societies with a complex division of labor between their members have evolved by different routes. Apart from the division of labor, and the economic advantages that result from it, the various types of society have one other feature in common. The existence of non-reproductive castes (the so-called workers) in the social insects and in some other social animals poses a formidable problem to the theory of evolution, as Darwin had already recognized. Why should worker bees give up reproduction? In what sense would this increase their fitness?

Relatedness

Haldane once stated that he was willing to lay down his life to save two brothers or ten cousins. His reason was that these relatives shared, on average, ½ and ⅛ of the genes possessed by him. Why should the proportion of shared genes matter? To answer this question, we have to take a '*gene's eye view*'. A gene that would cause Haldane to die but ten of his cousins to survive would cause more genes identical to itself to survive than would a gene that let Haldane live and his cousins die (in fact, $^{10}/_{8}$ copies of the gene, on average, would survive, compared with only one). In the same way, genes present in worker bees that cause their bearers to give up reproduction in order to rear their sisters can spread, provided that the advantage of cooperative breeding over individual reproduction is great enough. This consideration is expressed elegantly in Hamilton's inequality.

Eusociality

The degree of sociality in different species can be placed on a gradient. Most biologists are interested in what is called eusociality – 'real sociality'. By definition, eusocial animals must satisfy three criteria:

1. reproductive division of labor – that is, only some individuals reproduce;
2. an overlap of generations within the colony;
3. cooperative care of the young produced by the breeding individuals.

Eusociality is well known in ants, bees, wasps, and termites. It is less well known that a similar degree of eusociality can be observed in naked mole rats, spotted hyenas, African wild dogs, and some social spiders.

Table 2. Egalitarian and fraternal major transitions

	Egalitarian	*Fraternal*
Examples	Different molecules in compartments, chromosomes, nucleus and organelles, sex	Same molecules in compartments, organelles in the same cell, cells in individuals, individuals in colonies
Units	Unlike, nonfungible	Like, fungible
Reproductive division of labor	No	Yes
Control of conflicts	Fairness in reproduction, mutual dependence	Kinship
Initial advantage	Combination of functions	Economies of scale
Means of increase in complexity	Symbiosis	Epigenesis
Greatest hurdle	Control of conflicts	Initial advantage

Reproduced from Queller DC (1997) Cooperators since life began. *Quarterly Review of Biology* **72**: 184–188.

Super-organisms

Colonies of social animals can with some justification be regarded as 'super-organisms', in the sense that they display adaptations (traits that increase fitness) at the colony level. For example, the mound built by termites has a system of air channels that function as an air-conditioning system. By this analogy, the queen and the reproductive males are analogous to the germ line of multicellular organisms, and the non-reproductive individuals would be analogous to the soma of the super-organism.

THE ORIGINS OF HUMANS AND HUMAN SOCIETIES

Characteristics of Human Societies

Relatedness and individual recognition

Despite the obvious similarities between a termite mound and a human city, there are profound differences between the mechanisms that lead to cooperation in the two cases. One important feature of human societies, namely the recognition of individuals, already exists in some social mammals and birds. Although insects may recognize group membership, they do not recognize individuals. In contrast, a monkey recognizes other members of its troop as individuals, and behaves differently towards them. As the phrase 'pecking order' implies, the members of a flock of chickens sort themselves into a linear dominance hierarchy, and this probably requires individual recognition. Those who have studied baboons and other monkeys have observed the formation of alliances in which two or more individuals support one another in conflicts with other members of the group. Such alliances may be based on genetic relatedness, but this is not always so. The essential points are (a) that, in higher animals, social interactions within a group depend on individual recognition, and (b) that one individual's behavior towards another depends both on genetic relatedness and on a memory of previous interactions with that individual.

Cultural inheritance

It is often said that the defining characteristic of human societies is cultural inheritance – that is, individuals in a society acquire their beliefs and behavior, and their knowledge and skills, by learning from previous generations, and not by genetic inheritance. There is obviously much truth in this idea, particularly with regard to the differences between one individual and another, or between one society and another. At the level of the individual, differences in political opinions are not caused by differences between genes. Having said this, however, there are some reservations that need to be stated. First, there is some cultural inheritance in animals, a fact that is important when considering the origins of human culture (Table 3). Secondly, the ability of humans to learn, and to build societies that are dependent on cultural transmission, is genetic – human societies differ from chimpanzee societies because humans and chimps differ genetically. Thirdly, humans learn some things more readily than others – the human mind is not a blank slate upon which experience can write what it will.

Social learning

Different types of social learning are at the heart of cultural transmission (Table 4). Young rats can acquire a preference for a new food by smelling it on the coat of other rats. This is a type of cultural inheritance – two groups of rats feed on different foods, and the difference is transmitted by learning. This mechanism has been called *stimulus enhancement*, whereby the adults create an environment in which it is easier for the young to learn. This contrasts with *observational learning*, in which one animal watches what another is doing, and then copies it. It is difficult to believe that all culturally inherited traits in animals depend only on local enhancement. For example, in some areas of

Table 3. Criteria for culture

Invention of a new pattern, or modification of an existing pattern
Transmission from innovator to another
Consistent copying of pattern (often stylized)
Long-term persistence of pattern in the acquirer
Spread of pattern across social units
Pattern enduring across generations

Table 4. Examples of social learning

Type of learning	*Description*
Stimulus enhancement	B learns from A where to orient behavior
Observational learning	B learns to what circumstances a behavior should be a response
Imitation	B learns from A some part of the form of a behavior
Goal emulation	B learns from A the goal of an action

Greece, golden eagles feed mainly on tortoises. The bird is unable to break open the shell with its beak, so it picks up a tortoise, flies up to a considerable height, and then drops the tortoise on to the rocks below, thus breaking the shell. It would be absurd to suggest that in Greece, but nowhere else, this behavior in eagles is genetically programmed. A young bird could learn by local enhancement that tortoise shells contain meat that is good to eat, but how – other than by copying – could they learn to fly upward carrying a tortoise, and then drop it? A second example, involving chimpanzees, is given below.

The distinction between stimulus enhancement and observational learning is important, because only observational learning can lead to cumulative cultural change, which is the characteristic feature of human history. By observational learning, young individuals can learn from adults, but also, if one individual stumbles upon an improved way of doing something, that improvement can be copied. The result is that change can be continuing rather than occasional, and that an individual can learn, by copying, a skill that it could never have learned on its own.

Chimpanzee culture

It is clear that humans depend on observational learning, reinforced by teaching, including verbal instruction. As the above example of golden eagles shows, observational learning is not unknown in animals. There are examples in chimpanzees. Some (but not all) populations of chimps dip sticks into the nests of driver ants, and feed on the ants that crawl up the sticks. The chimps in Gombe use a different technique to those in Tai, and catch about four times as many ants per minute. Local enhancement could explain why some individuals in one population dip for ants, whereas others do not. However, it cannot explain why Tai chimps continue to use an inefficient technique, when there is no reason why they should not adopt a more efficient one. Yet continued use of an inefficient technique is what we would expect if young chimps copy their elders.

Language and culture

If higher animals are at least sometimes able to copy their elders, why is it that continuous cultural change does not occur among them, as it does in humans? Thus one population of chimps may differ from another for cultural reasons, but a given population is not continuously acquiring new habits. The likely explanation is that, in humans, the main mechanism whereby culture is transmitted is language. The nature and origin of language are discussed elsewhere. At the risk of repetition, two conclusions will be reiterated here, namely the close analogy between genetic and linguistic methods of transmitting information, and the implications of linguistics for the modular nature of the human mind.

From Ape to Human

Social groups

All Old World monkeys and apes live in social groups, with the single exception of the orangutan. Figure 4 shows a reconstructed phylogeny, or ancestral tree, of these animals. In Old World monkeys, females remain in the social group in which they were born, whereas males leave their natal group before sexual maturity, and must enter another group in order to breed. They are said to be 'female kin-bonded'. In chimpanzees, the situation is reversed – that is, males remain in their natal groups and females move. Other hominoids vary in their social systems, but none is female kin-bonded. The most parsimonious assumption is that male kin-bonding originated in the common

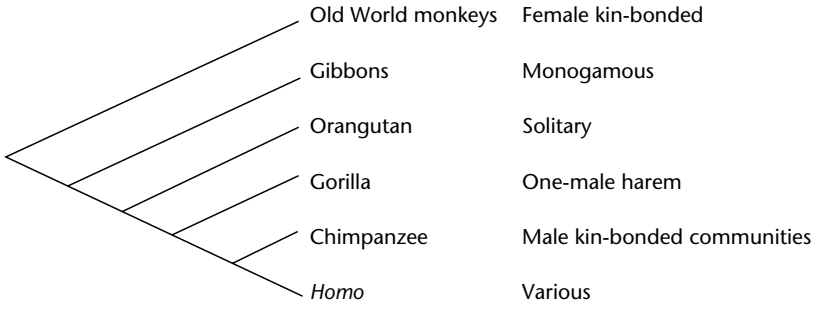

Figure 4. Primate phylogeny and social structure. Reproduced from Foley RA (1996) An evolutionary and chronological framework for human social behaviour. *Proceedings of the British Academy* **88**: 95–117.

ancestor of humans and chimps, since they are more closely related than either is to the gorilla. If this was so, then male kin-bonding is the ancestral condition for hominids. The social systems of modern humans are so varied that it is difficult to be sure whether this conclusion is correct, but it is the best we can do on the basis of the comparative evidence available.

Fossil records

The fossil record provides a second source of information about human origins (Figure 5). It is illuminating to compare this record with what is known of human technical achievements, if only because of the puzzles that the comparison raises. The australopithecines were bipedal and lived in open country. Their relative brain size was only slightly larger than that of the apes, and their tool kit was limited and uninventive. In the lineage from *Australopithecus* through *Homo habilis* and *Homo erectus* there was a gradual increase in brain size, but relatively little technical innovation. The most advanced tool used by *H. erectus* was the handaxe, made from a single block of stone worked on both surfaces, and symmetrical in shape. Such handaxes first appeared around 1.4 million years ago, and persisted almost unchanged for over a million years – hardly an example of cumulative cultural change.

Brain size

Although it seems that there was substantial brain evolution in *H. erectus*, the most rapid increase in relative brain size has occurred during the last

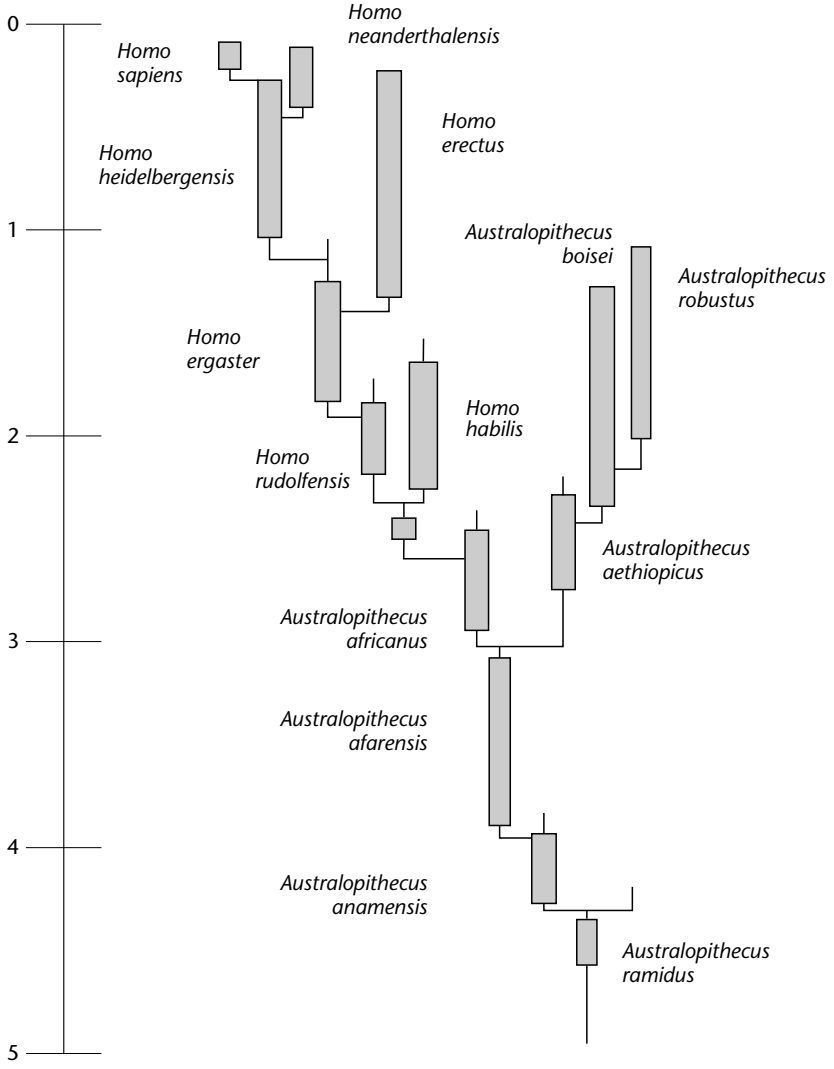

Figure 5. Fossil record of human origins.

300 000 years, culminating in the appearance of effectively modern humans about 100 000 years ago. Yet the acceleration in human technical inventiveness, with the appearance of a varied range of tools made of stone, bone and antler, dates back only 40 000–50 000 years. Burial of the dead, art in the form of cave paintings and musical instruments, personal adornment, and trade originated at much the same time. From around 40 000 years ago we are faced with evidence of continuing cultural innovation. This raises several questions. Why was there a delay of 50 000 years between the appearance of the first anatomically modern humans and the technological revolution? What selective force was responsible for the accelerated increase in brain size 300 000 years ago? When and why did language as we know it originate?

Modules

The problems are difficult, because a fossil skull can tell us relatively little about the brain that was once inside it, and stone tools tell us little about the society that made them. We may try to combine palaeontology, archaeology and psychology in order to obtain a tentative answer to these questions. The essence of this argument is as follows. The human mind does indeed contain modules that are adapted to particular tasks, as suggested by studies of linguistic competence. During much of human evolution these modules increased in efficiency, but they remained to a large degree isolated from one another. Language evolved in the first instance to serve social functions, but once grammatical competence had developed, it provided a means whereby the barriers between modules could be broken down. The burst of creativity during the last 50 000 years resulted from the breaking of these barriers.

Some authors have suggested the existence of three mental modules, concerned with social intelligence, technical intelligence, and natural history, respectively – that is, with the knowledge of animals and plants that is necessary for efficient foraging. We now look at each of these in turn.

Social intelligence

Social intelligence is a common characteristic of the primates. It has been argued that it is the main reason for the increase in brain size in monkeys and apes, as there is a striking correlation between brain size in a species, and the size of social groups in that species.

A crucial question concerns the degree to which apes and monkeys have what has been called a 'theory of mind'. To have a theory of mind is to be able to ascribe to others the possession of a mind like one's own, with similar desires and powers of reasoning. There is no convincing evidence that monkeys have such an ability. For example, a vervet monkey gives a different alarm call if it sees an eagle, a snake or a leopard, but it seems that the monkey does not have in mind the knowledge that another monkey may hear its call and respond appropriately. For example, a monkey may continue to call after all of the others have responded. However, many who have studied the social behavior of chimpanzees, and their skill in manipulation and deceit, are convinced that they do indeed have a theory of mind.

We can conclude that selection for social intelligence was a major cause of the increase in brain size in monkeys, apes, and humans, and that a theory of mind was likely to be present in the common ancestor of chimps and humans, around 5 million years ago.

Technical intelligence

Chimpanzees do use tools in the wild. For example, some populations use stones to crack nuts. However, even in captivity their ability to make tools is very rudimentary. Australopithecines used tools, but there is no convincing evidence for deliberate tool-making, which first appears to be associated with the remains of *H. habilis*, although the tools are little more than irregular chipped stones. *H. erectus* marks a clear advance, with the manufacture of symmetrical handaxes, indicating that the toolmaker had an image of the desired result in mind, and the skill to realize it. However, as was mentioned earlier, there remains an astonishing degree of conservatism. Thus there is evidence of a limited increase in technical intelligence, combined with a lack of inventiveness.

There is also evidence for a degree of independence of social and technical intelligence, even in modern humans. For example, researchers studying autism have suggested that autistic children have impaired understanding of the behavior of other humans (what has been called 'folk psychology') but better than average understanding of the behavior of inanimate objects ('folk physics').

Understanding of natural history

There was obviously selection for improved foraging skills, and hence for knowledge of the distribution and behavior of animals and plants. But was this achieved by an increase in general-purpose intelligence, or by the evolution of a specialized natural history module?

In favor of the latter, it has been argued that all human societies share certain ideas about the living world. First, all living things belong to one – and only one – 'natural kind'. An animal is a dog, or a cat, or a badger, and so on – it must belong to a particular 'species', it cannot belong to two, or to none, and it cannot change its species. Secondly, all human societies share the idea that natural kinds can be classified hierarchically into higher taxa. For example, a dog is a flesh-eater, a mammal (as opposed to a fish, reptile, etc.) and an animal (i.e., not a plant). These universal human attitudes to living things may reflect an innate predisposition.

The alternative is that they could be universally believed because they are true, or almost so, and would be learned by any human society to which knowledge of the living world was important. A second argument in favor of a special natural history module is the speed with which children acquire these beliefs. However, as yet the case for a special module is not decisive.

Coupling

The argument, then, is that the increase in human brain size prior to the emergence of modern humans around 100 000 years ago was associated with an increase in social, technical, and natural history skills, but that these abilities were to a large degree independent. Perhaps the competence in language, including grammar, also evolved during this period, although precise dating is obviously difficult. We may ascribe the cultural explosion that began around 50 000 years ago, and which has led to continuous and cumulative cultural change, to a breakdown of the isolation between mental modules as a result of the emergence of language. The essential point is that once words exist for social, technical, and living things, the same grammar can be used to say things about them.

THE ORIGINS OF LANGUAGE

Writing is much more recent than language. This is really unfortunate, because it is only by writing that language could have become 'fossilized'. We must therefore resort to comparative analyses in biology and linguistics, as well as to building theoretical models. Comparative analysis is also limited, because language is a uniquely human phenomenon. It is undoubtedly an adaptation, and a very complex one at that. Thus it is very unlikely to have arisen as a mere by-product of anything else, without considerable evolutionary fine-tuning by natural selection.

Generative Mechanisms

It is not the aim here to give a thorough description of language with all of its known components. Rather, this section will highlight some important features. First, the number of sounds, words, and grammatical rules that we use in any human language is finite. With these finite means we can potentially cover an indefinitely large domain of grammatically correct, possible sentences.

Symbols

Our vocabulary is finite but open-ended. Without the latter feature, cultural evolution would be impossible. Words are usually highly symbolic signs – they stand at the abstract end of the object–concept–sign triple. Because there is no *immediate* link between object and word, we can have words for purely imaginative concepts, such as *unicorn*.

The capacity for symbolic communication in overt or covert forms seems to be present in some other species as well as humans. For example, bottle-nosed dolphins, chimpanzees, and gray parrots are able to master protolanguage, defined bluntly as word use without grammar. Children under 2 years of age are also roughly at this level when they speak. This already suggests that the hardest nut to crack when contemplating the evolution of the language faculty is syntax.

Grammar

The syntax of every known human language can be characterized by a finite set of grammatical rules. By the application of these rules, all possible grammatically correct sentences can be generated – hence the term *generative grammar*. We are usually unaware of these rules, but we learn our language surprisingly fast, despite the fact that randomly assembled words hardly ever result in grammatical utterances. Our brain seems to be specially tuned, and genetically predisposed, to fast language learning – in short, we have an 'instinct' for language.

Biological Foundations

Genetics

Chimpanzees do not share the language instinct. This difference must ultimately be traced back to genetics. However, genetics of humans is notoriously difficult, because you cannot 'breed' humans as you can, say, breed fruitflies for genetic experiments. Instead, one must identify familial linguistic problems in the existing medical record. Such a

syndrome, or rather a collection of them, has been described and is called *specific language impairment* (SLI). It is specific because, at least for certain individuals, other cognitive deficits are not apparent. Some authors claim that a subgroup of affected individuals has something even more special, known as *grammatical SLI*. It is indeed true that in some such people only aspects of grammar are affected.

In some cases we have the genetic description of this syndrome. In an English-speaking family the problems are associated with a single autosomal dominant allele. It is very unlikely that we shall find many such genes. In contrast, most of the genes that affect the language faculty are likely to be *liability genes* – that is, other things being equal, these genes increase the probability that we will have a normal language competence.

Our remarkable ability to learn a very complex system so fast, and the hints at a specific genetic predisposition, appear to be consistent with the idea of a *language organ* – that is, a genetically determined module in the brain that processes linguistic information. Obviously this organ must be absent from chimpanzees, and must have evolved somehow during the last 5 million years.

Quest for a 'language organ'

However, there is a snag. From what we know of the brain, the language organ cannot be a macroscopically distinct anatomical unit. The fact that neural localization of language can be plastic is now widely known. Studies of brain injury have revealed that damage to the left hemisphere which occurs before a critical period is not lifelong, as the right hemisphere can take over the necessary functions. This does not contradict the finding that in normal individuals Broca's area does appear to be specialized for syntax. It thus seems that the common left-hemisphere localization of language is just the *most likely* outcome when there is no genetic or epigenetic disturbance. Non-invasive brain studies have revealed a truly shocking feature of language development, namely the localization of linguistic processing shifts during normal ontogenesis. The outcome in 'normal' individuals is also highly variable.

The following conclusions can be drawn from brain studies.

- Localization of language is not entirely genetically determined, as even large injuries can be tolerated before a critical period.
- Language localization to certain brain areas is a highly plastic process, both in its development and in its end result.
- It does seem that a surprisingly large part of the brain can sustain language. There are (traditionally recognized) areas that seem to be most commonly associated with language, but they are by no means exclusive, either at the individual level or at the population level, during either normal or impaired ontogenesis.
- Whereas a large part of the human brain can sustain language, no such region exists in apes.

Evolution

It simply cannot be the case that the language faculty originated by a single crucial mutation. This also suggests that linguistic performance itself has evolved. Unfortunately, we can be only hypothetical at the moment. Figure 6 illustrates a possible scenario. Note that, according to this flowchart, components of language have co-evolved and – by inference – the underlying neural networks must also have co-evolved. A much deeper understanding of the brain during processing of linguistic information will be needed before we can establish whether this scenario – or any alternative – is nearly correct or not.

THE USES OF LANGUAGE

Language and Society

It is impossible to imagine our society without language. The society in which we live, day and night, depends on it. Even as we sleep, information about us is being stored and maybe processed. Imagine that we apply for a job on the other side of the world. We are confident, or at least we hope, that our application will be fairly treated, and that the country to which we would like to move is running properly – that is, that social contracts are observed. Our lives depend on the social division of labor and on detailed social contracts which could not exist without language. No ape or dolphin could comprehend, even in spoken form, a contract for a job.

Both the genetic and linguistic systems are able to transmit an infinitely large number of messages by the linear sequence of a small number of distinct units. In genetics, the sequence of four bases enables the specification of a large number of proteins, which in turn, by their interactions, can specify an indefinitely large number of morphologies. In language, the sequence of some 30 to 40 distinct unit sounds, or phonemes, specifies a large number of words, and the arrangement of these words in grammatical sentences can convey an infinitely large number of meanings.

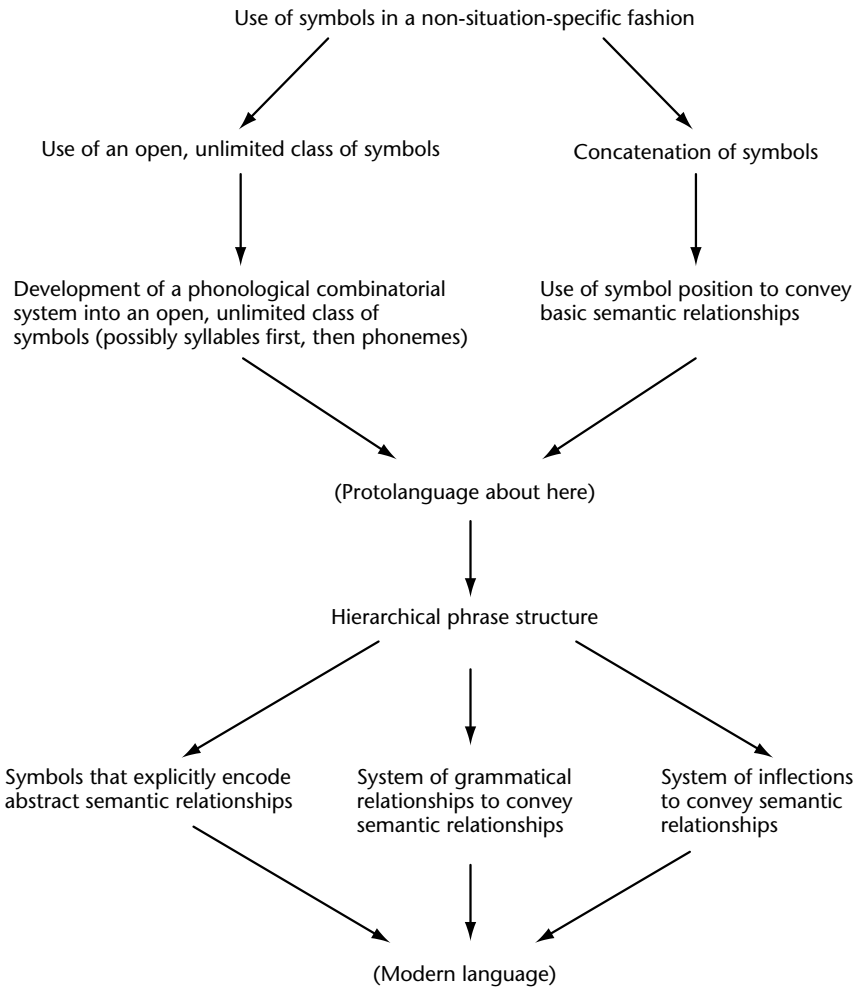

Figure 6. Scenario for the evolution of language. Reproduced from Jackendoff R (1999) Possible stages in the evolution of the human language capacity. *Trends in Cognitive Sciences* **3**: 272–279.

Language for Internal Representation

Language is not only for communication – it is also a means for powerful internal representation. If a person says to him- or herself 'I saw two leopards climbing up that tree; only one has come down, so it's better for me to stay away from that tree until the other one comes down, too', then this reasoning requires syntax that is functionally equivalent to syntax of natural language, even if it is not explicitly 'spoken' in one's head (although frequently it is). Some authors call such an internal language, that serves internal representation, *mentalese*. This emphasizes the idea that language, but not necessarily the spoken one, is a tool for thought as well.

Memes and Cultural Evolution

Richard Dawkins has emphasized the analogy between genetic and linguistic transmission, introducing the concept of a 'meme' – that is, the unit of cultural inheritance analogous to a gene. A meme, he argues, is a replicator. If we invent and tell you a limerick, you may tell it to your friends, and they may tell it to theirs. In this way a single original entity – the representation of the limerick in my brain – has replicated, as a gene might replicate. Clearly, there is room for selection. For example, if we invent a funny limerick, it is more likely to replicate than if we invent a boring one. Of course, whether a meme will replicate or fail depends on the nature of the human mind, and on the cultural milieu (i.e., on the other memes present in the population). However, the same is true of a gene – its increase depends on the environment and on what other genes are present.

There are of course differences. Genes are transmitted from parent to offspring, whereas memes can be transmitted horizontally, or even from offspring to parent. Yet there is a deeper difference

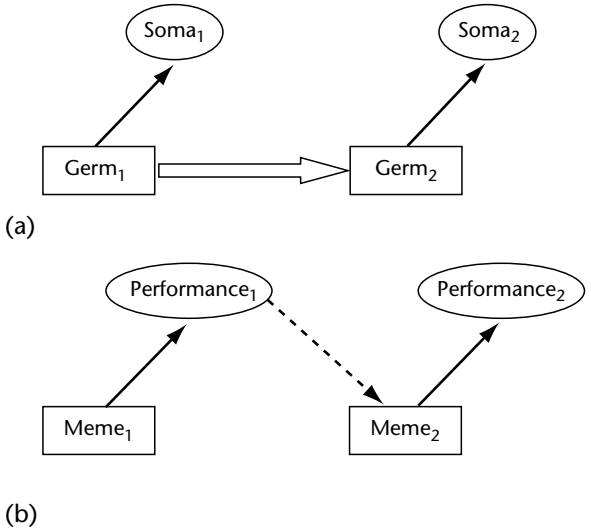

Figure 7. Transmission of genes and memes. (a) A so-called Weismann diagram, named after the famous late-nineteenth-century theoretical biologist. It expresses the idea that only information in the gametes is passed on, whereas the body (soma) cannot transmit its information by genetic means. Weismann thought that this also precludes the inheritance of acquired characteristics (Lamarckism). Although not strictly true, other formulations analogous to this diagram are more accurate and convey the message originally intended by Weismann. (b) Memes are passed on from the performance level ('phenotype'). Language itself is built up analogously from generation to generation. Reproduced from Szathmáry E (2002) Units of evolution and units of life. In: Pályi G, Zucchi L and Caglioti (eds) *Fundamentals of Life*, pp. 181–195. Paris, France: Elsevier.

between genes and memes. Genes specify structures or behaviors (i.e. phenotypes) during development. In inheritance, the phenotype dies and only the genotype is transmitted. The transmission of memes is quite different. A meme is in effect a phenotype – the analogue of the genotype is the neural structure in the brain that specifies that meme. When I tell you a limerick, it is the phenotype that is transmitted – I do not pass you a piece of my brain (Figure 7). It follows that, in the inheritance of memes but not that of genes, acquired characters can be inherited. If I tell you a limerick and you think of an improvement to it, you can incorporate it before you pass it on. In this sense, cultural inheritance is Lamarckian.

For these reasons, population genetic theory cannot readily be applied to cultural inheritance. However, the analogy between memes and genes can be suggestive in a qualitative sense if not in a quantitative one. Furthermore, although for the sake of simplicity we have illustrated the idea of a meme by the example of a limerick, it can refer to more important examples, such as a belief in the Trinity, or a knowledge of how to manufacture gunpowder.

Cultural Transmission and Diffusion

Advanced article

Robert Aunger, University of Cambridge, Cambridge, UK

CONTENTS

Cultural diffusion is the process by which information is disseminated through a population, typically by information exchanges among population members (cultural transmission), presumably with the involvement of social learning mechanisms.

INTRODUCTION

People rely heavily on shared beliefs and values to coordinate their social activities. Indeed, phenomena from ritualized greetings to the elaborate ceremonies that mark social events such as marriage can partly be explained by referring to the need to fulfill shared behavioral expectations. These expectations derive from norms and standards specific to each social group. The set of behavioral practices specific to a group constitute a pool of information which is typically what people mean by 'culture'. In anthropology textbooks, for example, culture is typically defined as a 'system of shared beliefs, values, customs, behaviours, and artifacts that the members of society use to cope with their world and with one another, and that are transmitted from generation to generation through learning' (Bates and Plog, 1990, p. 7). How these kinds of information and practices come to be shared by different people in the first place remains to be explained, however, even though it is arguably a central question in the social sciences.

CULTURAL TRANSMISSION PROCESSES

One explanation for shared culture is the exchange of information through social learning. However, considerable controversy attends this apparently common-sense notion. In particular, the recently burgeoning field of evolutionary psychology has claimed that much of what appears to be learned from others is in fact information already in place in people's brains – put there by a long history of natural selection for the retention of that information, which remains ready to be elicited by circumstances. In effect, some ecological trigger sets off an appropriate innate response, making so-called 'culture' a store of mental records – just like the way a jukebox stores musical records, any one of which can be chosen by punching the appropriate button (Tooby and Cosmides, 1992). The fact that people in different places do different things therefore cannot be taken as evidence that culture is transmitted, since they may be simply responding as individuals to subtle environmental differences. The crucial issue, then, is to distinguish the social transmission of information from individual phenotypic plasticity.

Advocates of the position that human beings and other social animals in fact depend significantly on social learning typically suppose that the need to acquire up-to-date information derives from the need to deal with quickly changing ecological conditions – including, in particular, the sometimes ephemeral nature of relationships with other organisms. Further, large brains had to evolve to support the ability to engage in such learning. Evolutionary psychologists counter, however, that big brains are necessary simply to store the many 'cultural' rules that might be elicited by varying circumstances. How can this deadlock be broken?

It seems likely that brains are not big enough to contain all the information required by the jukebox analogy. Many of the problems that contemporary urban life throws up, for example, could not yet have been incorporated into a genetic response: such fundamental experiences as living in large groups of unrelated people are simply too novel. Evolutionary psychologists acknowledge that

modern conditions are likely to spawn maladaptive responses from 'Stone Age' minds. But the fact is that modern culture on the whole seems to be highly adaptive because it has massively extended the niche in which humans can live, and tremendously increased the total population of our species. It seems unlikely that brain mechanisms selected when humans lived under different circumstances would lead to the adoption of behavioral traits that currently contribute so greatly to genetic fitness.

Further, there are reasons to expect that evolution would naturally settle on social learning as an optimizing strategy for the acquisition of information relevant to changing environmental circumstances (Boyd and Richerson, 1985). So it seems reasonable to suppose that at least some of our behaviors are informed by rules acquired from other agents. Social learning should particularly be favored when the lessons from individual trial and error are expensive (either cognitively or in fitness terms), such as determining what is edible when a species can live in a variety of habitats.

Biology therefore determines our general capacity for cultural learning and is responsible for universal abilities like language. However, cultural variations among peoples are attributable to learnt traditions and not to innate or genetic propensities. At the same time, specific psychological adaptations have probably evolved to foster the selective but accurate acquisition of rules through social learning. Language itself can be seen as such an adaptation; it generates signals that allow the reliable transmission of complex, highly contextualized rules for behavior between people.

However, questions remain as to the nature of cultural transmission. In particular, is it like a copying process, or is it a reconstructive one? Some argue that even though cultural information must make its way from person to person in the coded form of messages, this process nevertheless results in a high-fidelity duplicate being produced in the receiver's brain – much as if it had been faxed or photocopied – thanks to evolved mechanisms for social communication. On the other hand, studies of social interactions suggest that the receiver – given the relative paucity of information that actually passes between people – must reconstruct a considerable proportion of a message's content. The nature of the process that underlies human communication has implications for the nature of human psychology. However, if reconstruction and fax-like transmission are equally reliable, then they may exhibit the same population-level dynamics.

CULTURAL SELECTION PROCESSES

Not all social messages are equally attended to or adopted by their receivers. In effect, selection among messages occurs. A selection process requires a population of entities whose frequencies increase or decrease according to their relative fitnesses. Cultural selection can be distinguished from natural selection by the kinds of units on which it operates (Cavalli-Sforza and Feldman, 1981). Just as natural selection is supposed to influence the evolutionary fate of genes, cultural selection works on the prevalence of cultural traits over time.

Cultural selection can occur at each point in the process of communicating information from one individual to another. At the source, there can be psychological selection among potential messages. Once a message has been sent into its channel, physical selection pressures can also affect the chances of that signal reaching its destination. For example, sometimes the message's code does not match well with the modality in which it is sent. Then, after the signal has been detected by the receiver, further psychological biases can exist for attending to and adopting the idea expressed by the signal. Some kinds of information acquired through social learning might not be consistent with other beliefs that an individual holds, for example, and would be rejected for that reason. Later, for further transmission to occur, performances of the related behaviors must also be motivated. Thus, certain traits are favored in effect by the social or physical circumstances in which they find themselves.

Analysts of cultural evolution must be careful to distinguish cultural selection from natural selection, since both can affect the frequency of cultural traits. Some beliefs, for example, cause people to engage in behavior that is detrimental to their health, survival, or likelihood of reproducing. Belonging to a religious group that forbids engaging in sex is only the most obvious case of such an effect. In this form of natural selection, the frequency of a culturally acquired belief is reduced not by changes in belief but by the culling of hosts with such beliefs from the population. This makes cultural evolution a process of 'dual inheritance', in which cultural selection and natural selection operate in parallel or in opposition on cultural traits (Boyd and Richerson, 1985).

Where do the mechanisms of cultural selection come from? How do they in turn evolve? The values used to discriminate between incoming messages can themselves be the product of earlier social learning, or constitute biases produced by a

history of natural selection for discriminating between useful and harmful stimuli. Thus, some cultural traits can 'feather the nest' for later-arriving ones, suggesting that cultural evolution can engage in positive or negative feedback processes.

CULTURAL TRAITS

What is the unit of analysis in studies of culture? Traits – segregating particles of culture – or cultures themselves, taken as a whole?

Throughout its long history, anthropology has attempted to deal with the problem of identifying cultural traits. More recently, however, this attempt has largely been abandoned as impossible – and in any event unnecessary. According to this view, cultures are to be considered as unified wholes, or at least complexes, which are not necessarily divisible. Many ethnographers would argue that there is no 'atomic level' to culture, no way to uncover mutually exclusive entities with stable properties from which cultural compounds are formed. The tendency is now to describe culture as an ideal type, an artificial conglomeration of knowledge compiled from different people occupying varying social roles. However, this metaphysical Platonism – seeing culture as an integrated whole that transcends the minds of individuals – is analytically barren, since there is no contesting a representation built up by the imagination of the ethnographer.

Many would say that we have no legitimate basis for postulating that cultural transmission is intrinsically particulate. There may be no discrete variant that is reliably learned from others through observation or any other form of social interaction. Categories are imposed on a blended reality. You cannot count up cultural values in people's heads like votes for political parties. Traits are 'clumps' of culture content, not well-bounded entities (Gatewood, 2000). However, if culture is learned, and by individuals one at a time, then no one learns everything; culture winds up being distributed. Since learning a culture takes place through social interactions, only parts of culture can be acquired at any given moment: in effect, there must be units of transmission. Admittedly, after acquisition, these units may become amalgamated into complex mental representations which become difficult to tease apart. Nevertheless, these units of acquired information – the equivalent of the atom in physics, the molecule in chemistry, or the phoneme in linguistics – are the smallest possible meaningful unit of cultural information.

So culture must be analyzed as a set of traits, but these need not correlate with natural categories of things in the minds of those living in that culture. At the empirical level, an important question concerns the way in which one is supposed to pick out cultural traits. Where do the division points for defining categories come from – from 'outside' (researchers) or 'inside' (from the group members themselves)? Either is possible. Traits can be just some item of cultural content that the analyst finds it convenient to label – in effect, they become ethnographic conventions. Alternatively, much hard work can be devoted to ascertaining how expert informants themselves classify things.

Once the categories have been established, the question of how these traits are related to one another then arises. Computer scientists, who have thought hard about this problem, have come up with a variety of frameworks for representing knowledge bases, from nested hierarchies to network structures of nodes for concepts with links between them identifying kinds of relationships. What sort of representation is best? This may again be an empirical question, the answer to which depends on the analytical questions being addressed by a particular study.

What, then, is the locus of culture? What is the culture-bearing unit? The traditional solution of simply using the classification people apply to themselves retains considerable appeal, since it has the subjective authority of the participants in the study. However, the actual group influenced by some cultural process or knowledgeable about some domain of belief or practice may vary from domain to domain. This suggests that there is a fluid boundary to the social group to be identified as sharing cultural traits. At best, one might be able to identify a network of people who tend to be linked together for a wide range of cultural traits; but in the end, no easy solution to this problem has appeared.

ARTIFACTS

Human beings, along with many other species, engage in behaviors that significantly alter the environments in which they find themselves. This activity has been called 'niche construction' (Laland *et al*., 2000). Its importance from an evolutionary viewpoint is that such alterations can subsequently influence the kinds of selection pressures that any species interacting with that modified feature of the environment will experience. As a result, population dynamics and the course of evolution can change. Niche construction introduces a feedback loop between behavior and its physical products, artifacts.

The production of artifacts requires 'technique', or knowledge and skills specific to that production process, typically acquired through social learning as well as individual practice. Technology is then the combination of artifacts and technique in a manufacturing context. A technology plus its supporting procedures and institutions, as well as environmental and sociopolitical conditions, can be considered a technological system.

Artifacts themselves can be divided into two general classes: tools and machines. Tools such as hammers or rulers can originate as ideas which are then turned into physical objects by people (or machines) as the expression of that representation. Alternatively, the first exemplar of a tool type might be produced by accident while manipulating some object, or through modification of an existing tool. In any case, it is an object that skilled people can use to extend their physical or mental capacities. Machines, on the other hand, can be considered artifacts with multiple component parts that together perform a novel function which any of the parts, taken individually, would not be able to accomplish. Only humans produce machines, probably because the planning involved in the execution of the multistep process of machine construction is beyond the cognitive abilities of other species.

How do such complex objects evolve? By playing an important part in cultural evolution. The existence of artifacts in the environment can have a significant influence on the course of cultural evolution, because they can constitute a store of information or a channel for information transmission between people (e.g. telephone wires). Artifacts, as transformed objects, should be distinguished from signals and tokens. A signal can be considered to be a patterned particle stream flowing through a channel. A token consists of a physical substrate with information inscribed as pattern in or on it; it is a template for the generation of signals. A signal is 'natural' if it is directly produced by the body (e.g. speech), or 'artificial' if produced by machines (e.g. laser beams or internet 'packets'). It is worth distinguishing between signals and tokens because they have different evolutionary roles: signals are short-lived, dynamic and energetic, designed for the transport of information. Tokens, on the other hand, are static and inert, because they are meant to be secure stores of information. Communicative artifacts contain a token, and hence are able to facilitate the communication of ideas. This means that artifacts can act as signal templates because signals can, after contact with some token, exhibit a new pattern (e.g. amplitude or frequency), to reflect the fact that it now carries information about that artifact.

This kind of communication – mediated by artifacts – has many benefits over traditional face-to-face communication: people separated by distance and time can exchange information (e.g. through email); the effective population reached by a given message can be increased (e.g. through mass media); new communication channels can have novel effects on message receivers (e.g. 'spamming' in email); and greater control over the distribution of messages can be achieved (e.g. through 'gatekeepers' such as the media corporations). The net effect is that this progress in the design of more and more complex artifacts allows the information available to human groups to accumulate beyond that available to any other species (Tomasello, 1999). It is the highly constructed nature of the human niche that arguably makes our cultural adaptation unique.

MEMES, MEMETICS, AND ASSOCIATED CONTROVERSIES

'Meme' is a word coined by Richard Dawkins (1976) to identify cultural traits with the ability to replicate themselves. The word has gained sufficient currency to be included in recent editions of the *Oxford English Dictionary*, where it is defined as 'an element of a culture that may be considered to be passed on by non-genetic means, especially imitation.' This reliance on imitation as a special form of social learning has proved crucial to the definition of memes, since many assert that only the relatively quick copying of instructions (not just behavior, but the directives for instigating that behavior) can support the chains of replication events necessary to sustain an evolutionary lineage, and particularly the curiously cumulative quality of human culture.

What distinguishes memetics from other evolutionary approaches to the understanding of cultural evolution (such as evolutionary psychology or sociobiology) is the insistence that what is transmitted during social learning is a replicator. Although the concept of replication is itself in need of some theoretical work, it generally is a process in which a copy is made of some source. This process must involve causation – that is, the source must be causally involved in the production of the copy (a causation condition). Second, the copy must be like its source in relevant respects (a similarity condition). Third, the process that generates the copy must obtain the information that makes the copy similar to its source from that same source

(an information transfer condition). Finally, during the process, one entity must give rise to two or more (a duplication condition).

Thus, for a memeticist, not only are cultural traits identifiable as individualized units, but they have the power to cause their own duplication. Further, memes are cultural traits that behave as if they were interested in preserving themselves, using individual minds as hosts. Memes, in this view, are responsible for the persistence of certain cultural traits, including those that do not directly favor the biological fitness of the group in which those traits spread themselves.

It was originally thought that memes could encompass behaviors, artifacts or mental contents as varied as 'tunes, ideas, catch-phrases, clothes fashions, ways of making pots or building arches' (Dawkins, 1976). It seems unlikely, however, that replication could occur in a similar fashion in all of these contexts. In fact, behaviors generally do not replicate in the sense described above. It is true that one person can mimic the speech and even the accent of another, reproducing spoken phrases perfectly. Why is this not an example of cultural replication? The answer is that the spoken signal either dies 'in the air' prior to a second signal being constructed in response by the imitator; or it is converted into another form which circulates through the receiving brain before emerging again as the same spoken phrase. In either case, the signal is not duplicated; it either lives through a complex cycle of exchange between people, or a second example is produced after some lag. Thus, despite the facile appearance of a signal being replicated, behavioral mimicry does not hold up to our criteria for replication.

Similarly, the processes through which most artifacts are produced fail the information transfer condition. For example, on the factory floor, it is seldom the case that features of one car on the assembly line are determined by reference to those same characteristics in the previous exemplar. Instead, the assembler (a person or robot) relies on instructions from a centralized database such as a computer-derived datasheet to tell it what to do next. If one agrees with the majority of memeticists that behaviors and artifacts should be eliminated from consideration, then memes are restricted to minds, where the conditions for replication may hold.

As noted above, this means that imitation is the replication mechanism identified by memeticists. It has even been suggested that the human ability to imitate makes the existence of memes self-evident. The argument is that if imitation is defined as the ability to copy behavior or ideas by observing them, then surely the product of that observation must be replicated information. Although transmission is a process in which information is duplicated, it does not follow that the information itself is responsible. Other factors – such as common mental mechanisms for inferring mental or cultural content from sensory stimuli – could lead to the same result. The existence of memes therefore remains unproven (Aunger, 2002).

Neither is there any theoretical reason to suppose that just because culture evolves it must be founded on an independent replicator. Even though biological evolution is grounded in the replication of a biological entity (genes), this does not mean that every evolutionary process must be. In fact, evolution is a more general process than that. Why this is so requires some explanation.

The central concept in evolutionary theory, arguably, is that of a population. It is populations that evolve, and this evolution consists of shifts in the relative frequencies of various types of traits within the population. This population can consist of any collection of things. Simply divide these things up according to type. If these types have tendencies to increase or decrease in the local environment owing to the presence of instances of the same type, this is their relative fitness. If these types reproduce, that makes the process more 'biological', but it is not necessary. We only need to be able to establish objective criteria for determining what type of object something is, and ascertain it has fitness, to declare it subject to an evolutionary process. The replicator approach, however, makes additional demands – in particular, that changes in frequency result from the essential differentiating features of the type being copied from old tokens into the new ones.

Fitness, from this perspective, is just the tendency of a type to increase or decrease, given a specifiable suite of conditions in the local environment. Selection is change in the frequency of types owing to their relative fitness, and variation is change in a type's frequency independent of the type's fitness. Conspicuously missing from these definitions are the notions of replication, heredity (or copying fidelity) and the ancestor–descendant relation. This implies that we can understand evolution without invoking the concepts of either an evolutionary lineage, or replicators. Neither concept is a prerequisite for evolutionary theory to be fruitfully applied to some phenomena (Harms, 1996).

The natural conclusion, therefore, is that culture can evolve without memes. Support for memetics

must come in the form of empirical studies that identify replicators at work in cultural reproduction. Until that happens, we can remain convinced that culture evolves, despite having no firm idea about the mechanisms underlying the reappearance of cultural traits in each generation.

CONCLUSION

How people come to share similar mental contents remains an essential problem for social science to solve. Does culture provide big-brained creatures with a system of informational inheritance which operates independently of, but in parallel with, genes? Alternatively, are supposedly cultural responses induced by mental algorithms that simply reflect a cumulative history of natural selection for genetically directed behaviors? Unfortunately, it will require additional research to find a conclusive answer to this question. However, the fact that cultural change exhibits the basic characteristics of an evolutionary process – inheritance, variation, and selection – seems less open to debate. Whether there will be overarching rules for describing cultural transmission processes remains to be determined, and it seems likely that who learns what from whom will turn out to be specific not only to particular groups, but also to particular periods within the life history of each group – perhaps even to each kind of trait being considered. The goal of establishing general rules of cultural transmission and selection applicable to everyone everywhere remains elusive, making the study of cultural evolution intrinsically complex.

Theories from evolutionary biology have many implications for research in the cognitive sciences. Evolutionary psychologists have been using these theories to guide their research, the goal of which is to map the evolved, species-typical cognitive and neural architecture of humans (and other species).

INTRODUCTION

Evolutionary psychology (EP) is a paradigm that can be applied to any issue in psychology, rather than a subfield built around the study of a single topic such as vision, social psychology, or child development. As a result, evolutionary theories have opened up many previously unexplored research areas to investigation. Moreover, topics that have already been explored from other perspectives can be advanced empirically and theoretically by adding an evolutionary perspective to the mix. This is because few (if any) of the mechanisms that make up the human mind/brain have been completely mapped. Evolutionary analyses of the adaptive functions that a mechanism evolved to perform usually provide specific hypotheses about its as yet unmapped and undetected design features, prompting further discoveries. Even if the mechanism under study were fully mapped, a correct theory of its adaptive function would still be needed to explain how it came to exist, and why it has the computational design that it does; and to identify which of its components are design features (i.e., functional components), which are incidental byproducts of the mechanism's functional design, and which are evolutionary accidents. In this way, EP is playing the central role in transforming psychology from a largely atheoretical collection of findings to a discipline with principled explanations for why the components of the mind/brain have the designs that they do.

APPLICATIONS OF EVOLUTIONARY PSYCHOLOGY

Heuristic Role of Evolutionarily Derived Predictions

A feature that distinguishes evolutionary psychology from other approaches is that researchers have principled theoretical reasons for their hypotheses derived from evolutionary biology, paleoanthropology, game theory, and hunter–gatherer studies. Such theoretically derived hypotheses allow researchers to devise experiments that make possible the detection and mapping of mechanisms that no one would otherwise have thought to test for in the absence of such theories. Evolutionary psychologists argue that this practice allows a far more efficient research strategy than experiments designed and conducted without reference to the likely functions of the brain. A key insight that emerges from integrating psychology with evolutionary biology is that the mechanisms that psychologists study are adaptations – mechanisms that acquired their organization because that arrangement solved adaptive problems for our ancestors (i.e., had an adaptive function). This insight links the study of psychological mechanisms to theories of adaptive function developed in evolutionary biology. This, in turn, allows a large number of predictions to be derived about the design of human information-processing mechanisms from the large pre-existing body of theories already developed and empirically tested within modern evolutionary biology.

Using this new research program, many theoretically motivated discoveries have been made concerning, for example, internal representations of trajectories; social reasoning specializations; the frequency format of probabilistic reasoning representations; the decision rules governing risk aversion and its absence; universal mate selection criteria and standards of beauty; eye direction detection and its relationship to understanding others' mental states; principles of generalization; life history shifts in aggression and parenting decisions; social memory; reasoning about groups and coalitions; the organization of jealousy, and scores of other topics. Several examples are discussed in more detail below.

Social Exchange and Cheater Detection

Sometimes known as reciprocal altruism, social exchange is an 'I'll scratch your back if you scratch mine' principle: *X* provides a benefit to *Y* conditional on *Y* doing something that *X* wants. This mutual provisioning of benefits, each conditional on the other's compliance, is rare in the animal kingdom: some species (e.g., humans, vampire bats, chimpanzees, baboons) have the cognitive machinery necessary to engage in this behavior, whereas others do not. Robert Trivers, W. D. Hamilton, Robert Axelrod and other evolutionary researchers used game theory to understand the conditions under which social exchange can and cannot evolve. For adaptations causing this form of cooperation to evolve and persist, cooperators must have mechanisms that perform certain specific tasks. For example, reciprocation cannot evolve if the organism lacks reasoning procedures that can effectively detect cheaters (those who take conditionally offered benefits without providing the promised return). Such individuals would be open to exploitation, and hence selected out. Based on such analyses, Leda Cosmides and John Tooby hypothesized that the human neurocognitive architecture includes social contract algorithms: a set of circuits that were specialized by natural selection for solving the intricate computational problems inherent in adaptively engaging in social exchange behavior, including a subroutine for cheater detection.

Because conditionally delivered behavior requires conditional reasoning for its regulation, Cosmides and Tooby used the Wason selection task, an experimental protocol developed to study conditional reasoning, in order to test for the presence of social contract algorithms and their predicted properties. The Wason selection task asks subjects to look for violations of a conditional rule (*If P then Q*), such as 'If a person eats hot chili peppers, then he will drink a cold beer'.

A conditional rule is violated whenever *P* happens but *Q* does not happen (in this case, whenever someone ate hot chili but did not drink cold beer). In the Wason task, the subject is given incomplete information about four people (in this case, one ate hot chili peppers (*P*), one ate broccoli (*not-P*), one drank cold beer (*Q*), one drank hot tea (*not-Q*)). To respond correctly, the subject would need to investigate the person who ate chili and the person who drank hot tea (i.e., *P* and *not-Q*). Yet studies in many nations have shown that reasoning performance on descriptive rules like this is low: only 5–30 percent of people give the logically correct answer, even when the rule involves familiar terms drawn from everyday life.

To show that people who ordinarily cannot detect violations of conditional rules can do so easily when the rule expresses a social contract and a violation represents cheating would be (initial) evidence that the mind has reasoning procedures specialized for detecting cheaters.

Evolutionary psychologists found just that pattern: people who ordinarily cannot detect violations of if-then rules can do so easily and accurately when that violation represents cheating in a situation of social exchange. Given a rule of the general form, 'If you take benefit B, then you must satisfy requirement R' (e.g., 'If you borrow my car, then fill up the tank with gas'), people will point to the person who accepted the benefit and the person who did not satisfy the requirement – the individuals who represent potential cheaters. The adaptively correct answer is immediately obvious to almost all subjects, who commonly experience a pop-out effect. No formal training is needed. Whenever the content of a problem asks one to look for cheaters in a social exchange, subjects experience the problem as simple to solve, and their performance jumps dramatically. In general, 65–80 percent of subjects get it right, the highest performance found for a task of this kind. Further experiments showed that this does not occur because social contracts activate logical reasoning, but because they activate a differently patterned, specialized logic of social exchange. On social exchange problems when formal logic (i.e., the propositional calculus) and social exchange logic predict different answers, subjects overwhelmingly follow the evolved logic of social exchange.

Many cognitive scientists have now investigated social contract reasoning, and many of the predicted design features have been tested for and

found. For example, the mind's automatically deployed definition of cheating is tied to the perspective one has adopted, for the reasoning enhancement to occur, the violations must potentially reveal cheaters; if detecting violations of social contracts reveals only innocent mistakes, enhancement does not occur. Perhaps the strongest evidence that there is a neural specialization designed for cheater detection is the discovery that cheater detection can be selectively impaired by brain damage, without impairing other reasoning abilities. If social contract reasoning were a byproduct of a more general ability to reason, one could not lose the specific ability without also suffering damage to the general ability supposedly responsible for it. Consistent with its being a species-typical ability, social contract reasoning effects are found across cultures, from industrial democracies to hunter–horticulturalist groups in the Ecuadorian Amazon. Most surprisingly, people are just as good at detecting cheaters on culturally unfamiliar or imaginary social contracts as they are for ones that are completely familiar, providing a challenge for any counter-hypothesis resting on a general-learning skill acquisition account. (*See* **Reasoning**)

Foraging and Sex Differences in Spatial Ability

Before 1992 there were hundreds of studies published on sex differences in spatial abilities. Not one showed a replicable female advantage in spatial abilities, and many showed a male advantage.

While evolutionary psychologists do not assume that male and female psychological architectures must be identical in all respects, they do think that whatever differences exist will reflect the different distributions of tasks faced ancestrally by men and women (when they do not reflect differential treatment during development). If there was stronger selection for ancestral women for some spatial tasks, and stronger selection for ancestral men for others, this would produce female superiority in some tasks, and male superiority in others. Starting from an adaptationist perspective, Irwin Silverman and Marion Eals asked a question no spatial researcher had ever asked before: what kind of spatial cognition is required to be good at gathering plant foods? Finding plant foods is a predominantly female activity in foraging populations, and it poses different spatial problems than hunting. Unlike animals, plants do not change location. They do, however, develop over time: a vine, herb, bush, or tree yielding nothing edible now will bear ripe and edible fruit, nuts, tubers, or leaves later in the year. To be an efficient forager, therefore, one must be good at encoding and remembering the locations of thousands of different plants within a complex spatial array. Ideally, this information should be learned incidentally, as one goes about other activities.

Silverman and Eals designed spatial tests that could assess this ability. Some of these tests involved pictures of objects in a complex array, others involved objects in a room. Regardless of format, women consistently recalled more objects than men did. More critically, however, women were more accurate than men at recalling the locations of these objects. This held even controlling for the fact that women recalled more objects: given that an object was recalled, women's location memory was more accurate. This female advantage was large – about as large as the male advantage in tests of mental rotation – and it was found even in incidental learning paradigms.

A century of evolutionarily agnostic approaches to spatial cognition had failed to find a female advantage for any spatial task. But the first time evolutionary psychologists asked what kind of spatial problems ancestral women would have had to solve to forage efficiently, they were able to discover a new spatial ability that shows a large female advantage. As a paradigm, EP allows one to ask more specific questions about the computational design of cognitive sex differences without these being euphemisms for the age-old question of which sex is 'better'. With an adaptationist focus, questions of better or worse quickly disappear and are replaced with questions about the possible functions of a trait, design features predicted by those functions, and empirical data that confirm or falsify confirm those design features. (*See* **Spatial Cognition, Psychology of**)

Coalitional Psychology: Is Race Encoding a Reversible Byproduct of Coalition Encoding?

Ingroup favoritism paired with outgroup indifference or hostility exists in all human cultures. Field and laboratory studies have shown that this behavior is easy to elicit: the simple act of categorizing individuals into two social groups predisposes humans to discriminate in favor of their ingroup and against the outgroup in both allocation of resources and evaluation of conduct. This occurs even when subjects are assigned to groups temporarily and anonymously by an experimenter who used dimensions that are trivial, previously

without social significance, and random with respect to any real characteristics of the individuals assigned. Given that categorizing people into groups along nearly any dimension elicits discrimination, it would be discouraging to find that the human mind cannot help but categorize people on the basis of their race.

Yet, social psychologists had reluctantly concluded that the human mind has circuits that automatically encode (notice and remember) the race of each individual we encounter, as a normal part of impression formation. This conclusion was based on years of experiments in which researchers had searched in vain for ways to weaken the tendency for subjects to categorize others by race. However, the idea that automatic racial categorization is an evolved feature of the human mind is implausible from an evolutionary point of view. Our hunter–gatherer ancestors would rarely – if ever – have encountered a person of a different race, so natural selection could not have favored brain mechanisms designed to notice and remember a non-existent dimension of ancestral social life. This line of reasoning implies that race encoding is a side-effect of a mechanism designed to detect something else that was important for our ancestors.

Accordingly, Robert Kurzban and colleagues proposed and tested an alternative hypothesis: that the (apparently) automatic and mandatory encoding of race is instead a byproduct of brain mechanisms that evolved for an alternative function that was a regular part of the lives of our foraging ancestors: detecting coalitions and alliances. Hunter–gatherers lived in bands, and neighboring bands frequently came into conflict with one another. Similarly, there were coalitions and alliances within bands, a pattern found in related primate species and likely to be more ancient than the hominid line. Mechanisms designed to track these shifting alliances would have benefited our ancestors by helping them to predict the likely social consequences of alternative courses of action.

Brain mechanisms for detecting coalitions should identify patterns of coordinated action, cooperation, and competition. But behaviors that reveal who is allied with whom are rare; to allow judgments even when such events are not in process, coalition encoding mechanisms should note and boost the saliency of any perceptually available marker that is correlated with coalitional alliance. Otherwise arbitrary cues – such as accent, skin color, or manner of dress – should pick up significance only insofar as they acquire predictive validity for coalitional membership. In societies that are not completely racially integrated, shared appearance – a highly visible and always present cue – may be correlated with patterns of association, cooperation, and competition. Under these conditions, coalition detectors may perceive (or misperceive) race-based social alliances, and the mind will map 'race' onto the cognitive variable *coalition*.

Using the same unobtrusive measures that had led social psychologists to believe race encoding is intractable, Kurzban *et al*. showed that race encoding is instead a reversible byproduct of coalition encoding. By creating a social context in which race was not predictive of a cooperative alliance, evolutionary psychologists were able to drastically decrease the extent to which subjects encoded race. Even a few minutes' exposure to a world in which race no longer predicted alliance was enough to substantially deflate the tendency to notice and remember another's race. The experiments also confirmed predictions about the design features of the coalition detection system. Without being asked to do so, subjects nevertheless spontaneously grouped persons into coalitions, noticing and remembering who was affiliated with whom. They did so even in the absence of common appearance, simply on the basis of expressions of mutual ingroup support and outgroup emnity. Other conditions with appearance cues confirmed that the mind appears designed to pick up any perceptual marker, however arbitrary, that is correlated with patterns of cooperation and alliance. The same marker is ignored when it is not correlated with coalition. Humans appear to have an evolved coalition detection system.

Relevance of Evolutionary Psychology to Psychiatric Syndromes

Evolutionary psychologists argue that the paradigm provides fresh insight into psychiatric syndromes. According to Jerome Wakefield, the (implicit) consensus view in medicine is that disorders are conceptually defined as harmful dysfunctions. That is, to qualify as a disorder, a syndrome must consist of damage to one or more adaptations, and people must make the value judgment that these effects are harmful. (For example someone may suffer damage to their adaptations for incidentally learning plant locations or coalitional affiliations but neither notice nor care.)

This places the study of adaptations – computational ones in the case of mental illnesses, noncomputational ones in the case of other illnesses – at the center of medicine. Autism, for example, appears to

involve a breakdown in the psychological mechanisms that allow one individual to interpret the mental states of others. Some syndromes, such as postpartum depression, gestational diabetes, and the food aversions of pregnancy sickness, may not be disorders at all, but the expression of adaptations. Others – such as phobias to snakes and spiders – may result from a dysfunctional overactivation of an adaptive system designed to reduce poisonous bites among our foraging ancestors. Yet others may result from a mismatch between modern environments and the ancestral world our mechanisms evolved to operate in. For example, fat storage as a buffer against occasional famine – adaptive for a hunter–gatherer – may lead to obesity in calorie-abundant environments.

Example: postpartum depression

One fact about the past that researchers know with certainty is that raising offspring was, for both parents, very costly in terms of time and energy. These costs are particularly high when a baby is born. Nursing alone requires approximately an additional 500 calories per day above and beyond what the mother needs for herself. Our ancestors had to forage for all their food, and studies of hunter–gatherers and other primates indicate that food would often have been scarce. A mother in an ancestral foraging society would have benefited greatly from food and other assistance provided by the father and other family members, especially if she also had other children.

Robert Trivers pointed out that investment of scarce resources in one offspring decreases the investment that can be made in other offspring (or future offspring). In the unforgiving world of our ancestors, attempting to raise a newborn without sufficient food and help from others would sometimes have led to the death of the mother or her other children, or might have damaged her ability to have any future children. In the environment of evolutionary adaptedness, mothers who reduced or eliminated investment in offspring that were unlikely to survive and reproduce due to poor health or insufficient parental resources would have been able to increase their investment in other offspring that were more likely to survive and reproduce, and thus would have had a greater number of total descendents than mothers who invested in all offspring equally.

Martin Daly, Margo Wilson, Janet Mann, and Edward Hagen have argued that our ancestors would have been under heavy selection pressure to evolve a motivational system that evaluated the availability of resources, social support, and the health of the newborn to regulate the sentiments in a new mother that decide whether or not to expend her scarce resources on the newborn. Because in humans, evolved decision-making processes are often experienced as emotions, evolutionary psychologists predict that mothers with sufficient resources, social support, and a healthy baby will feel positive emotions towards the newborn, and will therefore invest in it. In contrast, mothers with low levels of resources, social support, or a very unhealthy baby may experience negative emotions towards the newborn (and a corresponding lack of positive emotions), and will therefore reduce their investment in it, saving this investment for other (or future) offspring that are more likely to survive and reproduce.

Postpartum depression (PPD), which is characterized by sustained low mood, sadness, loss of interest, and other symptoms, is suffered by about 10 percent of all mothers, and has been universally regarded as a mental illness, one probably caused as a byproduct of abnormal hormone fluctuations. A close look at PPD from an evolutionary perspective, however, suggests that it is not a disorder, because it exhibits a series of design features that would have been too functional in the world of our ancestors to have appeared by accident. PPD operates in a manner consistent with what would be expected in an adaptation whose function is to reduce investment in the newborn when there are insufficient resources and social support, or when the infant has serious health problems suggesting that it would not survive and reproduce in a foraging world. Studies by Hagen and others have confirmed that PPD is associated with lack of social support, lack of resources, and infant health problems, and that mothers with PPD reduce their investment in their newborns. Many studies have failed to find any association between PPD and abnormal hormone fluctuations, and the conclusion that PPD is not caused by abnormal hormonal fluctuations is strengthened by the fact that fathers (who, unlike mothers, are not experiencing dramatic hormonal changes) also suffer PPD. Even though mothers in industrialized countries typically have enough food, they nevertheless inherit adaptations designed to be sensitive to the availability of social support, a resource that would have been critical to successfully raising a child in ancestral environments. When this essential resource is in short supply, it would have been evolutionarily adaptive for mothers to lower their interest in their newborn.

Because this is a new theory, it cannot form the basis for clinical interventions in PPD cases without

considerable further testing. If this theory turns out to be true, however, it suggests that treatment of PPD should not consist of antidepressants alone, but should instead involve the judicious use of antidepressants in concert with providing the mother with what she needs: more social support and resources. (*See* **Depression**)

CRITICISMS OF EVOLUTIONARY PSYCHOLOGY

Storytelling

Some critics, such as Stephen Jay Gould, have argued that the field consists of post-hoc storytelling ('just-so stories'). It is difficult to reconcile such claims with the actual practice of EP, since in evolutionary psychology the evolutionary model or prediction typically precedes and causes the discovery of new facts, rather than being constructed post hoc to fit some known fact. Of course, all scientific fields from physics to geology also entertain new explanations for already known facts, and evolutionary psychology is no exception. However, new theories for already known facts almost always make new predictions that other theories do not, allowing them to be tested against each other. For example, race encoding was a known phenomenon, but the theory that it was a byproduct of coalitional specializations led to new predictions. Indeed, the value of any new scientific paradigm is measured by its ability to explain findings that other paradigms could not explain, by its ability to explain large sets of facts economically, and by its ability to make novel and significant predictions that are subsequently confirmed by observation.

Though evolutionary psychology is a young science with relatively few practitioners, its researchers have (1) predicted, tested for, and found, a large number of previously unknown mechanisms, whose existence was predicted in advance by evolutionary theory; (2) advanced theories that explain previously unexplained phenomena; (3) advanced theories that provide economical and unified explanations for previously unconnected findings.

Falsifiability

Another common assertion has been that evolutionary hypotheses are unfalsifiable, a claim that is sometimes justified by arguing that the evolutionary past cannot be observed. Evolutionary psychologists reply that there are two components to their theories: (1) hypotheses about the psychological architecture of modern humans; and (2) hypotheses about the ancestral selection pressures that designed the architecture.

Saying a mechanism evolved by natural selection to solve a particular function makes specific and testable predictions about the present design features of that mechanism. (For example humans will exhibit an enhanced ability to reason about cheaters, which can be selectively impaired while other reasoning abilities stay intact. When tested, women will exhibit an advantage in incidentally learning the locations of things.)

Only the second component (ancestral selection pressures) involves phenomena that are difficult to observe directly. In analyzing ancestral selection pressures, EP draws heavily on knowledge about ancestral environments, and critics have plausibly maintained that reconstructions of the past (which routinely go on in astronomy, geology, physics, and biology) are inherently speculative. This would be a problem if researchers had to have complete information about all aspects of the ancestral world to make progress. However, while some features of the ancestral world are difficult to investigate, researchers know with certainty or high confidence thousands of important things about our ancestors, many of which can be used to derive falsifiable predictions about our psychological architecture: our ancestors had two sexes; contracted infections by contact; collected plant foods; inhabited a world where the motions of objects conformed to the principles of kinematic geometry; chose mates; had color vision; were predated upon; had faces; lived in a biotic environment with a hierarchical taxonomic structure, etc. To the extent that reconstructions are uncertain or erroneous, they will simply lead to experiments that are no more or less likely to be productive than the blind guessing of evolutionarily agnostic empiricism, the alternative research strategy.

How Good are Adaptations?

Critics have argued that adaptationist analyses are misconceived, because (they assert) natural selection is a weak force in evolution, making adaptations poor, and rendering functional predictions irrelevant. However, researchers point out that the empirical record shows that selection regularly produces very well-engineered adaptations to long-enduring adaptive problems, providing a solid empirical foundation for analyzing the human psychological architecture in functional terms. Whenever engineers have attempted to duplicate any natural human competence (color

vision, object recognition, grammar acquisition, texture perception, object manipulation, language comprehension, etc.), even when using huge budgets, large research teams, and decades of effort, they are unable to engineer artificial systems that can come close to competing with naturally engineered systems. It seems illogical to assert as a theoretical precept that evolved systems are poorly designed when human engineers cannot produce anything nearly as good.

Why is Function Emphasized?

Because EP emphasizes function, critics have argued that proponents think that all traits are adaptive. This is untrue, either in theory or in practice (for example Kurzban *et al*.'s argument above is that race encoding is a byproduct, not an adaptation). Although evolutionary psychologists do not think all – or even most – traits are adaptations, they do emphasize the study of adaptations and their byproducts for four reasons.

1. Adaptationist theories of function provide clear and useful prior predictions about cognitive organization.
2. The functional elements of an adaptation are far more likely to be species-typical, making them easier to discover through experimentation.
3. Very few constrained or falsifiable predictions about cognitive architecture follow from analyses of the random or contingent components of evolution.
4. As yet, there are few, if any, useful or well-developed theories of non-adaptive constraint.

Finally, evolutionary psychologists do not maintain that the developed architecture of the human mind is immune to modification, that genes or biology are deterministic, that culture is unimportant, or that existing human social arrangements are fair or inevitable. Indeed, they provide testable theories about the developmental processes that build (and can change) the mechanisms that generate human behavior.

Evolutionary Psychology: Theoretical Foundations

Introductory article

Leda Cosmides, University of California, Santa Barbara, USA
John Tooby, University of California, Santa Barbara, USA

CONTENTS

Evolutionary psychology is an approach to the cognitive sciences whose goal is to map the evolved, species-typical cognitive and neural architecture of humans (and other species). Its focus is on integrating what is known about evolution into the research process, allowing evolutionary psychologists to derive hypotheses about the design of human information-processing mechanisms from the large pre-existing body of theories already developed and empirically tested within modern evolutionary biology.

INTRODUCTION

Evolutionary psychologists view the human mind as a set of computational machines that were designed by natural selection to solve adaptive problems faced by our hunter–gatherer ancestors. They argue that this basic Darwinian insight, when properly applied, can be uniquely informative for anyone who seeks to discover and understand the design of the human mind – that is for anyone who wishes to discover which programs reliably develop in the brains of all normal human beings, the conditions that activate these programs, and how each program processes information. In their view, attention to adaptive function will allow psychologists to (1) explain why the human mind contains those programs that are already known, (2) discover new programs that no one had thought to look for before, and (3) together with the analytical tools of the cognitive sciences, address previously intractable or neglected topics, such as emotion and motivation.

FOUNDATIONS

Although evolutionary psychology is an inclusive discipline that draws on many fields, its core ideas emerged from the intersection of three scientific research traditions: (1) work by David Marr, Noam Chomsky, and other cognitive scientists, that showed that the mind contains a number of different cognitive programs, many of which are specialized for performing a particular function (such as seeing or learning a language), (2) hunter–gatherer and primate studies, and (3) the revolution in evolutionary biology led by George C. Williams, W. D. Hamilton, John Maynard Smith, and Richard Dawkins, that replaced vague notions of function with a theoretically and empirically rigorous modern adaptationism, based on theories of natural selection that were formalized using game theory and replicator dynamics.

Out of replicator dynamics, evolutionary researchers derived a series of theories about how natural selection designs mechanisms that deal with parenting, mating, cooperation, kinship, communication, conflict, and dozens of other adaptive problems. These theories were then validated on thousands of animal and plant species. Evolutionary anthropologists have enriched this body of knowledge by studying primate and hunter–gatherer behavior and ecology, investigating hominid evolution and ancestral environments, and by extending evolutionary theory to cover novel features of the human species. This allows increasingly refined models of the adaptive problems our ancestors faced and how selection acted on them.

The understanding that natural selection is the only anti-entropic force known to scientists that builds functional machinery into organisms led to the third major insight: mechanisms studied by cognitive scientists necessarily had to be adaptations. This connected evolutionary research to cognitive science in the most direct possible way: cognitive science is the study of adaptations – computational adaptations. This allowed evolutionary psychologists to widen cognitive science

into a comprehensive mapping of the computational mechanisms that underlie all human behavior, not just traditional cognitive topics such as attention, learning, and memory. The fact that no single information-processing design can efficiently solve a diversity of adaptive problems means that specialized cognitive mechanisms are likely to have evolved to regulate human parenting, social interaction, mating, foraging, incest avoidance, sexual jealousy, coalitions, and so on. The goal of evolutionary psychology is the construction of a high resolution map of the whole species-typical computational architecture of humans, including motivational and emotional mechanisms.

Engineering and Reverse Engineering

Evolutionary psychologists approach their field conceptually as if it were a form of reverse engineering. Engineers start with a problem, and then design machines that are capable of solving that problem in an efficient manner. As a result, the machine's structure reflects its function: it has certain properties and components rather than others because those structures solve a problem better than alternative ones.

Engineers can also work in reverse: given a strange machine, they can figure out what its design features are – i.e., which of its components are functional and how their arrangement accomplishes the machine's function. Doing this is relatively simple if one knows what problem the machine was designed to solve, because one can then look for structures capable of accomplishing that function. But, as any engineer will confirm, reverse engineering is exceedingly difficult when one has no idea what the machine was designed to do. Without a theory of function, how does one determine which parts are functional.

Cognitive psychologists are engineers working in reverse: the brain is a strange machine, and cognitive psychologists are attempting to figure out how it works, i.e. which of its components are functional and how their arrangement accomplishes various functions. Doing this is difficult, however, without knowing what problems this organic machine was designed to solve.

Evolutionary biology is helpful because it provides theories about what problems the brain was designed to solve, that is, theories about the functions of its constituent programs. This is done using (1) knowledge about basic problems any organism must solve if it is to survive and reproduce (e.g., finding food efficiently, choosing a fertile mate), (2) knowledge about ancestral environments for the species in question, and (3) evolutionary game theory to model which of an array of possible solutions would have replicated fastest under ancestral conditions (and therefore have been favored by natural selection). From these elements, one can develop a task analysis for an adaptive problem, the first step in developing a design specification: an answer to the question, 'What would a machine capable of solving this problem well under ancestral conditions look like?' The answer(s) to this question then guide one's empirical investigations.

For example, certain species (including our own) trade goods and favors (cooperation for mutual benefit). But results from evolutionary game theory showed that natural selection will not favor cognitive machinery enabling this somewhat unusual form of cooperation unless the individuals involved are able to detect cheaters (those who do not reciprocate favors). This led Cosmides and Tooby to look for, and find, reasoning programs specialized for cheater detection. Baron-Cohen's research on 'mindreading' – programs that allow people to infer the intentions, beliefs, and desires of others – was guided by theories about coevolutionary arms races, as well as by knowledge about what information was available in ancestral environments for inferring mental states. In the evolutionary past (as now) eye direction provided reliable and useful information about the intentions of other people and of predators. Noting this, Baron-Cohen hypothesized that specialized eye direction detectors may have evolved as a component of social cognition and predator detection, and he designed experiments testing for their existence and design.

Despite all the obvious differences between living beings and human-made machines, reverse engineering is a successful strategy for studying organisms because the two resemble each other in one crucial respect. Like human-made machines, organisms are comprised of structures that reflect their function. This is an inevitable consequence of how natural selection works, and fundamental to the logic of evolutionary psychology (see below).

Evolutionary Restrictions on the Concept of 'Function'

George Williams's 1966 book, *Adaptation and Natural Selection*, played a key role in the development of evolutionary psychology. Williams elucidated the levels at which natural selection can operate

(genes and individuals, yes; groups, species, and ecosystems, weakly or not at all); he demonstrated why it will operate most powerfully in constructing adaptations at the level of the gene and individual; he clarified the logic of adaptationism; and he established standards of evidence that must be met before any trait can be considered an adaptation.

Before Williams, vague, panglossian functionalist thinking permeated evolutionary biology (and such thinking continues, implicitly, to saturate other fields even today). Evolutionary accounts explain the existence of traits by reference to their function, but many biologists (and psychologists) were attributing functionality merely by identifying a beneficial consequence to some entity, whether this was an individual, social group, species, or ecosystem. They did not focus on establishing whether the design systematically caused the propagation of its genetic basis reliably under ancestral conditions, as the theory of natural selection requires. Williams showed why looser notions of function were deficient, demonstrated how tightly constrained any adaptationist (i.e., functionalist) or byproduct claim had to be to be consistent with neo-Darwinism, and outlined the strict criteria such claims had to meet. Evolutionary psychologists attempt to apply these stringent adaptationist constraints on functionalism to limit the looser and less formalized ideas of function commonly employed in the cognitive, neural, and social sciences. They maintain that cognitive scientists should be aware that cognitive theories typically assume complex functional organization of types that are inconsistent with what evolution is likely to have produced.

Perhaps more importantly, when cognitive scientists do not understand what legitimately counts as a function in an evolved system, they fail to look for forms of complex functional organization that natural selection is likely to have produced. For example, although cognitive neuroscientists look for brain systems designed to cause fear in response to physical threats, they do not look for systems designed to cause sexual jealousy in response to threats to a mating relationship. This failure to investigate stems from an erroneous belief that 'beneficial' refers to survival rather than gene replication. A system that causes sexual jealousy jeopardizes the individual's survival by triggering aggressive conflicts, yet it would have promoted its own reproduction in the past in relation to the design alternative: indifference to a mate's extrapair sexual behavior. Unsurprisingly, adaptations to prevent others from having sexual access to one's mate have evolved in a large variety of animal species, including humans (as Buss, Symons and Daly & Wilson have shown).

THE DESIGN OF ORGANISMS

The goal of Darwin's theory was to explain the designs of organisms. Darwin asked, for example, why the beaks of finches differ from one species to the next, and have the forms that they do. Why do animals expend energy attracting mates, energy that could be spent on survival? Why are human facial expressions of emotion similar to those found in other primates?

Two Principles: Common Descent and Adaptation

One of the most important evolutionary principles accounting for the characteristics of organisms is common descent. An increasing body of evidence indicates that all organisms alive today are the descendents of a single originating organism. Over the course of evolutionary time, new species originate because one breeding population sometimes becomes subdivided into two or more populations, and stops interbreeding. Although they start out with the same set of genes, they subsequently can evolve independently because the different populations no longer exchange genes through matings. This process of species splitting gives a hierarchical tree structure of similarity to all species on Earth. Offspring inherit their parents' genes and design features, which stay the same across the generations unless selection or chance modifies genes. So, the more recently two species were descended from the same ancestral species, the more design features they will share in common. Hence, we expect to find many similarities between humans and our closest primate relatives. For example, humans and chimpanzees both use exactly the same set of muscles in making parallel facial expressions.

This is the phylogenetic approach, and it consists of the search for features (called 'homologous features') that are similar because both species inherited them from the species that was their common ancestor. This approach has a long and productive history in psychology. But as valuable as it is for many questions, this approach cannot adequately address features that evolved uniquely in only one lineage, because there are then no similarities to compare. Because there is the widespread misimpression that evolutionary psychology consists solely or primarily of applying a phylogenetic

approach, many take it as a given that evolutionary psychology cannot address the large set of properties that make us uniquely human. They think it is limited to the study of characteristics that we share with other animal species.

However, the second principle that accounts for the characteristics of organisms is that natural selection builds adaptations into their designs. Indeed, natural selection can cause the designs of different species to diverge from one another, sometimes producing characteristics that are unique to a given species, such as the elephant's trunk or the cognitive mechanisms that allow humans to learn language. *Adaptationism* is the name for the research program that gives a central role to exploring how natural selection functionally organizes the designs of organisms. It can be applied to analyze features that are unique to humans, because the theory of natural selection illuminates equally well features that are shared and features that are unique to a single species.

Although evolutionary psychologists certainly appreciate and invoke phylogenetic explanations where they are appropriate (as well as other relevant theories and analytic tools), it is the application of adaptationist logic that has provided the brightest illumination to formerly murky issues in human psychology.

Organization in Evolved Systems

Organisms, like watches or automobile engines, exhibit a multitude of parts and subassemblies that are arranged in precise and highly ordered ways so that they operate to achieve the functional ends they were designed to perform. The eyes, immune system, umbilical cord, cell nucleus, and lungs, to pick a handful of examples, all display a very advanced technology, built out of organic molecules. The more that chance events, such as accidents or violence, act to randomize this internal order, the more the watch, automobile, or organism is damaged. In a world where everything is bombarded by chance forces, where did all this functional order in animals and plants come from?

The evolutionary process has only two components, chance and natural selection, that govern how the genes in a species change over time. Chance processes act to randomize relationships within the organism, and so cannot account for the accumulation of the highly ordered arrangements of functional parts that permeate organisms. For this reason, modern researchers now understand that natural selection is the only component of the evolutionary process that can build complex functional organization into a species' structure. This means that all complex *functional* design in organisms was created by natural selection. Consequently, we know that all functional organization in humans must be built in a way that is consistent with the principles of natural selection. This recognition is what makes evolutionary biology the foundation of psychology and neuroscience, not to mention anatomy, physiology, the medical sciences, and the social sciences. Our functional order originally comes from evolution.

To be sure, there is much that is not functional in organisms as well, introduced by chance evolutionary and non-evolutionary processes. But the functional architecture of organisms is central to their organization, and they would not exist without it. Indeed, in evolved systems there is a sense in which function determines structure, and that is the key to understanding the design of the human cognitive architecture.

Natural Selection: How (and Why) Function Determines Structure

The notion that species evolve – that their design changes over time – had been proposed and hotly debated before Darwin was born. But the early evolutionists lacked a clear and convincing account of how or why this happens. That is what Darwin and Wallace provided. They discovered a materialist mechanism – natural selection – that explains how organisms acquire their design, as well as why that design changes over time. The revolution that ensued bears Darwin's name because he is the one who elaborated the theory, provided the most extensive evidence for it, and was willing to pursue its implications wherever they led – even when they led to the human mind.

Many breakthroughs in science happen not because of new data, but because of a new way of looking at things. This was true for Darwin. Everyone already knew that organisms reproduce, and that when they do, they give rise to similar organisms: rabbits give birth to rabbits, not to ducks. They also knew that, while offspring closely resemble their parents, they are not perfect replicas of them. They vary a bit, and some of these variants are able to perform certain tasks, such as producing milk, better than others. This was common knowledge based on centuries of animal husbandry in which people selectively bred individual animals with special abilities – cows that produced more milk, sheep that grew softer wool. And Darwin, like Descartes, Harvey, and many others before

him, knew that an organism can be thought of as a machine: a system whose parts are designed to perform certain functions.

All of these facts fall into place, Darwin realized, if you think of an organism as a self-reproducing machine. What distinguishes living from nonliving machines is reproduction: the presence in a machine of devices (organized components) that cause it to produce new and similarly reproducing machines. Given a population of living machines, this property – self-reproduction – will drive a system of positive and negative feedback that can explain the remarkable fit between organisms and their environment.

In contrast to human-made machines, which are designed by inventors, living machines acquire their intricate functional design over deep time, as a downstream consequence of the fact that they reproduce themselves. Indeed, modern Darwinism has an elegant deductive structure that logically follows from Darwin's initial insight that reproduction is the defining property of life, the driving force that causes species to change over time. That logic is as follows. When an organism reproduces, replicas of its design features are introduced into its offspring. But the replication of the design of the parental machine is not always error-free. As a result, randomly modified designs (mutants) are introduced into populations of reproducers. Because living machines are already exactingly organized so that they cause the otherwise improbable outcome of constructing offspring machines, random modifications will usually introduce disruptions into the complex sequence of actions necessary for self-reproduction. Consequently, most newly modified but now defective designs will remove themselves from the population – a case of negative feedback.

However, a small number of these random design modifications will, by chance, improve the system's machinery for causing its own reproduction. Such improved designs (by definition) cause their own increasing frequency in the population – a case of positive feedback.

This increase continues until (usually) such modified designs outreproduce and thereby replace all alternative designs in the population, leading to a new species-standard design. After such an event, the population of reproducing machines is different from the ancestral population: the population- or species-standard design has taken a step 'uphill' toward a greater degree of functional organization for reproduction than it had previously. Over the long run, down chains of descent, this feedback cycle pushes designs through state–space towards increasingly well-engineered – and otherwise improbable – functional arrangements. These arrangements are functional in a specific sense: the elements are well-organized to cause their own reproduction in the environment in which the species evolved.

For example, if a mutation appears that causes individuals to find family members sexually repugnant, then they will be less likely to conceive children incestuously. They will produce children with fewer genetic diseases, more of these children will mature and reproduce than will the children of those who are not averse to incest. Such an incest-avoiding design will produce a larger set of healthy children every generation, down the generations. By promoting the reproduction of its bearers, the incest-avoiding circuit thereby promotes its own spread over the generations, until it eventually replaces the earlier-model sexual circuitry and becomes a universal feature of that species' design. This spontaneous feedback process – natural selection – causes functional organization to emerge naturally and inevitably, without the intervention of an intelligent designer or supernatural forces.

Genes are simply the means by which design features replicate themselves from parent to offspring. They can be thought of as particles of design: elements that can be transmitted from parent to offspring, and that, together with stable features of an environment, cause the organism to develop some design features and not others. Genes have two primary ways they can propagate themselves: by increasing the probability that offspring will be produced by the organism in which they are situated, or by that organism's kin.

An individual's genetic relatives carry some of the same genes, by virtue of having received some of the same genes from a recent common ancestor. This means that a gene in an individual that causes an increase in the reproductive rate of that individual's kin will, by so doing, tend to increase its own frequency in the population. A circuit that motivates an individual to help feed her sisters and brothers, if they are starving, is an example of a program that increases kin reproduction. As W. D. Hamilton pointed out, design features that promote both direct reproduction and kin reproduction, and that make efficient trade-offs between the two, will replace those that do not (a process called 'kin selection').

How well a design feature systematically promotes direct and kin reproduction is the bizarre but real engineering criterion determining whether a specific design feature will be added to or discarded from a species' design. Therefore, we can

understand why our brains are constructed in the way they are, rather than in other perfectly possible ways, when we see how its circuits were designed to cause behavior that, in the world of our ancestors, led to direct reproduction or kin reproduction.

The concept of *adaptive behavior* can now be defined with precision. Adaptive behavior, in the evolutionary sense, is behavior that tends to promote the net lifetime reproduction of the individual or that individual's genetic relatives. By promoting the replication of the genes that built them, circuits that – systematically and over many generations – cause adaptive behavior become incorporated into a species' neural design. In contrast, behavior that undermines the reproduction of the individual or his or her blood relatives removes the circuits causing those behaviors from the species, by removing the genes that built those circuits. Such behavior is *maladaptive*, in the evolutionary sense.

So, evolutionists analyze how design features are organized to contribute to lifetime reproduction not because of a warped and biasing obsession with sexuality, but because reproduction was the final causal pathway through which a functionally improved design feature caused itself to become more numerous with each passing generation, until it became standard equipment in all ordinary members of the species.

Adaptive problems create adaptations

Enduring conditions in the world that create reproductive opportunities or obstacles, such as the presence of predators, the ability to pool risk through food sharing, or the vulnerability of infants, constitute adaptive problems. Adaptive problems have two defining characteristics. First, they are conditions or cause-and-effect relationships that many or most individual ancestors encountered, reappearing again and again during the evolutionary history of the species. Second, they are that subset of enduring relationships that could, in principle, be exploited by some property of an organism to increase its reproduction or the reproduction of its relatives. Enduring relationships of this kind constitute reproductive opportunities or obstacles in the following sense: if the organism had a property that interacted with these conditions in just the right way, then this property would cause an increase in its own reproductive rate.

One can think of these reproductive opportunities and obstacles as problems. A property is a solution to such a problem when it allows organisms with this property to take advantage of prevailing conditions, where 'advantage' means a reproductive advantage. If a bird would realize a reproductive advantage by being able to travel at night, and stars are prevailing conditions that – given the right brain mechanism – would make this possible, then a brain mechanism that uses stars for navigation would be a solution to the problem of traveling at night. Egg-eating predators pose an obstacle to a bird's reproduction. A property that circumvents this obstacle – such as a program that causes the bird to remove from its nest broken eggshells whose bright white interiors are easily spotted by predators – would be a partial solution to this problem. A property is a solution to an adaptive problem if it had the systematic effect, over generations, of increasing the reproduction of individual organisms or their relatives. The causal chain linking that property to reproduction may be indirect, and the effect on the organism's own offspring or the offspring of kin may be relatively small. As long as its consequences on relative reproduction are the cause of its spreading through the population, that property is a solution to an adaptive problem. All solutions are, of course, temporary and subject to improvement over time. But each modification that spread because it improved reproduction – however stop-gap or impermanent it may turn out to have been – counts as a solution to an adaptive problem.

Most adaptive problems have to do with relatively mundane aspects of how an organism lives from day to day: what it eats, what eats it, who it mates with, who it socializes with, how it communicates, and so on. Adaptive problems for our hunter–gatherer ancestors included such recurrent tasks as giving birth, winning social support from band members, remembering the locations of edible plants, hitting game animals with projectiles, breast-feeding, breathing, identifying objects, recognizing emotional expressions, protecting family members, maintaining mating relationships, self-defense, heart regulation, assessing the character of self and others, causing impregnation, acquiring language, maintaining friendships, thwarting antagonists, and so on.

An enduring adaptive problem constantly selects for design features that promote the solution to the problem. Over evolutionary time, more and more design features accumulate that fit together to form an integrated structure or device that is well engineered to solve its particular adaptive problem. Such a structure or device is called an 'adaptation'. Indeed, an organism can be thought of as largely a collection of adaptations, such as the functional subcomponents of the eye, liver, hand, uterus, or circulatory system. Each of these adaptations exists in the human design now because it contributed

to the process of self and kin reproduction in the past.

Recognizing adaptations

Natural selection is a hill-climbing feedback process that chooses among alternative designs on the basis of how well they function. It has produced exquisitely engineered biological machines – the vertebrate eye, photosynthetic pigments, efficient foraging algorithms, color constancy systems – whose performance is unrivaled by any machine yet designed by humans.

Because adaptations are problem-solving machines, they can be identified using the same standards of evidence that one would use to recognize human-made machines (e.g., TV versus stove): design evidence. One can identify an aspect of the phenotype as an adaptation by showing that (1) it has many design features that are complexly specialized for solving an adaptive problem, (2) these phenotypic properties are unlikely to have arisen by chance alone, and (3) they are not better explained as the byproduct of mechanisms designed to solve some alternative adaptive problem.

Adaptations, byproducts, and noise

The features of a species' cognitive or neural architecture can be partitioned into: adaptations, which are present because they were selected for (e.g., the enhanced recognition system for snakes coupled with a decision-rule to acquire a motivation to avoid them); byproducts, which are present because they are causally coupled to traits that were selected for (e.g., the avoidance of harmless snakes); and noise, which was injected by the stochastic components of evolution (e.g., the fact that a small percentage of humans sneeze when exposed to sunlight). The standards for recognizing adaptations also allow one to recognize byproducts and noise.

One payoff of integrating adaptationist analysis with cognitive science was the realization that, in long-lived, sexually recombining species (like humans), complex functional structures will be overwhelmingly species-typical. That is, the complex adaptations that compose the human cognitive architecture must be human universals (at least at the genetic level), whereas variation caused by genetic differences is predominantly noise: minor random perturbations around the species-typical design. This principle allows cross-cultural triangulation of the species-typical design, which is why many evolutionary psychologists include cross-cultural components in their research.

WHAT IS A COMPUTATIONAL ADAPTATION?

Organisms are composed of many parts, but only some of these parts are computational. By *computational* we mean that they are designed to (1) monitor the environment for specific changes, and (2) regulate the operation of other parts of the system functionally on the basis of the changes detected. For example, the diaphragm muscle, which causes the lungs to contract and expand, is not computational. But the system that measures carbon dioxide in the blood and regulates the contraction and extension of the diaphragm muscle is. The plastic cover on a thermostat is not computational, nor are the parts of a furnace that generate heat. But the thermocouple that responds to ambient temperature by toggling the switch on the furnace, and the connections between them, form a computational system. Muscles are not computational, but the visual system that detects the presence of a hungry-looking lion, the inference mechanisms that judge whether that lion has seen you or not, and the circuits that cause your muscles either to run to a nearby tree (if the lion has seen you) or freeze (if it hasn't seen you) do compose a computational system. The language of information-processing can be used to express the same distinction: one can identify the computational components of a system by isolating those aspects that were designed to regulate the operation of other parts of the system on the basis of information from the internal and external environment.

By 'monitoring the environment for specific changes', we mean the system is designed to detect a change in the world. That change can be internal to the organism (such as fluctuations in carbon dioxide levels in the blood or the activation of a memory trace) or external to the organism (such as the onset of a rainstorm or the arrival of a potential mate). Changes in the world become *information* when (1) they interact with a physical device that is designed to change its state in response to variations in the world (i.e., a transducer), and (2) the changes that are registered then participate in a causal chain that was designed to regulate the operation of other parts of the system. A photon, for example, does not become information until it causes a chemical reaction in a retinal cell, which was designed for this purpose and is part of a causal system that was itself designed to regulate an organism's behavior on the basis of inferences about what objects exist in the world and where they are.

A set of features is not computational unless it was *designed* to exhibit these properties. For example, the outer cells of a dead tree stump expand in the rain, and as this happens, the inner portions of the stump might become compressed. But these dead cells were not designed for detecting changes in weather. More importantly, although their swelling does cause a change in the inner part of the stump, it is not *regulating* the operation of the stump. Regulation means more than merely influencing or changing something. It means systematically modifying the operation of a system so that a *functional* outcome is achieved. In the case of a thermostat, that function was determined by the intentions of the engineer who designed it. In the case of an organism, that function was determined by natural selection, which acted to organize the properties of the organism.

The Relationship between Brains, Computation, and Selection

Neurons do not perform any significant metabolic function for an organism. They exist because of the computational relationships they create. Natural selection retains neural mechanisms on the basis of their ability to create functionally organized relationships between information and behavior (e.g., the sight of a predator activates inference procedures that cause the organism to hide or flee) or between information and physiology (e.g., the sight of a predator increases the organism's heart rate in preparation for flight). Each neural program was selected for because it created the correct information–behavior or information–physiology relationship, and, so long as a physical implementation produces this relationship, its particular form is free to vary according to other factors. (Indeed, when people recover function after brain damage, repair processes often restore the original information-processing relationship – but using a different set of physical connections.)

In other words, the brain was designed by natural selection to be an information-processing device. The brain has the physical structure that it does *because* this structure embodies a particular set of programs, and each program has the computational structure that it does *because* that structure solved a particular problem in the past. This is the causal chain that licenses inferences from function to program structure to physical structure. If one knows what problems our ancestors faced, then one can make educated guesses about what programs evolved to solve them, including what computational procedures they would have required. Once the existence of these programs has been experimentally confirmed, one can search for their neural basis. Having a theory of adaptive function is useful to psychologists and neuroscientists because it allows one to look for programs and neural systems that otherwise one would not look for. It also allows one to understand why programs already known have the computational design that they do.

Function Determines Computational Structure

In principle, a computer or neural circuit could be designed so that any given stimulus in the environment (e.g., feces) could cause any kind of resulting behavior (avoid it, eat it, dance around it, meditate, declaim, sculpt, etc.). Which behavior a stimulus gives rise to is a function of the neural circuitry of the organism. This means that if you were a superhuman designer of brains, you could have engineered the human brain to respond in any way that you wanted, to link any environmental input to any behavioral output. You could have made a human being who frowns when pleased, is erotically transported by tree bark, or howls and devotedly incubates chicken eggs with her body heat whenever the days grow short enough. To explain behavior, therefore, we need a theory of brain organization that describes how circuits are designed to respond to environmental inputs throughout the lifecycle, and why they have the form they do. We will call this organization 'the design of the mind'. Because how the brain is organized to respond to the environment, prior to experience, cannot itself be supplied by the environment, it is easy to see that the design of the mind – including its learning circuits – must be built in to the developing brain. This means that the design was created by evolution.

Adaptive problems that required information-processing for their solutions selected for neural adaptations organized to compute these solutions: function determined computational structure. Over evolutionary time, neural circuits were cumulatively added to the design of the human brain because they reasoned or processed information in a way that enhanced the adaptive regulation of behavior and physiology for these enduring adaptive problems. Such cognitive adaptations include emotion programs, such as fear of falling, fear of snakes, or parental love; motivational programs, such as sexual attraction or revenge; reasoning instincts such as cheater detection algorithms; and learning programs such as the language acquisition device or the food aversion system.

Even 'learned' behaviors, such as speaking English, are the product of evolved learning programs. Evolutionarily novel skills, such as reading and writing, are learned via programs that evolved for learning other, evolutionarily important skills, such as language acquisition – reading and writing are byproducts of adaptations designed for learning other things. Consequently, the mental and neural organization that results from learning is simply another example of the operation of our evolved adaptations, not an exception.

NATURE AND NURTURE

At a certain level of abstraction, every species has a universal, species-typical evolved architecture. For example, we all have a heart, two lungs, a stomach, and so on. This is not to say there is no biochemical individuality, especially in quantitative features. Stomachs vary in size, shape, amount of HCl produced, but all stomachs have the same basic functional design. They are attached at one end to an esophagus and at the other to the small intestine, secrete the same chemicals necessary for digestion, etc. Presumably, the same is true of the brain and, hence, of the evolved architecture of our cognitive programs – of the information-processing mechanisms that generate behavior. Evolutionary psychology seeks to characterize the universal, species-typical architecture of these mechanisms.

Our evolved cognitive architecture, like all aspects of the phenotype from molars to memory circuits, is the joint product of genes and environment. But the development of architecture is buffered against both genetic and environmental insults, such that it reliably develops across the (ancestrally) normal range of human environments. Adaptations are not impervious to environmental conditions: a certain envelope of environmental conditions must be present for any adaptation to develop properly. Moreover, the evolutionary function of computational adaptations is to make behavior (and physiology) sensitively contingent upon information from the environment.

A mechanism – computational or otherwise – need not be present at birth to be considered an adaptation or part of the human evolved architecture (consider teeth and breasts). The development of an adaptation may be triggered at any point in life-history; the trigger can be an internal, physiological event or a set of external conditions (including social conditions).

Evolutionary psychology is not behavior genetics. Behavior geneticists are interested in the extent to which *differences* between people can be accounted for by *differences* in their genes. Evolutionary psychologists are interested in individual differences primarily insofar as these are the manifestation of an underlying architecture shared by all human beings. Because their genetic basis is universal and species-typical, the heritability of complex adaptations (e.g., the eye) is usually low, not high. Moreover, sexual recombination constrains the design of genetic systems, such that the genetic basis of any complex adaptation (such as a cognitive mechanism) *must* be universal and species-typical. This means the genetic basis for the human cognitive architecture is universal, creating what is sometimes called the 'psychic unity of humankind'.

Evolutionary psychologists do not assume that genes play a more important role in development than the environment does, or that 'innate factors' are more important than 'learning'. Instead, they reject the traditional nature/nurture dichotomies as ill-conceived. In their view, there is not a zero-sum relationship between 'nature' and 'nurture'. For them, 'learning' is not an explanation; it is a phenomenon that requires explanation. Learning is caused by cognitive mechanisms, and to understand how it occurs one needs to know the computational structure of the mechanisms that cause it. The richer the architecture of these mechanisms, the more an organism will be capable of learning: toddlers can learn English while the family dog cannot because the cognitive architecture of humans contains mechanisms that are not present in that of dogs.

DOMAIN-SPECIFICITY AND FUNCTIONAL SPECIALIZATION

Evolutionary psychologists do not assume that 'learning', reasoning, or memory are unitary phenomena. The learning mechanisms that cause the acquisition of grammar, for example, are different from those that cause the acquisition of snake phobias. Corkscrews and cups have different properties because they are solutions to different problems; similarly, machinery that causes predator fears to be reliably and efficiently acquired lacks properties that cause the reliable and efficient acquisition of grammar, and vice versa. This applies to choice as well as learning: in many cases, the computational requirements for producing adaptive behavior in one domain are incompatible with those for another. Consider, for example, the domains of food and sex. The computational structure of programs designed for choosing nutritious foods will fail to produce adaptive behavior unless

they generate different preferences and trade-offs than programs designed for choosing fertile sexual partners.

Because natural selection tends to produce mechanisms that are well designed for solving adaptive problems, evolutionary psychologists expect the human mind will be found to contain a large number of information- processing devices that are functionally specialized and therefore domain-specific. Most think the multipurpose flexibility of human thought and action is possible precisely because our cognitive architecture contains a large number of these expert systems.

The proposed domain-specificity of many of these computational devices separates evolutionary psychology from those approaches to the cognitive sciences that assume the mind to be composed of a small number of domain-general, content-independent, general-purpose mechanisms.

Relevance to Modularity Debate in Cognitive Science

In cognitive science, computational systems that are functionally specialized and domain-specific are sometimes called 'modules'. The criteria for calling a device a module are inconsistent and vague (some view information encapsulation as criterial; others emphasize specialization, etc.), especially when compared to the crisp criteria for calling a device an 'adaptation'. As a result, evolutionary psychologists are more comfortable discussing functional specialization rather than modularity. That said, it is fair to say that most take a more modular view of cognition than do many cognitive scientists. (*See* **Modularity)**

Examples of evolved computational devices that show evidence of being specialized in function include: face recognition systems, a language acquisition device, mindreading systems, navigation specializations, animate motion recognition, cheater detection mechanisms, and mechanisms that govern sexual attraction. Most evolutionary psychologists are skeptical that an architecture consisting predominantly of content-independent cognitive processes, such as general-purpose pattern associators, could solve the diverse array of adaptive problems efficiently enough to reproduce themselves reliably in complex, unforgiving natural environments that include, for example, antagonistically coevolving biotic adversaries, such as parasites, prey, predators, competitors, and incompletely harmonious social partners. Such systems may be able to detect some patterns in the environment, but they are value-free: that is, they contain no criteria for deciding between alternative courses of action in a way that would have tracked fitness in ancestral environments. Indeed, evolutionary psychologists have argued that there is no single criterion for adaptive behavior that could be applied across domains yet still track fitness and, for this reason, evolution could not have produced a completely domain-general cognitive architecture.

Some cognitive scientists have argued in favor of domain-general computational processes (usually of an unspecified nature) on the grounds that they can solve a wider array of problems, including evolutionarily novel ones (such as learning to read or write). Even if this were true (and there are strong reasons to believe it is false, having to do with combinatorial explosion and the greater inferential power of a knowledge-rich over a knowledge-poor reasoning system), it would provide no basis for assuming that the human cognitive architecture is composed primarily of domain-general, knowledge-free (i.e., content-independent) computational systems.

This is because selection drives design features to become incorporated into architectures in proportion to the actual distribution of adaptive problems encountered by a species over evolutionary time. There is no selection to generalize the scope of problem-solving to include never or rarely encountered problems at the cost of efficiency in solving frequently encountered problems. To the extent that problems cluster into types (domains) with statistically recurrent properties and structures (e.g., facial expression statistically cues emotional state), it will often be more efficient to include computational specializations tailored to inferentially exploit the recurrent features of the domain (objects always have locations, are bounded by surfaces, cannot pass through each other without deformation, can be used to move each other, etc.). Because the effects of selection depend on iteration over evolutionary time, evolutionary psychologists expect the detailed design features of domain-specific inference engines to intricately reflect the enduring features of domains. Consequently, they are very interested in careful studies of enduring environmental and task regularities, because these predict details of functional design. Adaptationist predictions of domain-specificity have gained support from many sources (e.g., from cognitive neuroscience), demonstrating that many dissociable cognitive deficits show surprising content-specificity, and from developmental research indicating that infants come equipped with evolved domain-specific inference engines (an intuitive physics, a mindreading system, a folk biology, etc.).

The Environment of Evolutionary Adaptedness (EEA)

Evolutionary psychologists do not study behavior *per se*; they study the cognitive machinery that generates behavior, using the theory of evolution by natural selection to develop hypotheses about its design and function. According to this view, behavior in the present is generated by information-processing mechanisms that exist because they solved adaptive problems in the past – in the ancestral environments in which the human line evolved.

As a result, evolutionary psychology is relentlessly past-oriented. Cognitive mechanisms that exist because they solved problems efficiently in the past will not necessarily generate adaptive behavior in the present (e.g., a taste for fat, adaptive in fat-poor ancestral environments, can generate maladaptive behavior in a modern environment flush with fast-food restaurants). Indeed, evolutionary psychologists reject the notion that one has 'explained' a behavior pattern by showing that it promotes fitness under modern conditions.

Although the hominid line is thought to have evolved on the African savannas, the environment of evolutionary adaptedness, or EEA, is not a place or time. It is the statistical composite of selection pressures that caused the design of an adaptation.

Gene–Culture Coevolution

Intermediate article

Kevin N Laland, University of Cambridge, Cambridge, UK

CONTENTS

Evolution in species with a dynamic, socially transmitted culture may be different from evolution in other species. Population geneticists have proposed the gene–culture coevolutionary approach to describe the way in which cultural change may drive a population's biological evolution.

INTRODUCTION

Many researchers have noted analogies between the processes of biological evolution and cultural change. For instance, both genes and culture are informational entities that are differentially transmitted from one generation to the next. These similarities have led to the idea that culture evolves, and prompted the development of mathematical models of cultural evolution.

The main scientific approach to the study of how culture evolves is a branch of theoretical population genetics, known variously as 'cultural evolution', 'gene–culture coevolution', or 'dual inheritance' theory. This intellectual tradition has nothing in common with the nineteenth-century 'cultural evolution' schools, which, based on an erroneous view of evolution as progressive, set out to model stages of societal development. Rather, the population genetics approach regards culture as an evolving pool of ideas, beliefs, values, and knowledge that is learned and socially transmitted between individuals. Researchers focus on a single trait, such as a preference for drinking milk, or for sons over daughters, and employ a rigorous mathematical approach to describe how the cultural trait changes over time, sometimes coevolving with genetic variation. Where the cultural entity is a discrete package, it has much in common with Richard Dawkins' idea of the 'meme', defined as a cultural analogue of the gene (Dawkins, 1976).

Stone tools appear in the archeological record approximately two and a half million years ago. If, as is widely believed, lithic technologies and skills were transmitted from one generation to the next, these simple artifacts represent the earliest evidence for culture. In fact, comparative evidence for social learning in a variety of vertebrate species suggests that cultural transmission almost certainly preceded *Homo habilis* by a considerable length of time. However, social learning in other animals is rarely stable enough to support traditions in which information accumulates from one generation to the next. For at least 2 million years our ancestors have reliably inherited two kinds of information, one encoded by genes, the other by culture.

There is only one evolutionary approach to the study of human behavior that takes up the challenge of understanding genetic and cultural evolution simultaneously by focusing directly on their interaction. Gene–culture coevolutionary theory (or dual inheritance theory), together with evolutionary psychology and human behavioral ecology, is one of three principal evolutionary approaches that emerged in the aftermath of the human sociobiology debate (Smith, 2000).

Conceptually, gene–culture coevolution is like a hybrid between memetics and evolutionary psychology, although its methods are quite different, relying as they do on rigorous mathematical theory. Like memeticists, gene–culture coevolution enthusiasts treat culture as evolving learned knowledge. Like evolutionary psychologists, these researchers believe that the cultural knowledge individuals adopt may sometimes – although certainly not always – depend on their genetic constitution. Moreover, selection acting on the genetic system is commonly generated or modified by the spread of cultural information. For gene–culture coevolutionary theorists, the 'leash' that ties culture to genes tugs both ways. The advent of culture was a precipitating evolutionary milestone, generating selection that favored a reorganization of the human brain, and leaving it specialized to acquire, store, and use cultural information. It was culture,

loosely guided by genes, that allowed humans the adaptive flexibility to colonize the world.

The quantitative study of gene–culture coevolution began in 1976, when two population geneticists, Luca Cavalli-Sforza and Marc Feldman of Stanford University, published the first simple dynamic models with both genetic and cultural inheritance. The fundamental innovation that Cavalli-Sforza and Feldman instigated was that, in addition to modeling the differential transmission of genes from one generation to the next, they incorporated cultural information into the analysis, allowing the evolution of the two systems to be mutually dependent. However, one curious feature of the history of gene–culture coevolution is that both archetypal sociobiologists and some of their most severe critics almost simultaneously recognized the importance of gene–culture interactions, with each starting to develop methods to address the problem. By the late 1970s, Charles Lumsden and Edward Wilson at Harvard University were engaged in a race with Cavalli-Sforza and Feldman to produced the first book on this topic. While Lumsden's and Wilson's *Genes, Mind and Culture* was published first (Lumsden and Wilson, 1981), it was not well regarded (Maynard-Smith and Warren, 1981). In contrast, Cavalli-Sforza's and Feldman's more cautious tome *Cultural Transmission and Evolution* (Cavalli-Sforza and Feldman, 1981) was much better received.

Together with many co-workers, Cavalli-Sforza and Feldman gradually built up an impressive body of mathematical theory exploring the processes of cultural change and interaction between genes and culture. Frequently they took advantage of the parallels between the spread of a gene and the diffusion of a cultural innovation to borrow or adapt established models from population genetics. Drawn by the ongoing sociobiology debate, other mathematically minded researchers joined the fray, most notably anthropologists Rob Boyd and Peter Richerson, whose book *Culture and the Evolutionary Process* introduced a variety of novel theoretical methods and stimulating ideas (Boyd and Richerson, 1985). Gradually a consensus as to the most appropriate methods for tackling gene–culture interactions began to emerge, which today forms the basis of modern coevolutionary theory.

The technical and explicitly mathematical nature of modern gene–culture coevolution is one of several features that distinguishes this perspective from alternatives such as evolutionary psychology. A second is the incorporation into analyses of a variety of genetic and cultural processes in addition to the natural selection of genes. Gene–culture coevolution exhibits a concern for nonadaptive and even maladaptive outcomes of the evolutionary process. This stance continues both to surprise and confuse outside observers used to characterizing all these evolutionary approaches as 'sociobiology'. However, the rigorous theoretical approach has led to little experimentation or other forms of empirical work, and this school remains the prerogative of a comparatively small band of workers.

The emerging body of theory has developed in a variety of ways. One class of models investigates the inheritance of behavioral and personality traits, extending traditional models by incorporating a transmitted cultural component into the analysis. Other models address general questions about the adaptive advantages of learning and culture. More recently, these methods have been applied to address specific cases in which there is an interaction between cultural knowledge and genetic variation that influences its prevalence. These include the evolution of language and of handedness, an analysis of changes in the genetic sex ratio in the face of sex-biased parental investment, the spread of agriculture, the coevolution of hereditary deafness and sign language, the emergence of incest taboos, and an exploration of how cultural niche construction affected human evolution (see Feldman and Laland, 1996).

As the rules of cultural transmission are usually different from those of genetic transmission, similar selective regimes may result in very different equilibria. A good example of this is provided by the hypothesis of Boyd and Richerson (1985) that group selection can act on cultural variation. The theoretical argument against group selection is based on models which assume genetic inheritance, and the criticisms may not hold for culturally transmitted traits. When individuals adopt the behavior of the majority a conformist transmission is generated (Boyd and Richerson, 1985). As a result of its frequency dependence, conformist transmission can act to amplify differences in the frequency of cultural traits in different subpopulations, but reduce variance within groups. Boyd and Richerson showed that one of the by-products of a conformist bias is an increase in the strength of the group selection of cultural variation so that it may be a strong force relative to forces acting within groups, such as natural selection. Since selection between groups may favor beliefs and attitudes that benefit the group at the expense of the individual, Boyd and Richerson's theory provides a new explanation for human cooperation.

EVIDENCE FOR TRANSMITTED CULTURE

For most social scientists 'culture' is a given. The notion that much of the variation in the behavior of humans is brought about by their being exposed to divergent cultures is so widespread and intuitive that is beyond dispute. While it used to be fashionable to define culture as the interwoven complex of behavior, ideas, and artifacts that characterize a particular people (e.g. Tylor, 1871), among social scientists this view has been superseded by a more cognitive perspective that restricts culture to information stored in the brain. In contrast, biological approaches to culture (including those of most sociobiologists, human behavioral ecologists, and evolutionary psychologists) tend to regard the transmitted elements of culture as either exerting a comparatively trivial influence on human behavior, or that whatever influence they have is strictly circumscribed by genes.

For advocates of gene–culture coevolution these biological perspectives underemphasize one critical factor: socially transmitted culture. Too much culture changes too quickly to be feasibly explained by genetic variation, while the fact that different behavioral traditions can be found in similar environments would appear to render environmental explanations of behavior impotent much of the time. To give an example, Guglielmino *et al*. (1995) analyzed variation in cultural traits among 277 contemporary African societies, and found that most traits examined correlated with cultural history rather than with ecology. Such findings suggest that most human behavioral traits are maintained in populations as distinct cultural traditions, rather than evoked by the natural environment. Genes and environment undoubtedly account for some variation in human behavior, but the socially transmitted component of culture is also important.

A capacity for culture is an unusual adaptation. It allows humans to learn about their world rapidly and efficiently. We do not have to scour our environment for sources of food and water, devise our own means of communication, or reinvent technological advances from first principles. Our capacity to acquire valuable skills and information from more knowledgeable others, such as parents, teachers or friends, as well as indirectly through artifacts such as books and computers, furnishes us with a short cut to adaptive (and sometimes maladaptive) behavior. Advocates of gene–culture coevolution share with the vast majority of social scientists the view that what makes culture different from other aspects of the environment is the knowledge passed between individuals. Culture is transmitted and inherited in an endless chain, frequently adapted and modified to produce cumulative evolutionary change. This infectious, information-based property of transmission is what allows culture to change rapidly, to propagate a novel behavior through a population, to modify the selection pressures acting on genes, and to exert such a powerful influence on our behavioral development.

Gene–culture enthusiasts point to countless studies that have found that the attitudes of parents and offspring are similar. They maintain that the most obvious explanation for this is that children learn social attitudes in the family. For instance, a study of Stanford University students revealed that the religious and political attitudes were strongly consistent between parents and offspring (Cavalli-Sforza *et al*., 1982). The same applies to nonindustrial societies. For instance among Aka pygmies, an African group of hunter-gatherers, there was evidence for parent to child transmission of many customs (Hewlett and Cavalli-Sforza, 1986). Such correlations do not prove cultural transmission to be prevalent: for instance, there could be heritable genetic effects. However, the weight of evidence supports the notion of a transmitted culture; see Boyd and Richerson (1985) for a more extensive collation of evidence for cultural transmission.

TYPES OF CULTURAL SELECTION

Researchers in the gene–culture coevolution tradition have described a number of processes that underpin cultural change. In order to distinguish cultural from biological evolution, Cavalli-Sforza and Feldman (1981) defined 'cultural selection' as a process by which particular socially learned beliefs, or pieces of knowledge, increase or decrease in frequency owing to their adoption by other individuals at different rates. In contrast, natural selection can change the frequency of a cultural preference through the differential survival of individuals expressing different types of preference. For instance, in developed countries fertility control (contraception) is at a clear disadvantage in natural selection as users typically have fewer offspring, but has spread by virtue of its advantage in cultural selection since fertility control is a popular choice. Working on these two interacting subsystems simultaneously helps us to understand how nonadaptive cultural traditions could evolve (Cavalli-Sforza and Feldman, 1981). When it has

sufficiently high cultural fitness, cultural information can increase in frequency despite decreasing genetic fitness. Cavalli-Sforza and Feldman's framework also considers cases in which cultural selection operates without affecting Darwinian fitness (e.g. a preference for a particular soft drink).

Researchers in gene–culture coevolution are also interested in how information spreads within populations. The mode of transmission is the route by which cultural knowledge spread among individuals (Cavalli-Sforza and Feldman, 1981), and different models are required for alternative modes of information transmission. Social transmission can occur vertically (that is, from parents to offspring), obliquely (from the parental to the offspring generation; for instance, learning from teachers or religious elders) or horizontally (that is, within-generation transmission such as learning from friends or siblings). Genetic inheritance is exclusively vertical, and as social transmission frequently occurs through some combination of these modes of information transmission, cultural evolution and gene–culture coevolution will exhibit quite different properties from those of biological evolution.

Boyd and Richerson (1985) extended the taxonomy of cultural processes by splitting the general concept of 'cultural selection' into subtypes. One such subtype is 'guided variation', which refers to a process by which individuals acquire information about a behavior culturally, and then modify the behavior on the basis of their personal experience. Here cultural variation is guided by individual experience which, as human behavioral ecologists envisage, allows behavioral traditions to evolve gradually towards the adaptive optimal behavior for that environment.

Another set of processes that Cavalli-Sforza and Feldman (1981) and Boyd and Richerson (1985) consider is known as 'biased cultural transmission'. Biased transmission occurs when, given a choice between two alternative behavior patterns, individuals are more likely to adopt one variant than another. Various types of bias exist. In direct bias, individuals choose which of two or more alternative behavior patterns to adopt. A direct bias might result from a genetic predisposition to favor certain types of information. Stanford University anthropologist Bill Durham has argued that the individual choices underpinning these cultural processes are guided, but not determined, by predispositions and prior knowledge (Durham, 1991).

In the case of frequency-dependent bias, however, the commonness or rarity of a behavior affects the probability of information transmission. When, as frequently seems to be the case, individuals are predisposed to adopt the behavior of the majority, this frequency-dependent bias generates conformity. People may also use cues about one trait, for example, wealth, to choose which individuals to observe in order to acquire information about another trait, such as clothes fashions. Boyd and Richerson call this 'indirect bias'.

A Case Study: Coevolution of Dairy Farming and Genes for Processing Milk

The evolution of the ability of adult humans to consume dairy products represents a good example of gene–culture coevolution. Unlike that of human infants, virtually all of whom can all drink milk without problems, the milk digestive physiology of adult humans varies considerably. In fact, if the entire world's population is considered, consuming dairy products makes the majority of adult humans ill. This is because the activity level of the enzyme lactase in their bodies is insufficient to break down the energy-rich sugar lactose in dairy products, and milk consumption typically leads to sickness and diarrhea. The ability of adult humans to digest lactose largely depends on whether they possess the appropriate variants of a single gene. A correlation exists between the incidence of the genes for lactose absorption and a history of dairy farming in populations, with absorbers reaching frequencies of over 90% in dairy-farming populations, but typically less than 20% in populations without dairy traditions (Durham, 1991). The correlation is extremely suggestive. Milk and milk products have been a component of the diets of some human populations for over 6000 years, roughly 300 generations. Is it conceivable that dairy farming might have created the selective regime under which the allele for absorption was favored?

Feldman and Cavalli-Sforza (1989) used gene–culture coevolutionary models to investigate the evolution of lactose absorption. They assumed that the capacity to absorb lactose was affected by alleles (variants) of a single gene, with one particular allele allowing adults to digest milk. In addition, they modeled the cultural transmission of milk usage. The analysis suggested that whether or not the allele allowing adult lactose absorption and milk digestion achieves a high frequency depends critically on the probability that the children of dairy-product users themselves become milk consumers. If this probability is high, then a significant fitness advantage to the genetic capacity for lactose absorption will generally result in the selection of

the absorption allele to high frequency within 300 generations. However, if a significant proportion of the offspring of milk users do not exploit dairy products, then unrealistically strong selection favoring absorbers would be required for the gene for absorption to spread. In other words, differences in the strength of cultural transmission between cultures may account for genetic variability in lactose absorption. The analysis is able to account for both the spread of lactose absorption, and the culturally related variability in its incidence. Moreover, there is a broad range of conditions under which the absorption allele does not spread despite a significant fitness advantage, indicating that traditional genetic models would frequently give the wrong answer. Cultural processes complicate the selection process to the extent that the outcome may differ from that expected under purely genetic transmission.

The traditional view among the scientific community was that adult lactose tolerance in humans is an adaptation to reduced exposure to the sun, as both the sun and the enzyme lactase promote calcium absorption (Durham, 1991). However, an analysis by Holden and Mace (1997) of a phylogeny of human cultural groups using sophisticated statistical techniques found no evidence for the latitudinal theory, but strong support for the dairy-farming hypothesis. Moreover, their analysis revealed that dairy farming evolved first, which then favored tolerance to lactose, and not the other way around. Holden and Mace's analysis provides compelling confirmation of the findings of this gene–culture coevolutionary analyses.

DO GENES AND CULTURE COEVOLVE?

It is frequently suggested that genetic evolution is too slow and cultural change too fast for the latter to drive the former. In fact, selection experiments and observations of natural selection in the wild reveal that biological evolution may be extremely fast, with significant genetic and phenotypic change sometimes observed in a small number of generations. At the same time, observations of hominid stone tool technologies reveal that cultural change can be extraordinarily slow. Acheulian and Oldowan stone tools traditions remained very similar for hundreds of thousands – even millions – of years. Even cultural institutions such as labor markets can be extremely persistent, albeit on a shorter time scale. Furthermore, theoretical analyses have revealed that cultural transmission may change selection pressures to generate unusually fast genetic responses to selection in humans (Feldman and Laland, 1996). It is thus entirely feasible that genetic and cultural evolution could operate at similar rates. In fact, the past 2 million years of human evolution may even have been dominated by gene–culture coevolution. Culture can, of course, cause rates of environmental change that really are too fast for human genetic evolution to track, and it is probably doing so increasingly. In fact, in the last 25 000–40 000 years the dominant mode of human evolution has probably been exclusively cultural.

Gene–Culture Coevolution and Niche Construction

Organisms frequently choose, regulate, construct, and destroy important components of their environments, such as nests and burrows, in the process changing the selection pressures to which they and other organisms are exposed. These processes are known as niche construction (Odling-Smee, 1988). Niche-constructing traits are more than just adaptations, because they have the additional role of modifying natural selection pressures. Like natural selection, niche construction can be regarded as an evolutionary process potentially capable of generating a complementary match between organism and environment. Organisms may adapt to environments, and environments may be shaped by organisms. In humans, culture has greatly amplified our capacity for niche construction and our ability to modify selection pressures, and cultural niche construction may frequently instigate further biological or cultural change (Laland *et al*., 2000).

Standard gene–culture analyses incorporate niche construction implicitly, by assuming that some human cultural activities feed back to modify some selection pressures in human environments, and thus cultural transmission may affect the fate of some selected human genes. Generally, the relevant aspect of human selective environments is defined as cultural. For example, the trait that affected human genetic evolution in the lactose tolerance case was milk usage (Durham, 1991). Here, gene–culture theory is applicable because the link between milk usage and its genetic consequences are sufficiently simple to allow it to be modeled without bringing in any intermediate variables (Feldman and Cavalli-Sforza, 1989).

However, standard gene–culture coevolutionary models are less appropriate in more complicated situations. Take, for example, the case of Kwa-speaking yam cultivators in West Africa, who increased the frequency of a gene for sickle cell

anemia in their own population as a result of the indirect effects of yam cultivation. These people traditionally cut clearings in the rainforest, creating more standing water and increasing the breeding grounds for malaria-carrying mosquitoes. This, in turn, intensified selection for the sickle cell allele, because of the protection offered by this allele against malaria in the heterozygotic condition (Durham, 1991). Here the causal chain is so long that simply plotting the cultural trait of yam cultivation against the frequency of the sickle cell allele would be insufficient to yield a clear relationship between the cultural trait and allele frequencies (Durham, 1991). The crucial variable is probably the amount of standing water in the environment caused by the yam cultivation, but standing water is an ecological variable, not a cultural variable, and it partly depends on factors (rainfall) that are beyond the control of the population. So here the simplifying assumption of a direct link between cultural and genetic inheritance distorts reality too much to allow their interaction to be modeled in the standard way. This time the two human inheritance systems can interact only via an intermediate, abiotic, ecological variable subject to niche construction, which should be included to complete the model.

This shortcoming led Laland *et al*. (2000) to propose an extended version of gene–culture coevolutionary theory, which incorporated niche construction as a general evolutionary process. Culturally modified selection pressures are regarded as a part of a more general legacy of modified natural selection pressures bequeathed by humans to their descendants. Laland *et al*. (2001) used extended gene–culture coevolutionary models to explore the evolutionary consequences of culturally generated niche construction through human evolution. The analysis revealed circumstances under which cultural transmission can overwhelm natural selection, accelerate the rate at which a favored gene spreads, initiate novel evolutionary events, and trigger hominid speciation. Because cultural processes typically operate faster than natural selection, cultural niche construction is likely to have more profound consequences than gene-based niche construction, and is likely to have played an important role in human evolution.

Empirical Studies of Gene–Culture Coevolution

While gene–culture coevolution has a strong and rigorous theoretical foundation, it is vulnerable to the charge that it has not spawned a vigorous empirical science. Where gene–culture analyses have been applied to specific case studies they do make a variety of testable predictions; for instance, Soltis *et al*. (1995) used data on rates of population extinction in New Guinea to test Boyd and Richerson's group selection hypothesis. Yet no general empirical method has been established. The closest to a general approach is that advocated by anthropologist Bill Durham, who illustrates with compelling examples, each backed by considerable data, how variability in human behavior and society may be interpreted as resulting from interactions between genetic and cultural processes (Durham, 1991). Durham identifies five categories of interaction:

- genetic mediation, where genetic differences underlie cultural variation, as may be the case for the terms used by humans to describe color which reflect features of the human nervous system;
- cultural mediation, where culture drives genetic change, such as with the evolution of adult lactose absorption in populations that consume dairy products;
- enhancement, where culture reinforces genetic predispositions, as with the emergence of incest taboos that guard against the deleterious effects of inbreeding;
- neutrality, where memes are adopted independently of an individual's genotype, as is the case for learning different languages;
- opposition, where culture leads to maladaptive traditions, for instance the cannibalism of the Fore, a New Guinea community, which spread the deadly nerve disease kuru.

CONCLUSION

Gene–culture coevolutionary theory has rarely been subject to the same level of criticism as human sociobiology or evolutionary psychology. In fact, in the debates over human sociobiology and its progeny, it has been almost completely ignored, perhaps because of its technical nature. However, some social scientists have objected to the idea that culture can be modeled as if composed of discrete psychological or behavioral characteristics, while others have questioned the legitimacy of 'borrowing' population genetics processes to model culture, or criticized the analyses as promoting a false gene–culture dichotomy. However, for gene–culture researchers these assumptions do not represent ideological stances but are made purely for pragmatic reasons. Culture is difficult to analyze unless it is broken down into manageable units. Building on population genetic models is a reasonable place to start developing models of cultural evolution (providing the differences between

biological and cultural processes are accommodated). Gene–culture methods represent comparatively simple descriptions of the interactions between genetic and cultural processes. However, approaches that focus on a single process (be it exclusively cultural or exclusively genetic) have made the fundamental and sweeping assumption that the processes do not interact, or that there is only one process that matters.

Gene–culture coevolutionary analyses suggest that evolution in species with a dynamic, socially transmitted culture may be different from evolution in other species. Culture is a particularly effective means of modifying natural selection pressures and driving the population's biological evolution, as was the case for lactose absorption. Culture may generate new evolutionary processes, for instance cultural group selection. Moreover, cultural transmission may strongly affect evolutionary rates, sometimes speeding them up and sometimes slowing them down. Such findings suggest that traditional evolutionary approaches to the study of human behavior may not always be adequate.

CONTENTS

Human behavioral ecology applies theory and method developed in evolutionary biology, anthropology and economics to elucidate adaptive variation in human behavior, particularly social behavior. Hypotheses about resource use, mating and parenting strategies, cooperation and competition, and life history are derived from models using a selectionist logic, and empirically tested to increase our understanding of how humans adapt to their natural and social environments.

INTRODUCTION

Human behavioral ecology (HBE) is one of several approaches in the evolutionary social sciences (Smith *et al*., 2001), other prominent ones being evolutionary psychology and cultural evolution (or meme) theory. Like these other approaches, HBE combines theory and methods from a number of different academic disciplines. From evolutionary biology it draws mathematical or graphical models anchored in basic principles of evolution by neo-Darwinian natural selection. From neoclassical economics it adopts concepts and analytical techniques such as optimization, marginal value analysis, and game theory. From anthropology, it borrows ethnographic research methods: the extended recording of behavioral observations in their immediate socioenvironmental context, often in small communities, supplemented with data collected by survey, interview or archival research. Human behavioral ecology emphasizes quantitative methods such as those characteristic of ethology (naturalistic observation of animal populations): focal follows, scan sampling, and the like.

The topics analyzed in HBE research can be grouped into three main categories (Winterhalder and Smith, 2000): production (resource acquisition and related topics), reproduction (mating and parenting), and distribution (exchange, sharing, and coercive transfers).

Behavioral ecology has developed as the behavioral branch of the larger field of evolutionary ecology, the study of evolution and adaptive design in ecological context. Evolutionary ecology emerged as a distinct field in the 1960s, and includes topics ranging from the structural and behavioral traits of organisms to the organization of ecological communities. Behavioral analyses have been an integral element of evolutionary ecology from the beginning, treating topics such as foraging strategies, mating systems, spatial organization, and competition. The first textbooks on behavioural ecology appeared in the late 1970s and early 1980s, and there is now a voluminous literature, including monograph series, dedicated journals (e.g. *Behavioural Ecology* and *Behavioural Ecology and Sociobiology*) and a widely read series of books edited by Krebs and Davies.

ECOLOGICAL SELECTIONISM

The adaptationist program in contemporary evolutionary biology assumes that natural selection has designed organisms to respond to local socioenvironmental conditions in fitness-enhancing ways. With this as a starting point, behavioral ecologists formulate and test formal models incorporating specific optimization goals, currencies, and constraints. Because their subject is behavior, and particularly social behavior with a strong cultural component, human behavioral ecologists must analyze a much more labile and causally complex set of phenomena than an evolutionist studying, for example, skeletal morphology or even avian courtship behavior.

Human behavioral ecology generally attempts to explain such complex patterns of cultural and behavioral variation as forms of phenotypic adaptation to varying social and ecological conditions. The field is less concerned with genetic variation

on evolutionary time scales than with variation in behavior that occurs within an individual's lifetime (often in minutes or hours), or that accumulates over a few generations through cultural change. The link between such phenotypic or cultural adaptation and genetic evolution is provided by positing that the former is guided by 'decision rules' – cognitive or problem-solving propensities that themselves evolved genetically through natural selection. However, the genetic basis of these phenotypic capacities is not addressed directly in HBE, which takes an agnostic view of the underlying causal mechanisms that might shape adaptive variation in behavior. Rather, the focus is on testing predictions about the match between environmental conditions or payoffs and behavioral variation, without worrying too much about developmental or learning mechanisms that create or maintain this match.

MODELS AND DECISION RULES

In common with many scientific fields, including general behavioral ecology, HBE research is strongly theory-driven. The research strategy is built around mathematical models of particular phenomena. Any given model is designed to answer a particular set of questions: for example, what is the optimal set of prey to harvest? How much should a parent invest in male versus female offspring? Models are used to generate hypotheses that can then be tested empirically, and the results of these tests indicate whether the model appears to capture correctly essential features of the phenomenon being investigated, needs significant modification, or should be discarded. As an area of research develops, sets of related models are linked together to form a body of theory (e.g. optimal foraging theory, or parental investment theory) covering a relatively broad empirical domain.

A complete HBE explanation combines models of circumstance and models of mechanism (Winterhalder, 1997). Models of circumstance ask how socioecological factors shape the costs and benefits associated with alternative behavioral strategies in a given domain. Models of mechanism attempt to specify how natural selection, or a variant such as sexual, kin, or cultural selection, will act on these costs and benefits. By combining these two elements, the HBE approach avoids some of the problems associated with functionalist explanation in the social sciences. In particular, neo-Darwinian theory identifies a restricted set of units, costs, and benefits that have a significant role in evolutionary processes (for example, ruling out strategies that increase longevity without increasing number of surviving descendants or other genetic kin).

All HBE models incorporate a goal (which the strategy under consideration is designed to optimize), a currency (for measuring the relevant costs and benefits), a set of constraints (characterizing the social and environmental context in simplified form) and a decision set (the range of behavioral options considered). Different evolutionary goals may require different optimization methods: deterministic, stochastic, or dynamic optimization, as well as game-theoretic analysis.

Human behavioral ecology usually frames the study of adaptive design in terms of decision rules, which are presumed to be panhuman adaptations that have evolved by natural selection in order to generate behavioral variation that is sensitive to environmental context. These decision rules are often conditional strategies that take the general form 'In context *X*, adopt one behavioral tactic; in context *Y*, switch to the other tactic' (and more complex variants for strategies with more than two tactics). For example, the polygyny threshold model (Figure 1) assumes that female mate choice follows the evolved decision rule 'If the bachelor suitor has at least half the resources of an already married suitor, accept his offer; otherwise, become the second wife of the married suitor.' Behavioral variation arises as individuals match their conditional strategies to their particular current socioecological settings.

THE PHENOTYPIC GAMBIT

Emphasizing generality, most HBE models strive to be as simple as possible. They seek to capture the essential features of an adaptive problem, and thus analyze complex socioecological phenomena in a relatively reductionistic fashion. Such models are thus caricatures of reality intended to be heuristic tools, rather than realistic descriptions of the cognitive or ontogenetic processes that produce human behavior. This sacrifice of realism is made in order to obtain compensating benefits (increased generality and analytical tractability).

More generally, HBE research often assumes that the details of genetic, phylogenetic, and cognitive mechanisms do not, to a first approximation, seriously constrain human adaptive responses to ecological variation. This strategic short cut, known as the 'phenotypic gambit', is taken because it makes it much easier to build and test general (widely applicable) models, focused on ultimate adaptive design. The phenotypic gambit may of course

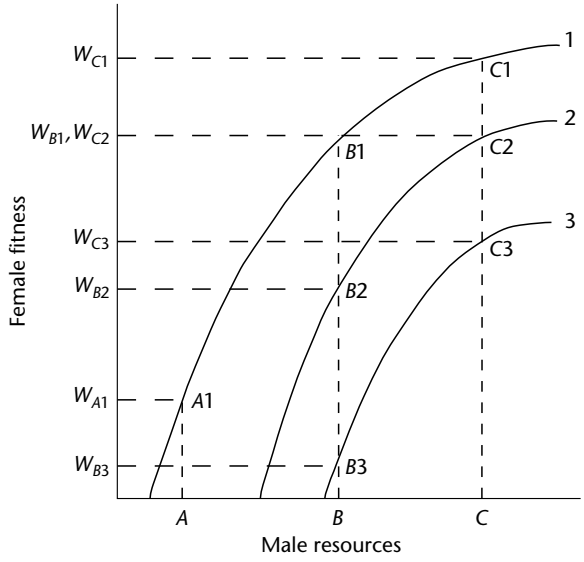

Figure 1. The polygyny threshold model. When female fitness is at least partially a function of the resources controlled by her mate, females may benefit reproductively by mating polygynously with males controlling higher amounts of resources. In this example, a female who became the third wife of a male controlling *C* amount of resources would obtain higher fitness (W_{C3}) than if she were to be married monogamously to a male controlling *A* resources, or the second wife of a male controlling *B* resources. She would have higher fitness if married monogamously to a poor male controlling *A* (W_{A1}) than being the third wife of a male controlling *B*.

be wrong in any particular case: humans may, as some evolutionary psychologists claim, be easily addicted to sugar and fats because in our ancestral environments these nutrients were rare and of high adaptive value. Ignoring such an evolved bias might lead to erroneous predictions about the adaptive value of diets in modern populations. On the other hand, humans seem to have the cognitive and cultural machinery needed to produce adaptive responses quickly to novel environmental conditions (including, in the present example, dieting regimens, gymnasiums filled with exercise equipment, and nutritional and medical knowledge for dealing with the threats posed by overeating). Hence, it is probably premature to draw any firm conclusions about the overall validity of the phenotypic gambit.

EMPIRICAL RESEARCH

Production

Research into HBE can be grouped into three broad topical areas: production, reproduction, and distribution. Analyses of production – resource acquisition behavior – draws on optimal foraging theory (OFT), a family of models initially developed by biologists borrowing heavily from neoclassical economics. These models address resource choice, time allocation, and movement between different habitat sectors or 'patches'. By far the most popular has been the prey choice model (sometimes termed the diet breadth model). It is used here to exemplify the HBE research strategy.

As with all HBE models, the prey choice model (PCM) incorporates a goal, a currency, a set of constraints, and a decision set. The PCM predictions test our assumption that foragers have the goal of choosing the set of available prey types that, under given environmental conditions, yield the maximum value per unit foraging time. Because it can be readily measured and is quite general, the currency used in the PCM is usually the net energy acquisition rate (e.g. kilojoules per hour). Net acquisition rate is appropriate if foragers are time-limited (i.e. gain more from freeing time for other activities than from harvesting additional resources), energy-limited (i.e. gain more from additional units of harvest than from reduced foraging time) or face foraging conditions that expose them to hazard levels greater than those they experience when not foraging (e.g. predation, higher risk of injury, or climate stress). Thus, contrary to common intuition, energy return rate may be adaptively important even if food energy is not strictly limiting.

The constraints of the PCM include those endogenous to the forager, such as available information, cognitive capacities, and technology, as well as exogenous factors such as the availability, behavior and nutritional value of the potential prey resources. In any given application all constraints but one are considered to be relatively fixed, and the remaining constraint becomes the independent variable that predicts choices among the decision set. For example, the independent variable might be the encounter rate with various resource types, the foraging technology for pursuing them, or information processing capabilities, depending on the researcher's interest. The decision set specific to the PCM consists of all the possible combinations achieved by stepwise addition of resources which have been ranked by their pursuit and handling profitability.

The model predicts that diet breadth will shrink as high-ranking prey become more abundant, and that increased abundance of a resource outside of the optimal set will not cause it to be harvested. These and other predictions, as well as ones

derived from other OFT models, have been tested among a variety of hunter-gatherer populations (Kaplan and Hill, 1992). The theory is relatively successful in explaining observed patterns of prey choice and patch use, as well as shifts in subsistence patterns in response to such factors as changes in technology, climatic fluctuations, anthropogenic prey depletion, and human population growth. The OFT framework has illuminated why children harvest different resources from adults in the same society, why hunters often fail to conserve prey species, why some resources are processed at the harvest or kill site and others transported whole back to camp (of great significance for interpreting archaeological data), and even why foragers in various parts of the world have independently engaged in a process of plant and animal domestication leading to agricultural production systems (Winterhalder and Smith, 2000).

Given the universal and recurrent short-term need for metabolic energy, it is reasonable to assume that foraging strategies that maximize the net acquisition rate of energy while foraging have higher fitness, at least within broad limits. We should expect selection to favor cognitive mechanisms and culturally inherited rules of thumb that produce behaviors keyed to this goal. However, most optimal foraging models are general enough that the currency could be any rate measure of resource value – protein capture, raw material value, monetary return, or prestige. For instance, application of the PCM has been used to examine the circumstances under which sexual selection might favor different currencies for males and females (Bliege Bird, 1999).

Distribution

Foraging models concern themselves with the short-term production decisions of individuals. However, for humans and their hominid ancestors, the harvesting and consumption of resources generally occur in a social group, a context that adds a host of theoretical and empirical challenges.

Cooperative subsistence efforts may offer several advantages: increased per capita resource harvest rate, reduced variation in harvest rates, reduced losses to competitors, and increased vigilance and predator detection. However, group foraging can also increase resource depletion and competition; and even where cooperation is beneficial, modeling has shown that optimal group size itself may be unstable owing to conflicts of interest between existing members and potential joiners (Figure 2). Once groups form they provide the context for complex social dynamics, including competition and conflict.

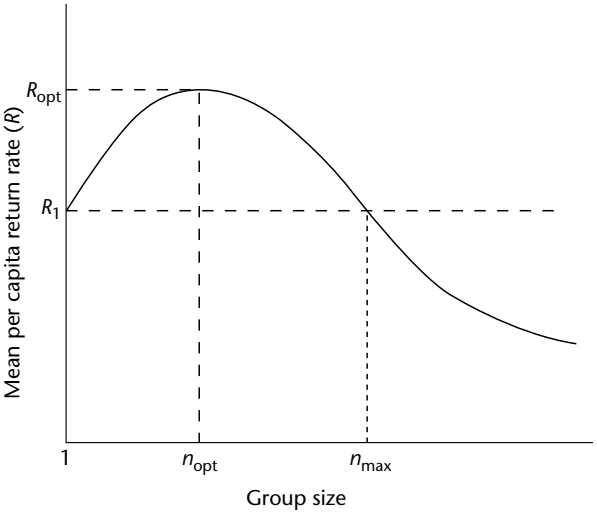

Figure 2. Optimal group size and member–joiner conflict. When the per capita return rate R (e.g. kilo joules per forager per hour) reaches a maximum (R_{opt}) at a group size of $n_{opt} > 1$, then members of a group will suffer a decline in their share of group production if additional individuals join, but potential joiners have an incentive to join as long as their share will be greater than what they can obtain through solitary production (R_1), up to the equilibrium group size n_{max}.

The conditions favoring different kinds of resource transfers (sharing, scrounging, and so on) have been the focus of considerable research in HBE. Unlike most other primates, human foragers and agriculturalists often harvest resources of sufficient 'package size' (e.g. large game) or in sufficient bulk (e.g. an agricultural crop) that some combination of transfer to those without the resource or storage for later use is likely. There are a variety of models to study this, each making somewhat different assumptions about the socioecological circumstances and the evolutionary mechanisms that may shape resource transfers.

All resource transfer models address a common circumstance, the unsynchronized acquisition of valuable resource packets by individuals within a group. The models differ primarily in the additional circumstances specified (e.g. group size, information flow, frequency of interactions among the individuals involved, the nature of the resource) and in the evolutionary mechanism they invoke (e.g. individual, kin, sexual, group or cultural selection) (Winterhalder, 1997). Simple individual-level selection will generate transfer by scrounging (also known as tolerated theft) when those not possessing a resource packet benefit

more by taking portions than the holder can benefit by defending them. Voluntary resource sharing is usually modeled in terms of the delayed, cost–benefit calculus of reciprocal altruism. For example, if resource harvest is unpredictable and relatively unsynchronized, harvesters might benefit by pooling the catch and thereby minimizing subsistence risk (variance in resource consumption).

In by-product mutualism the individual discovering or possessing a resource obtains a net gain as a result of encouraging others to participate in its capture, defense or consumption. In this case short-term cooperation is mutually beneficial, so defection or cheating, a potential threat to reciprocal altruism, is not an issue. One form of by-product mutualism is costly signaling: by successfully harvesting and then distributing difficult-to-capture resources, individuals reliably signal their prowess, benefiting themselves as well as potential allies, mates or competitors, who gain both food and useful information about the provider (Smith and Bliege Bird, 2000). In trade, individuals swap unlike resources or services because both will gain by doing so. Finally, inclusive fitness selection should lead to transfers through kin-provisioning that balance costs and benefits against degrees of relatedness.

There are several empirical studies assessing the relative importance of one or more of the proposed resource transfer models. Collectively, these studies indicate that transfer behaviors are much more diverse and context-specific than has been appreciated in the standard ethnographic literature. These studies also suggest that transfer behaviors are probably multicausal in origin, the result of several selective pressures whose relative importance depends on the situation.

Reproduction

While classical sociobiology analyzed reproductive behavior in terms of factors inherent in sexual reproduction, such as genetic relatedness and gamete asymmetry, HBE analyzes variation in reproductive behavior as a function of local ecological context. In contrast to evolutionary psychology, HBE posits that this variation involves phenotypic tracking of current circumstances, rather than the playback of relatively fixed behavioral routines specific to species, sex or age that were adaptive in our remote evolutionary history. Nevertheless, HBE approaches overlap considerably with these other two evolutionary traditions and with certain versions of cultural evolution, as well as with less explicitly neo-Darwinian fields such as demography and reproductive ecology.

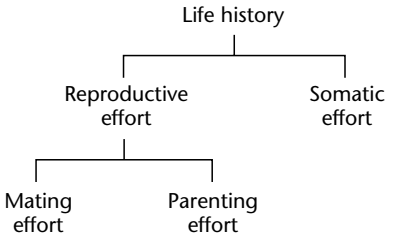

Figure 3. The domains of adaptive effort defining major life history trade-offs.

In HBE, analyses of reproductive behavior can be divided into three topics: life history, mating, and parenting (Borgerhoff Mulder, 1992). Life history is the broadest category, subsuming in principle the entire range of activities involved in survival and reproduction (Figure 3). The central concept in life history theory is the principle of allocation (Hill and Hurtado, 1996): any effort (time, energy, resources) allocated to one domain (for example, enhancing one's own survival and maintenance) cannot be allocated to another domain (for example, reproduction). Mating and parenting together constitute reproductive effort, and models often assume that effort allocated to mating cannot be allocated to parenting (and vice versa). Thus, the principle of allocation can be used to define a set of key trade-offs that are amenable to optimization models.

Mating strategies

The distribution of key resources strongly shapes the behavior of males and females, generally through different routes. If some males can monopolize resources necessary for female survival and reproduction, they can use this control to attract mates, or to compete with other males for social dominance. Polygyny and increased variance in male mating success is the predicted result. Male resource control coupled with female mate choice is the basis for the polygyny threshold model mentioned earlier (see Figure 1). The outcome predicted by the simplest versions of this model is an 'ideal free distribution', in which the number of mates per male will match the resources each can offer, and female fitness will be equal across mateships.

The polygyny threshold model has received broad support in empirical tests among a variety of human societies, though with various qualifications (Borgerhoff Mulder, 1992; Winterhalder and Smith, 2000). For instance, the male-controlled

resources may be political rather than economic. Male coercion (especially by agnatic kin groups) may severely constrain female choice. Females mated polygynously may face reduced reproductive success due to competition with co-wives, though this may be compensated for in the next generation if the sons of polygynously married women have increased chances of inheriting wealth and mating polygynously themselves.

Polygyny has been the preferred marriage form for the great majority of societies in the ethnographic record. Even in putatively monogamous societies, extramarital mating and remarriage biased towards wealthier or more powerful males creates a situation of effective polygyny. Human behavioral ecologists have also analyzed monogamous systems, especially those involving social stratification and dowry, as well as the rare but intriguing polyandrous case (though serial polyandry, in which women remarry to find better mates, is presumably much more common, but has only recently begun to be studied).

Parenting

Whatever form the mating system takes, human offspring require extensive and extended parental care. This parental investment begins with gestation and, among humans, can continue beyond the parent's death (through the bestowing of land, wealth, and other forms of property inheritance). Human behavioral ecology analyses ask how the amount and timing of such investment might vary according to social and environmental constraints. Most research falls into one of three categories: birth spacing, differential investment in offspring (by sex or expected reproductive value), and interactions between mating and parenting.

Birth spacing

If parental time and resources are finite, higher fertility rates should result in less parental investment per offspring and may eventually reduce total reproductive success. This insight provided the basis of the optimal clutch-size model first developed by behavioral ecologists to study avian reproduction, but easily generalized to apply to any species with parental investment, including humans (Figure 4(a)). This model predicts that beyond a certain point, increased fertility (larger clutches, or shorter interbirth intervals) will result in lowered overall parental reproductive success.

Blurton Jones (1986) used this approach to show that among the !Kung San hunter-gatherers of southern Africa, interbirth intervals much shorter than the actual mode of 4 years resulted in increased offspring mortality, sufficient to cause a net loss in expected reproductive success. At least one careful attempt to replicate the !Kung results among Ache foragers of Paraguay failed, possibly because Ache offspring mortality is less sensitive to variation in interbirth interval (Hill and Hurtado, 1996). Alternatively, it may be that in many cases the relationship between fertility and offspring survival is confounded by phenotypic correlation,

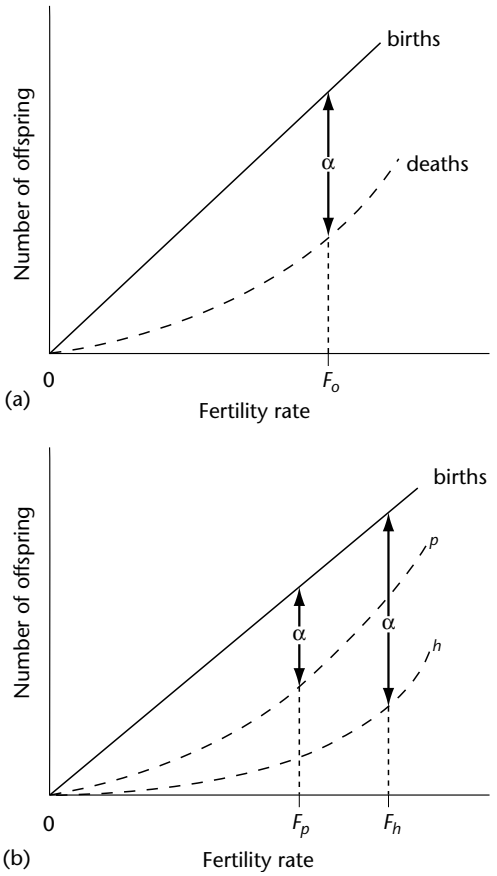

Figure 4. A graphical model of optimal fertility rate. Solid lines represent fertility rate (births per unit time), while dashed lines represent mortality as a function of fertility rate, the latter curving upwards to reflect the effect of reduced parental investment per offspring. The net difference between these is the number of surviving offspring, with a local maximum of α. The model assumes that selection favors maximizing α given the constraints that a parent faces, and hence favors an optimal fertility rate F_o. (a) Fertility rate of a single parent. (b) Comparison of two parents with different constraints and hence different offspring mortality curves as a function of fertility (parental investment). A poorly endowed parent suffers higher offspring mortality (P) at a given fertility rate, and hence a lower optimal fertility rate F_o than a higher-quality parent (h) with optimal fertility rate F_o.

which generally will mask the predicted functional relationship of the optimal clutch-size model (Figure 4(b)).

Phenotypic correlation occurs when hidden heterogeneity in uncontrolled variables confounds the effect of the causal variable under investigation. For example, wealthy individuals might tend to have more expensive houses and more expensive cars (a phenotypic correlation), even though we have good reason to expect a negative correlation between investment in houses and investment in cars due to the fact that the same dollars cannot be spent on both. If selection has designed the reproductive system to adjust facultatively to situational constraints, then interbirth intervals will be short when the parent's resources are relatively abundant and long when their condition is poor; there is abundant evidence for such adaptive variability in human reproductive ecology. Solutions to this problem include multivariate analysis, use of historical data to track functional links between birth spacing and resources, and experimental manipulation (the latter being unlikely in the human case).

Differential investment

Parental investment affects a child's health, survival and future mating success, and thus the parents' inclusive fitness. Parental fitness payoffs depend on three sets of variables: (1) the genealogical relatedness between parent (or other caregiver) and offspring, (2) the effect of investment on the expected reproductive value of the offspring (as well as present and future siblings), and (3) the effect of investment on the caregiver's own reproductive value. Sets (2) and (3) are more directly affected by ecological variables, and hence are at the center of HBE analyses.

Postpartum parental investment decisions range chronologically from whether or not to keep the child – the alternatives being infanticide, abandonment, or adopting out – to delegation of care to others, to investments in nurturing and education, to wealth transfers that often accompany marriage (bride price or dowry), to any legacy the child may receive upon death of the parents. Fitness payoffs for nearly all of these decisions may differ according to the sex of the offspring. A variety of parental investment hypotheses have been the subject of ethnographic and historical research in HBE (Table 1).

Parenting-mating interactions

Following the lead of primate and avian behavioral ecologists, HBE researchers have begun to consider when paternal care and resource provisioning, rather than simply being forms of parental investment, may be designed to attract or maintain a relationship with a mate. For example, men in Albuquerque, New Mexico, as well as Xhosa men in South Africa, invest more time and resources in stepchildren who are offspring of their current mates than they do in stepchildren from former relationships (though less than they invest in genetic offspring under comparable circumstances). This pattern does not match predictions from parental investment theory, but it does make adaptive sense if viewed as investment in maintaining a current mating relationship (i.e. as mating effort). Unravelling interactions such as these is a promising area for future HBE research.

Life History Strategies

Life history is a broad topic, subsuming in principle the entire range of activities involved in survival and reproduction. In practice, life history analyses center on a few key decision categories: the timing of growth and maturation, subadult and adult dispersal strategies, the onset of reproduction, the timing of reproductive events (e.g. birth spacing, weaning, menopause), mortality patterns, and senescence. Most HBE work on life history thus far has focused on four topics: links between production and reproduction; reproductive effort and maturation; menopause and extended human life span; and evolutionary analysis of the so-called 'demographic transition' (reduction in fertility and family size with modernization). The first three of these topics are given exemplary treatment in an extended case study by Hill and Hurtado (1996), while the fourth is reviewed by Borgerhoff Mulder (1998).

CONCLUSION

Human behavioral ecology applies neo-Darwinian theory and ethnographic and ethological methods to elucidate adaptive variation in human behavior, particularly social behavior. It combines elements from a number of different academic disciplines, including anthropology, economics, ethology, and evolutionary biology. Mathematical or graphical models anchored in basic principles of evolution by natural selection are used to derive hypotheses concerning how humans adapt to their natural and social environments. Predictions are then tested with ethnographic, historical, and archeological data. Human behavioral ecology assumes that human decision-making is guided by evolved 'decision rules' or conditional strategies, but focuses

Table 1. Human behavioral ecology analyses of parental investment (PI)

Predictions tested	*Representative studies (locales and authors)*[a]
Reduced genetic relatedness or reproductive conflicts of interest lead to lower PI	Cross-cultural (Daly and Wilson); USA and South Africa (Anderson *et al*.); Mali (Strassman)
Offspring with reduced prospects of survival receive lower PI	Cross-cultural (Daly and Wilson)
Parents reduce PI per offspring as number of offspring increases	Tanzania (Borgerhoff Mulder); Paraguay (Hill and Hurtado)
Parental investment per child is increased when marginal benefit of PI is higher	Hungary (Bereczkei); USA (Kaplan *et al*.)
Adoption and fostering are adaptively modulated according to parental circumstances	Cross-cultural (Silk); Botswana (Pennington)
Mothers able to delegate nursing and infant care gain increased reproductive success	Hungary (Bereczkei); Europe (Hrdy); Ifaluk, Micronesia (Turke)
Postmenopausal women allocate resources and care to grandchildren or other close relatives	Paraguay (Hill and Hurtado); Tanzania (Hawkes *et al*.)
Parents with less resources preferentially invest in offspring (usually daughters) with lower variance in expected RS	Historic Portugal (Boone); Tanzania (Borgerhoff Mulder); North America (Gaulin and Robbins); USA (Judge and Hrdy); North America (Mealey and Mackey)
Offspring of the sex that faces better adult economic opportunities receive higher PI	Cross-cultural (Hewlett); historic Sweden (Low *et al*.); historic Germany (Voland *et al*.)
Offspring of the sex that has greater probability of contributing to future support of siblings receive higher PI	Tanzania (Borgerhoff Mulder); cross-cultural (Hewlett); Paraguay (Hill and Hurtado); Canada (Smith and Smith)
Offspring of the sex that has greater probability of competing with siblings for resources or mates receive lower PI	Tanzania (Borgerhoff Mulder); East Africa (Mace); historic Germany (Voland *et al*.)
If daughters (or sons) have greater future mating opportunities, they receive higher PI	Historic Asia (Dickemann); historic Portugal (Boone); Hungary (Bereczkei and Dunbar); Kenya (Cronk)
If daughters (or sons) are better able to claim and hold political power, they receive higher PI (especially inheritances)	North America (Hrdy and Judge); historic Portugal (Boone); cross-cultural (Hewlett)
Parental resources with increasing marginal benefits to offspring characterized by unigeniture (single heirs)	Historic Portugal (Boone); historic Germany (Voland *et al*.)
Increasing marginal benefit of biparental care leads to increased pair-bond stability	Paraguay and Venezuela (Hurtado and Hill); Tanzania (Blurton Jones *et al*.)

Human Brain, Evolution of the

Introductory article

Michael C Corballis, University of Auckland, Auckland, New Zealand

CONTENTS

The human brain has evolved to be about three times as large as predicted in a primate of our body size. This may explain such uniquely human attributes as language and theory of mind.

INTRODUCTION

The brain is the seat of cognition. Without it we would have no consciousness, no perception and no memory. As humans, we are blessed with extraordinarily large brains, containing around 10 000 million neurons, each of which may connect to 100 other neurons. The ways in which these neurons receive information from the environment, interact with each other, and generate action provide the basis for our uniquely human intelligence.

BODIES, BRAINS, AND ENERGY

The body, including the brain, requires energy, which is why we must eat. This energy requirement can be measured in terms of the *basal metabolic rate* (BMR), which is the rate at which energy obtained from food is used by an animal at rest in a temperature-neutral environment – that is, an environment which is neither too cold nor too hot, so the animal does not have to expend energy trying to warm up or cool down. The BMR depends on the body weight of the animal, but not in a straightforward linear fashion. Rather, the BMR in mammals is proportional to body weight raised to the power of 0.75. Since this power is less than one, it means that energy requirements per unit body weight are lower for larger animals than for smaller ones. Figure 1 illustrates the extent of variation in brain size in a sample of mammals.

Brain size also tends to increase with body size, and interestingly the relationship is the same as that relating BMR to body weight – that is, the brain size of mammals is roughly proportional to body weight raised to the power of 0.75. This reflects the fact that in most animals the brain is largely concerned with routine bodily functions. However, the human brain is exceptionally large for an animal of our size, as we shall see below. The excess of brain volume over that required for basic bodily functions is presumably dedicated to functions that we might think of as 'intelligent'.

Yet having a large brain comes at a cost. The brain is especially demanding of energy, and the problem is compounded in our own species, where the brain is out of proportion to our body weight. In an adult human, the brain weighs only about 2% of the total body weight, but takes up around 20% of the BMR, and in infancy the latter proportion is over 60%. In the adult chimpanzee, the proportion is only about 8%. Moreover, the brain has no energy reserves, and is therefore continually dependent on blood supply. If the supply is interrupted for only a few minutes, brain tissue can die and can bring about permanent dysfunction.

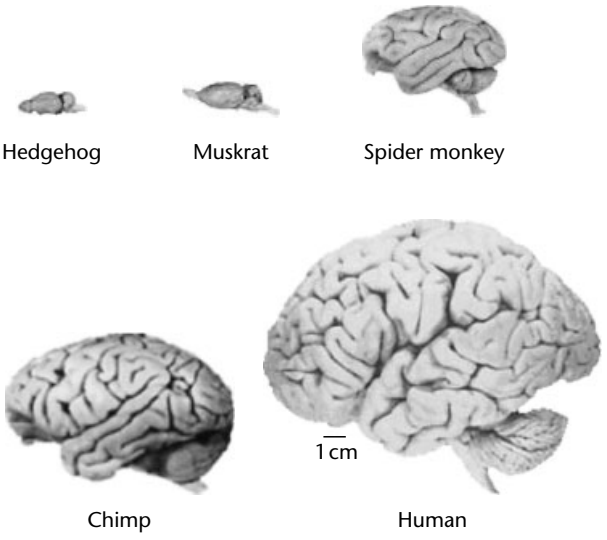

Figure 1. A sample of mammalian brains, equivalently scaled.

Cerebral bloodflow accounts for around 12–15% of the total output from the heart, and the brain consumes around 20–25% of the oxygen intake, and 70% of the total consumption of glucose (which neurons require in order to function). The supply remains largely constant, but is distributed to different parts of the brain according to demand. Measurement of relative bloodflow to different parts of the brain forms the basis of brain-imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), which show which parts of the brain are active during different types of mental processing.

EVOLUTION OF LARGE BRAINS

Although we are large-brained creatures, there are animals with larger brains. Whales lead the way, with brains weighing a massive 6800 g, followed by elephants (about 4700 g) and then dolphins (at around 1700 g). In humans, the male brain typically weighs about 1440 g and the female brain weighs about 1230 g. This does not mean that men are more intelligent than women. Rather, it is a reflection of the fact that men are typically slightly larger than women, and simply require more brain in order to maintain their basic metabolism. In any case there is no evidence that intelligence in humans varies with brain size, even though brain size itself varies quite markedly from one person to another. Nevertheless, it is fairly generally accepted that variations in intelligence between species do depend, at least in part, on brain size.

However, to compare species in terms of the brain volume available for intelligent behavior, we need to correct for variations in body size. One way to do this is in terms of what has been called the *encephalization quotient*, which is the ratio of actual brain size to that expected of an animal of equivalent body size. In these terms, humans do indeed top the list, with a quotient of about 7.44. The dolphin, interestingly, comes second (with a quotient of about 5.31), followed by our closest relative, the chimpanzee (at about 2.49). On this scale, the elephant is well down in the league, with a ratio of about 1.87, and the rat, which once formed the basis for much psychological theory, has a quotient of only about 0.40. Nevertheless, the phrase 'rat-like cunning' suggests that this figure might well underestimate that resourceful creature, and the quotients probably provide only an approximate ranking at best. Even so, they provide some reassurance that we humans are the most intelligent of earthly species.

The Brain in Primate Evolution

Humans belong to an order of animals known as primates, which includes monkeys and apes. More specifically, we belong to a group of large-bodied primates known as great apes, whose present-day members include orangutans, gorillas, chimpanzees, bonobos (or pygmy chimpanzees) and humans. The great apes have all emerged relatively recently in primate evolution, and the most recent common ancestor of ourselves and the chimpanzee and bonobo probably lived around 5 or 6 million years ago.

Primates are generally intelligent, curious, manipulative creatures, and by mammalian standards they are relatively large brained. However, even by primate standards our own brains are exceptionally large. It is estimated that the human brain is about three times as large as one would expect of a primate of the same body size, and no other primate even comes close. For example, a typical human adult may weigh around 70 kg, but our brains have a volume of around 1200 to 1400 mL. The orangutan is around the same size, but its brain volume is only around 400 mL while our nearest relative, the chimpanzee, has a body weight of around 55 kg but has a brain volume of some 340 mL. It is fairly likely that the added brain size has something to do with such uniquely human capacities as language and what is known as 'theory of mind' (i.e. the ability to take the mental perspective of others).

Another way of calibrating the evolution of the brain focuses on the neocortex, which makes up the outer layers of the brain, and which emerged in mammalian species and represents the bulk of the brain in humans. It is especially critical to higher mental processes such as language, perception, imagination, and memory. It has been suggested that the ratio of the size of the neocortex to that of the rest of the brain might provide a more useful index of brain evolution than the overall size of the brain. This ratio has been termed the *neocortical ratio*. Humans have the largest neocortical ratio, at 4.1, clearly ahead of our close relative the chimpanzee, with a ratio of 3.2, although the gap seems smaller than that implied by the encephalization quotient, and might perhaps restore a little humility to our evaluation of ourselves. In gorillas the neocortical ratio is 2.65, and in orangutans it is 2.99. Across different primate species, the neocortical ratio is roughly proportional to the size of the social groups to which animals belong, which suggests that intelligence may be partly driven by the complexities of social interactions. This idea underlies

what has been termed 'Machiavellian intelligence,' and is discussed more fully below.

The Brain in Hominin Evolution

The family of species that split from the branch leading to chimpanzees and bonobos around 5 or 6 million years ago is known as the *hominins*. Around 20 different hominin species have now been tentatively identified from their fossil remains, but with the exception of *Homo sapiens* all of them have become extinct. These species have been classified into several genera, including *Ardipithecus* (possibly the first of the hominins to emerge), *Australopithecus*, *Paranthropus*, *Praeanthropus*, and *Homo*. Although there is considerable debate about the naming and classification of these species, the common characteristic that distinguished them from their great ape cousins is that they were bipedal. In other words, whereas chimpanzees and bonobos move around on all fours, in a style known as knuckle-walking, the hominins walked upright on two legs.

However, in most other respects the early hominins were like great apes. When corrected for body size, their brains were of about the same size as that of a chimpanzee. The dramatic increase in brain size did not begin until the emergence of the genus *Homo* around 2.5 million years ago. Larger brains posed a special problem because the bipedal posture imposed limits on the size of the birth canal. This meant that the infants were effectively born prematurely, before their brains had grown too large to pass through the birth canal, and as every mother knows it is still a difficult passage – which is why it is called labor. It is estimated that human infants are born around nine months prematurely relative to what would be expected of a primate of our size. Whereas the brain of a newborn chimpanzee is about 60% of its adult size, that of a newborn infant is only about 24% of its adult dimensions. It is likely that this premature birth goes back at least 1.6 million years to *Homo erectus*, whose brain size was already more than twice that of the chimpanzee.

However, premature birth proved to be an unexpected bonus, since it means that most of the growth of the brain takes place outside the womb, where it is exposed to environmental input. Since the brain is most receptive to learning while it is still growing, it can be shaped by the environment to a larger extent than is possible in other great apes, such as the chimpanzee. This may partly explain why humans have developed skills such as language to such a high level of complexity. As with many questions about human evolution, it is not clear whether premature birth was merely a by-product of increasing brain size, or whether it was one of the adaptive features that drove the selection of larger brains.

Some of the characteristics of hominin behavior that can be inferred from fossil evidence and other artefacts probably reflect this increase in brain size and the concomitant extension of postnatal growth. Manufactured stone tools date from around 2.5 million years ago, which is also the earliest known date of *Homo rudolfensis*, the first member of our genus so far identified, although stone tools are more firmly associated with a slightly later species, *Homo habilis*. Moreover, up until this time the hominins were confined to Africa, mostly to the east of the Great Rift Valley, but around 2 million years ago they began to migrate out of Africa, starting with the migrations of *Homo erectus* to Asia. Migrations and the gradual development of manufacture were no doubt associated with the increase in brain size, and perhaps the emergence of more complex thought, such as language and the ability to plan complex activities in advance.

Later waves of migrants reached Europe, probably via Asia, and were to form the Neanderthal population who survived in Europe until around 30 000 years ago. Our own species, *Homo sapiens*, probably emerged in Africa around 150 000 years ago. There is recent evidence that the ancestors of present-day *Homo sapiens* remained in Africa until as recently as about 52 000 years ago, when they began to migrate. These and subsequent migrants eventually replaced all of those who had migrated earlier, including the Neanderthals in Europe, *Homo erectus* in South-East Asia, and probably members of their own species in Europe and Asia. They were eventually to populate the entire globe.

It is not clear why these late-migrating members of our species were able to achieve such dominance. It is sometimes suggested that there was some biological change that gave them an edge, but this was unlikely to have been a further increase in brain size. The evidence suggests that the Neanderthals actually had slightly larger brains, although they also had slightly larger bodies. It is perhaps more likely that *Homo sapiens* had developed superior technology and representational abilities, as reflected in cave drawings in Europe that date from around 35 000 years ago, as well as other evidence of advanced technology. These advances need not imply larger brains, but they may have been due to a combination of cultural influences and perhaps subtle changes in brain organization.

THE BRAIN OF *HOMO SAPIENS*

It is wrong to think that brains became larger or more complex simply as a natural consequence of evolution itself. Natural selection does not inevitably lead to greater size or complexity. After all, the dinosaurs did not survive, and many small-brained creatures, such as ants, have adapted successfully to existence on the planet and may well out-survive *Homo sapiens*. Moreover, we are the only surviving species of the large-brained genus *Homo*, and even the Neanderthals, who had larger brains than our own, became extinct. The increase in brain size and the intellectual capacities that go with it were almost certainly adaptations to specific and perhaps unusual environmental challenges, and not an inevitable consequence of evolving systems. What might those challenges have been?

To answer this question, we need to go back to our primate heritage and consider what changes have occurred since that time, and during our hominin past. For most of their existence, primates were adapted to life in the trees. We still exhibit characteristics from our ancient tree-dwelling past, such as the use of the hands for grasping and the ability to raise the arm directly above the head, still enabling us to swing from branches. Around 2.5 million years ago there was a global shift to cooler climates and a shrinkage of forested areas in eastern Africa, as a consequence of which our forebears were increasingly thrust into more open, savannah-like areas. Having been preadapted to the relative safety of the forest, they were relatively ill-equipped physically for life on the savannah, a landscape populated by dangerous killers such as saber-toothed cats and hyenas. It was the change from one type of environment to another that may have shaped the unique characteristics of the human mind.

The life of our forebears on the savannah largely coincides with the epoch known as the Pleistocene, dating from about 1.64 million years ago until about 10 000 years ago. Evolutionary psychologists have argued that selective pressures operating during this epoch formed most of the distinctive characteristics of the human mind. Our hominin ancestors could not compete physically with professional killers such as saber-toothed cats, nor could they easily flee like fleet-footed antelopes from danger. In order to survive they had to live on their wits, occupying what has been called a 'cognitive niche'. At first they probably scavenged for food, but they then became increasingly proficient at hunting for live prey. They evolved a hunter–gatherer mode of existence, and indeed a few hunter–gatherer societies persist to this day. This type of existence would have depended on cooperation and communication, favoring the selection of larger brains.

Compared with the brains of other primates, the human brain is not only larger, but it is also structured differently. For example, it has been estimated that the prefrontal cortex is about double the size one would expect of a typical primate with a human-sized brain. This is why our foreheads are higher and more protruding than those of the other great apes. The prefrontal cortex is involved in complex planning of action, and includes areas concerned with language and so-called 'theory of mind' (see below). Other parts of the brain, such as the visual areas in the occipital lobes at the rear of the brain, the primary auditory cortex in the temporal lobe, and the motor and premotor cortices just anterior to the central fissure, may be proportionally reduced. In short, the areas of brain that are devoted to basic sensorimotor functions may not have changed much at all, with the major increase occurring in the prefrontal cortex and perhaps in other areas, such as the parietal lobes, that are concerned with higher-level thought processes which are relatively independent of the immediate input or output.

The Social Brain Hypothesis

The structure of the brain may have changed in much more specific ways as a result of natural selection during the Pleistocene epoch. Evolutionary psychologists have proposed what might be termed the 'social brain hypothesis', in which the human brain is likened to a society in which different members each develop their own different trades and professions. By analogy, the mind is conceptualized as consisting of independent processing units known as 'modules'. This is also sometimes called the Swiss-army-knife theory, in which the mind is likened to a knife with a collection of blades, each of which serves a different purpose. Although it is often supposed that these mental modules map on to specific brain regions, this is undoubtedly an over-simplification, since individual modules may involve different brain areas, and specific brain areas may contribute to different modules. Nevertheless, it has generally proved useful to identify different brain areas in terms of their specific psychological functions, while at the same time bearing in mind that mental processes typically involve multiple areas.

For example, language seems to consist of a specialized module that is more or less independent of

other aspects of thought, yet which involves a number of dispersed areas of the brain, mostly in the left cerebral hemisphere. There are also submodules within language. One of these is concerned with grammar. Damage to an area in the left prefrontal cortex can produce difficulties in both producing and understanding grammatical aspects of language, a condition that is known as *agrammatism*. This area is called Broca's area, after the nineteenth-century French physician who first discovered its role in speech. Damage to another area around the junction of the left temporal and parietal lobes produces difficulties in comprehension, but may leave grammar more or less intact, so that people with damage to this area of the brain produce meaningless but grammatically correct speech. This area is known as Wernicke's area, and it may be part of a submodule concerned with the comprehension of language (see Figure 2).

There may also be a face-recognition module that gives us our remarkable ability to recognize the hundreds if not thousands of people whom we know by sight. This is all the more extraordinary when we consider that human faces are all broadly similar to one another, unlike most of the other objects in the world that we recognize. Brain damage can sometimes result in a very specific loss of this ability, while the ability to recognize other objects remains intact. This condition is called *prosopagnosia*.

There may also be a 'theory of mind' module, probably involving the frontal lobes of the brain. For example, it has been argued (somewhat controversially) that the disorder known as autism is well described in terms of an inability to empathize with others, or to understand what is going on in other people's minds. Autistic children often have relatively normal language, including grammatical competence, but they are deficient in that aspect of language, known as *pragmatics*, which is concerned with understanding the speaker's intentions or tailoring one's own speech to the expectations and understanding of listeners. In short, the apparent deficit in theory of mind of autistic children appears to affect their language as well as their general social behavior.

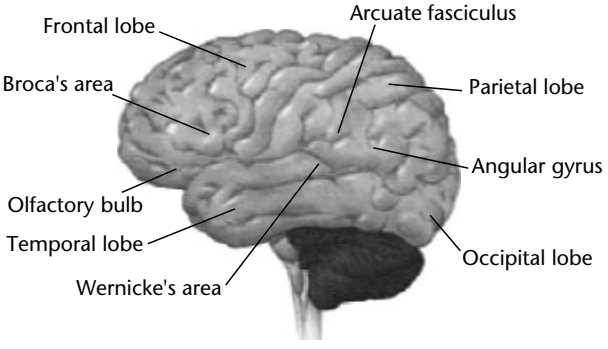

Figure 2. Major areas of the brain, including portions specialized for language.

It has been proposed that social pressures during the Pleistocene epoch led to what has been called 'Machiavellian intelligence'. People sometimes deliberately set out to deceive, and human interactions often involve a subtle interplay between trust and deception, or between coalition and conspiracy. Instances of apparently spontaneous tactical deception have also been recorded in the great apes, although rarely if ever in other primates, and humans undoubtedly surpass all other primates in the frequency and complexity of ways in which they deceive one another, as well as in the ability to detect deceptive practices.

However, there is a caveat to the social brain hypothesis. In its extreme form, it lends itself too readily to the postulation of new modules to account for every neurological deficit, and the often over-facile account of how each such module might have been selected during the hunter–gatherer phase in the Pleistocene epoch. At least some modules may depend on the environmental shaping of the mind that occurs during the long period of postnatal growth, rather than on specific 'hard-wired' biological adaptations. One example of this is reading, which has modular characteristics but cannot have evolved during the Pleistocene epoch. Evolution more often involves tinkering with existing characteristics than the emergence of completely new ones.

Moreover, studies of intelligence show us that although people differ with regard to specific abilities (e.g., verbal ability, mechanical ability, spatial ability), these specific abilities are all positively correlated with one another, implying that there is also a general intelligence underlying them. This general intelligence, which is sometimes simply called 'g', can be expressed as an 'intelligence quotient' or IQ, although psychologists have generally been unable to come up with a good definition of intelligence, other than to suggest that it is what intelligence tests measure!

The Asymmetrical Brain

There is one respect in which human brains have clearly divided functions. In around 90% of us, speech is controlled by the left side of our brains,

while the right side is essentially mute. The left side of the brain also has a more complete ability to understand language than the right, and in addition it is dominant for written language and for the sign languages of the deaf. Conversely, the right side of the brain seems to have the dominant role in spatial abilities, especially in spatial attention. For example, damage to the right side of the brain can produce a striking phenomenon called hemineglect, in which the sufferer is unable to attend to events on the left side of space, even though the sensory systems themselves are unimpaired. People with this condition may dress only the right side of the body, eat from only the right side of a plate, and ignore objects on the left or voices that address them from the left side. Damage to the left side of the brain seldom causes comparable inattention to the right side, and any right-sided neglect is typically temporary, whereas left-sided neglect may be permanent.

The functions of the two sides of the brain have been strikingly revealed in studies of 'split-brained' individuals who have undergone section of the corpus callosum (the main fiber tract connecting the two sides of the brain) for the relief of intractable epilepsy. They are unable to read words or name objects shown to the left side of visual fixation, since the left side of visual space projects to the mute right side of the brain. They can easily name things shown to the right of fixation, since the right half of visual space projects to the left side of the brain, which is capable of articulate speech. Yet split-brained people can point to the names of objects in left space, or point to the objects represented by names, which indicates that the right side of the brain can identify objects and has at least some limited verbal understanding. There are some perceptual tasks, such as imagining shapes rotated into different orientations, or seeing how incomplete pictures would look if they were completed, that the right brain seems to accomplish more efficiently than the left brain.

A more obvious manifestation of brain asymmetry is handedness. Around 90% of humans are right-handed. Most of the remainder are left-handed, although a small minority are ambidextrous. The asymmetry resides in the brain processes that control the hands, rather than in the hands themselves. With the exception of superficial signs such as the wearing of rings or a watch, it is generally not possible to tell whether people are left- or right-handed simply by inspecting their hands.

It is not entirely clear when these asymmetries evolved. Although other individual primates, and indeed mammals, may prefer to use one hand or paw over the other for various activities, there are generally as many left-handed animals as right-handed ones. There is some evidence for a slight overall tendency for monkeys to be left-handed when reaching, and for captive chimpanzees to prefer to use the right hand when gesturing or feeding, but these asymmetries are neither as extreme nor as general as human right-handedness. The pattern of wear on stone tools suggests that there may have been a preponderance of right-handed individuals as far back as 2 million years ago, but it is not clear whether the proportion matched that of modern humans.

There is better documentation of other types of cerebral asymmetry in animals. A wide range of species, including birds and rodents, appear to show a left-brained dominance for aggression, and a right-brained dominance for spatial processing. There is also evidence that the left side of the brain is dominant for vocalization in a wide range of species, including frogs, birds, mice, rats, and monkeys. Furthermore, an area of the brain known as the *temporal planum*, which roughly corresponds to part of Wernicke's area, is larger on the left than on the right in the majority of chimpanzees, as it is in humans. Cerebral asymmetry in humans may have emerged from these earlier asymmetries, although it also seems to exhibit unique characteristics, perhaps partly because the two activities for which human cerebral dominance is most marked, namely language and tool use, themselves have distinctively human properties.

Some insight into the evolution of cerebral asymmetry comes from studies of the brain area corresponding to Broca's area. In monkeys, this area seems to be involved in the planning and perception of reaching and grasping movements of the hands. There is now evidence that Broca's area is involved in the orchestration of hand movements in humans, too. However, in monkeys both sides of the brain seem to be equally involved, whereas in humans there is a strong left-sided dominance – although it has recently been suggested that the equivalent area on the right may be involved in musical syntax. At some stage in the evolution of our own species, the functions of Broca's area became lateralized to the left side of the brain, and began to incorporate speech as well as gesture. This transition has been taken by some authors to imply that language originated in manual gestures, and was perhaps at one stage similar to the present-day sign languages of the deaf. It may have been the final switch to vocal language that resulted in the eventual dominance of *Homo sapiens* over other large-brained hominins.

CONCLUSION

Humans are descendants of hominin species that split from the other great apes in Africa around 5 or 6 million years ago. However, the enlargement of the brain that characterizes our species began only around 2.5 million years ago with the emergence of the genus *Homo*, and may be associated with the emergence of stone tool manufacture and migrations out of Africa. Many of the distinctive organizational characteristics of the human brain were probably selected for during the Pleistocene epoch, when our forebears adapted to a hunter–gatherer existence on the African savannah. These adaptations were fundamentally social, including the emergence of complex language and the development of a sophisticated theory of mind. It is less clear when the distinctive asymmetry of the brain that underlies human right-handedness and left cerebral dominance for language evolved.

Human Evolution

Introductory article

Marta Mirazón Lahr, University of Cambridge, Cambridge, UK

CONTENTS

The origin of human species and their relationships with the apes have been reassessed in the light of genetic studies. Hominins are now believed to have emerged in Africa about 7--5 million years ago.

INTRODUCTION

Human evolution is more than the evolution of humans. More than 15 species have existed since the time of our last common ancestor with the apes. The features that make humans different from apes did not evolve at once, or in the same ancestor, and no single trait made the difference. Humans are unique among the apes in the way they move, their global distribution, the size of their brains, their dependency on technology, their linguistic abilities, their slow growth, and their demography. These distinguishing features evolved at different times, each giving an advantage to some individuals at the time they were competing with those lacking them, only to then become part of the heritage of subsequent generations. Progress in understanding human evolution has come through the amazing discoveries of new fossils and archeological sites, the development of sound chronological and paleoecological frameworks, and the application of new techniques such as molecular genetics to the subject. Paleoanthropology is an interdisciplinary subject by its very definition.

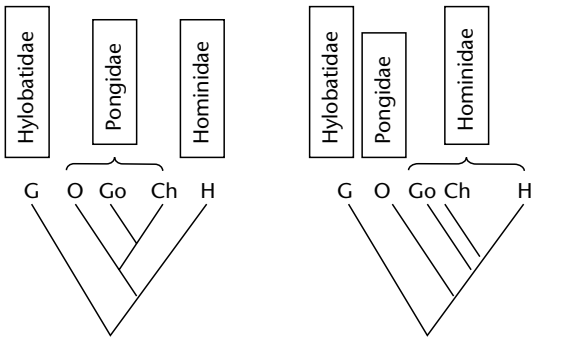
HOMININ ORIGINS AND EARLY HOMININ DIVERSITY

When and Where Hominins Evolved

Fossil and genetic evidence indicates that hominins emerged in Africa between 7 million and 5 million years ago (Mya) in the late Miocene. The earliest fossils that have been clearly identified as hominin date to 4.4 Mya. Earlier, seemingly hominin remains have been found dating from 6.0--5.8 Mya, although their relationship to the hominin or chimpanzee lines remains controversial given the lack of fossil remains of the apes that would have given rise to them. Between the earliest hominin and fossil apes dated to about 9.0 Mya, the African hominoid fossil record does not exist. However, genetic evidence allows us to establish who, among living apes, are our closest relatives, as well as to confirm the dates established from fossils. In fact, these very early hominin fossils have been discovered only in the last few years, and it has been on the basis of genetic evidence that the age of divergence between apes and hominins has been established.

The genetic comparison of apes and humans, with a view towards establishing their pattern of relationships, was pioneered by Sarich and Wilson in the late 1970s. These comparisons, now based on the study of a large number of different genes and gene products, established three key facts: first, that the African apes form a clade within the great apes; second, that within that clade, chimpanzees and humans are more closely related to each other than either is to the gorillas; and third, that on the basis of a molecular clock, hominins and chimpanzees diverged from each other between 7 Mya and 5 Mya. These results have had a major impact on hominoid systematics (Figure 1), as well as establishing a chronological and ancestral framework for the study of hominin origins.

However, controversy exists as to who were the ancestors of the living African apes and where they lived. The fossil record of Miocene apes is a relatively rich one, and yet two very contrasting hypotheses exist regarding the biogeography of hominin origins. The Miocene is a long period (25--5 Mya), which can be divided into two phases. The first of these is characterized by climatic warming and expansion of African forests, in which early apes diversified. The second phase is



(a) Early classification and inferred phylogenetic relationships of living hominoids

(b) Accepted correct classification and phylogenetic relationships of living hominoids

Figure 1. Hominoid systematics. Traditionally the superfamily Hominoidea has been seen as consisting of three families, the Hylobatidae, the Pongidae, and the Hominidae. These groupings emphasized the similarities of the great apes and the distinctiveness of humans. Molecular approaches have radically changed this, and shown a close relationship between humans and African apes, especially the chimpanzees. As one of the aims of taxonomy is to reflect phylogeny, the traditional classification has changed. Orang›utans are the only living representatives of the family Pongidae, while gorillas, chimpanzees and humans form the family Hominidae. This reclassification also changes the vernacular of these scientific names, so that instead of using the term hominid to describe humans and their ancestors, the term hominin (reflecting the subfamily status Homininae) is used. Ch, chimpanzees, genus *Pan*; H, humans, genus *Homo*; G, gibbons, genus *Hylobates*; Go, gorillas, genus *Gorilla*; O, orang›utans, genus *Pongo*.

characterized by global cooling, contraction of forests, lowering of sea levels, and major geotectonic changes. During this period the continents and oceans acquired the general shape by which we know them, the Rift Valley and the Himalayas were formed, the Antarctic partially froze, and the Arabian peninsula emerged forming a permanent land bridge between Asia and Africa. These two continents exchanged fauna through this land bridge, and some apes dispersed to Eurasia for the first time. Among those Eurasian apes we find fossils that represent forms ancestral to orang›utans.

For many years the ancestors of African apes were sought among those apes who in the middle Miocene remained in Africa. In this context, the origin of hominins has been interpreted as part of the process by which East and West African faunas differentiated as the Rift Valley was formed. Hominins would represent an African ape who adapted to the drier and more open environments of East Africa from an arboreal forest ancestor. However, the genetic evidence implies that Asian and African great apes share a common ancestor who lived after apes had dispersed into Eurasia, suggesting that the ancestors of the African apes (and hominins) should be found among late Miocene Eurasian forms. In this context, the differentiation of African apes, including the origin of hominins, would result from the geographical separation of populations of an ancestral species as it dispersed into Africa from the north›east. Therefore, although we know hominins evolved in Africa from a common ancestor with chimpanzees around 6--5 Mya, fascinating issues relating to the origin of that common ancestor will be resolved only by new fossil finds from the crucial period between 8 Mya and 5 Mya in Africa and possibly Arabia.

What Made Early Hominins Different?

Early anthropologists had two main expectations in relation to the origins of humans and their ancestors: that they had diverged from apes a very long time ago, and that this divergence was based upon the development of a large brain. Both were proved wrong. Hominins have a relatively short history, and we now know that brain expansion began in the last 2 million years. What set hominins apart from other apes was their locomotion.

Bipedalism has long been recognized as the key adaptation of the hominin lineage. In terms of morphology, it requires the modification of most of the skeletal system, although such modifications were not all in place at once. The selective advantages of bipedalism are much debated. As a means of terrestrial locomotion, it clearly provides an efficient way of moving in open environments for long periods, especially when compared with knuckle›walking animals, such as gorillas and chimpanzees, rather than true quadrupeds. It also results in more efficient thermoregulation during the middle of the day, as less body surface is exposed to the sun in comparison with quadrupeds. Other advantages may relate to predator vigilance and potential for carrying. Most researchers would argue that a combination of these factors gave bipedal apes a competitive advantage in relation to their quadrupedal relatives at the time.

However, when considering the selective pressures that led to the evolution of bipedal apes, two factors should be taken into account. First, early hominin bipedalism was significantly different from ours. The fragmentary fossil record of the earliest hominins shows clear evidence that these animals had already changed key aspects of their

anatomy towards a bipedal stance. However, the earliest associated fossil skeleton -- that of the famous Ethiopian *Australopithecus afarensis* fossil nicknamed Lucy -- shows that several of the changes that make bipedalism more efficient, such as the shape of the ribcage, the curvature of fingers and toes, and the elongation of the legs, had yet to take place. Therefore, although it sets early hominins apart from other apes, bipedalis itself took millions of years to evolve. The second factor is related to the first. It has become clear that early hominins still spent significant amounts of time in trees. Models of energy expenditure stress that the advantages of bipedalism would become meaningful only when hominin ancestors had to spend a large percentage of their time on the ground.

The Origin of the Lineage That Gave Rise to Modern Humans

Early hominins were clearly successful in the niche they colonized -- that of a terrestrial bipedal ape, with a body and brain size similar to present›day chimpanzees and a broadly similar diet based on fruits, young leaves, and probably some meat. This success led to demographic growth and a greater distribution in East and South Africa, and eventually, competition among themselves for the resources offered in this new niche. Competition can lead to progressive specialization, in which animals become better and better at processing the resources on which they depend, and to differentiation, in which animals try to exploit new resources to avoid their competitors. Hominin evolution in the Pliocene (the period between 5 Mya and 2 Mya) is characterized by both.

Among these bipedal apes, two adaptive trends became established. One of these was towards comparatively specialized animals, who adapted their teeth, masticatory muscles and the shape of the face to maximize their ability to crush large quantities of rough food. They are known as the robust australopithecines, and they consist of several very successful species, usually grouped under the genus *Paranthropus*. This group of hominins was well established before 2 Mya, and survived until approximately 1 Mya in Africa. The other adaptive trend was towards animals who became encephalized, had larger body sizes, slower growth, and appeared behaviorally more flexible, as suggested by their association with stone tools, their wider distribution, and the apparent consumption of larger quantities of meat. In this suite of characteristics, researchers recognize the appearance of many features that we identify with humans, and indeed, this group of animals represent the origins of the genus *Homo* to which we belong.

Establishing the precise point of beginning of new adaptive trajectories in evolution is always difficult, and accordingly much controversy exists as to which fossils mark the threshold between *Australopithecus* and *Homo*. The hominin fossil record in East Africa around 2 Mya shows, besides the big›toothed *Paranthropus*, a very variable collection of animals, grouped under the species name *habilis*, with some but not all of the *Homo* characteristics listed above. Nevertheless, by about 1.8 Mya, a new group of hominin can be identified -- *Homo erectus/ergaster*, who shows the complete combination of incipient *Homo* traits, including the ability to disperse widely. *Homo erectus/ergaster* is the first hominin to leave Africa, and fossils of this group from 2--1.5 Mya are found not only throughout East and South Africa, but also in North Africa, the Caucasus, and Java.

How can we interpret the combination of features that differentiates the genus *Homo* from earlier hominins and represents our own distinct evolutionary heritage? Some of these traits can be seen as fundamental biological changes in behavior, anatomy and growth, while others represent the consequences of these changes given energetic and morphological constraints. Among those fundamental changes it is impossible to determine which came first, as their evolutionary success depended on their concerted modification. However, it could be argued that new adaptive trajectories become established when new behaviors resulting in greater reproductive success lead to selection of individuals whose genetic make›up facilitates those behaviors. In this context, the fundamental behavioral shift associated with early *Homo* was probably the shift to a more carnivorous diet in conjunction with the manufacture of tools that allowed its better exploitation. A more carnivorous diet, rich in protein and fats, would have both released the energetic constraints to increasing the size of the body and the brain (the most energetically expensive organ), and favored more intelligent individuals with greater memory, and capable of more complex cooperation and planning. Furthermore, greater carnivory is associated in mammals with larger geographical ranges and less dietary exclusivity, and thus the underlying condition for dispersal. Encephalization, in turn, would have posed new pressures upon these animals, both in terms of the need for greater maternal energy intake during pregnancy and lactation (most of the period during which human

brains grow), and in terms of maintaining metabolic rate relative to body size.

These animals seem to have pursued two separate strategies for meeting these pressures, strategies that have a feedback effect. On the one hand, researchers have argued that the increasing energetic costs to mothers imposed by encephalized infants were met by budgeting these costs over a longer period, thus leading to slower growth rates. On the other hand, research has shown that while humans have brains significantly larger than expected for their body size, their guts show the reverse condition. On this basis, researchers have argued that there was a trade›off between the energy channeled towards brains and guts so as to maintain stable metabolic rates, and that this was possible through the smaller absorptive gut surface necessary in carnivores in relation to herbivorous animals. These correlated changes and their feedback effects (Figure 2) represent the underlying adaptive trend of the genus *Homo*.

HUMAN EVOLUTION IN THE PLEISTOCENE

Paleoenvironmental Context for the Evolution of Neanderthals and Humans

One of the distinguishing features of the genus *Homo* is its wide geographical distribution. For more than 3 million years, hominins existed and diversified within sub›Saharan Africa. In the subsequent period, the Pleistocene epoch (1.8--0.01 Mya), hominins colonized first the northern and southern (temperate) extremes of Africa (by 1.8 Mya), south›western Asia (by 1.7 Mya), tropical south›east Asia (by 1.8 Mya), then east Asia (by 1.0 Mya) and Europe (by 0.8 Mya). Human evolution in the Pleistocene is no longer an African affair, and allopatry becomes a key issue in interpreting the patterns of differentiation among species and populations. Under a simple allopatric model, Neanderthals and modern humans represent,

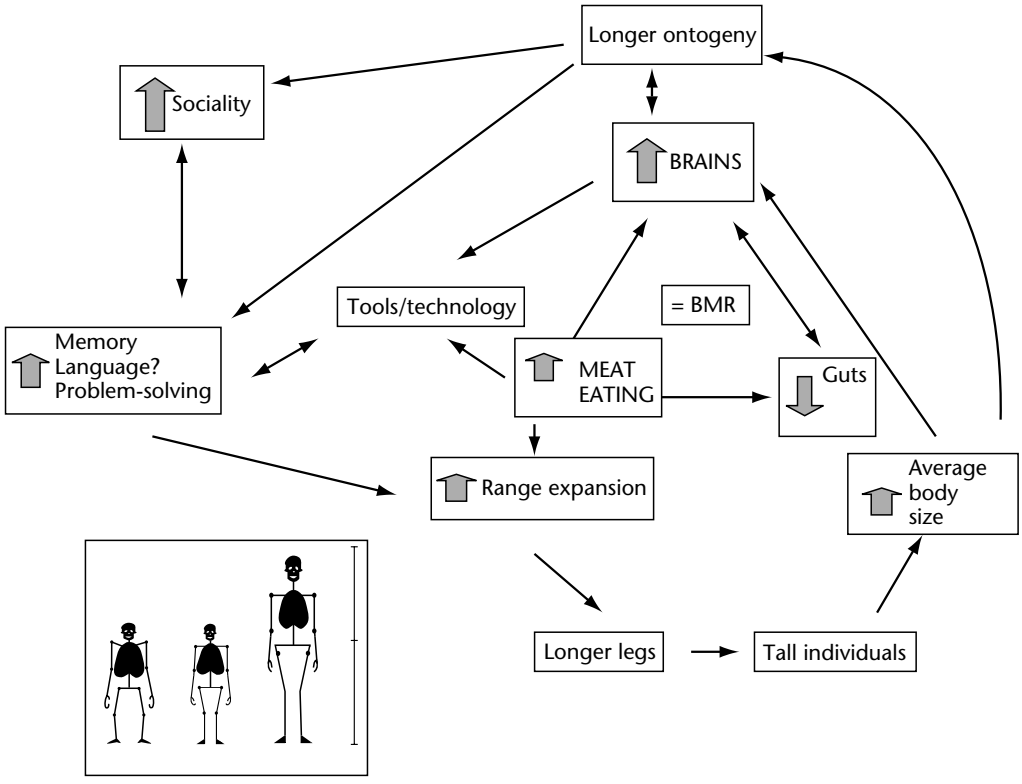


Figure 2. The complex adaptive system that underlies the evolution of the genus *Homo*. BMR, basal metabolic rate.

respectively, the contemporaneous European and African descendants of a Pleistocene hominin species (Figure 3).

However, in order to understand why Neanderthals and modern humans evolved, and why they had such different fates, it is necessary to understand the overall conditions that established their selective environments. Evolution is the result of changes in the competitive environment of species that lead to new patterns of mortality. These establish new parameters of individual fitness, which underlie the process of natural selection and consequently adaptation. The competitive environment of any species has both biotic and abiotic components, which determine the conditions in which the evolutionary process takes place. Understanding climatic change, with its potential for promoting expansion or contraction of ecological niches, is essential for interpreting the diversification of species. The Pleistocene climate was marked by alternation between relatively cold glacial periods, and warmer interglacial ones. The duration and amplitude of the glacial periods both appear to have increased around 800 000 years ago. These climatic changes had effects on faunal distributions and survivorship, some of which are predictable and some of which are not.

A glacial cycle lasts approximately 100 000 years, although each cycle varies in extent and severity. Most of the cycle is characterized by a long period of low, fluctuating temperatures, during which continental ice accumulates at high latitudes. This accumulation of water in the form of ice sheets leads to a drop in sea levels, with the consequent exposure of continental shelves, and to increasing aridity in the tropics. As temperatures increase, the ice sheets which had taken tens of thousands of years to build start to melt, and interglacial phases begin. That excess of circulating water leads to a short period of extreme precipitation in the tropics, creating extended freshwater networks and high lake›level stands. When this water eventually drains to the seas, conditions similar to those of the present day set in. The overall effect for hominins, depending on where they were, was one of expanding and contracting ranges, of alternating rich and scarce resources, and of highly variable thermal conditions.

By 1 Mya hominin populations were established throughout Africa, and in tropical and temperate Asia as far north as northern China. Soon afterwards, hominins occupied Europe for the first time. This broad spatial distribution, in the context of small population sizes, sets the conditions for regional differentiation among the various groups of encephalized hominins. That differentiation becomes very apparent in the Middle Pleistocene (0.8--1.25 Mya). The main distinction in both morphology and archeology is between east and west, along what is known as the Movius line. In the east, hominins have not changed from their *Homo erectus* ancestry. Both in Java and China, fossils in the time›span between 1.0 Mya and 300 000 years ago are *Homo erectus*, associated with relatively simple tools. *Homo erectus* continued to inhabit south›east Asia until about 50 000 years ago, suggesting long›term isolation from other regions of the world. The situation in China becomes increasingly more complex after 300 000 years ago, when fossils displaying a quite distinct morphology make their appearance alongside *Homo erectus* ones, and their affinities are still a matter of debate. In the west, hominins change, losing many of the *erectus* features, as well as showing an overall increase in body size and brain size. This morphology was for a long time referred to as archaic *Homo sapiens*. Most researchers today attribute it to a new species -- *Homo heidelbergensis*. The main specimens of *H. heidelbergensis* are the fossils from Bodo, Lake Ndutu, Kabwe, and Elandsfontein in Africa, and from Arago, Boxgrove, and Petralona (among many others) in Europe.

What makes *H. heidelbergensis* really interesting is not only the strong similarities between the early African and European forms (around 0.5--0.4 Mya), but how they differentiate afterwards. In Europe, a number of fossils of late Middle Pleistocene date (0.3--0.125 Mya) show characteristics later to be found only among Neanderthals. In Africa, differentiation from *H. heidelbergensis* also takes place, with the appearance of features that we identify as modern human traits. Thus we have in *H. heidelbergensis* an even larger›brained hominin species that in the middle of the Pleistocene epoch extended from Africa to Europe. It is this species, or its possible descendant, *Homo helmei*, which in the opinion of many researchers represents the last common ancestor of Neanderthals and modern humans.

The Origins of Modern Humans and Neanderthals

The climatic cycles of the last half›million years promoted periods of recurrent contact between African and European hominins (as shown by the strong similarities between *Homo heidelbergensis* in both continents), while the timing of such cycles suggests that the direction of contact was from Africa to Europe. It is in these contacts that the origin of the lineages leading to modern humans

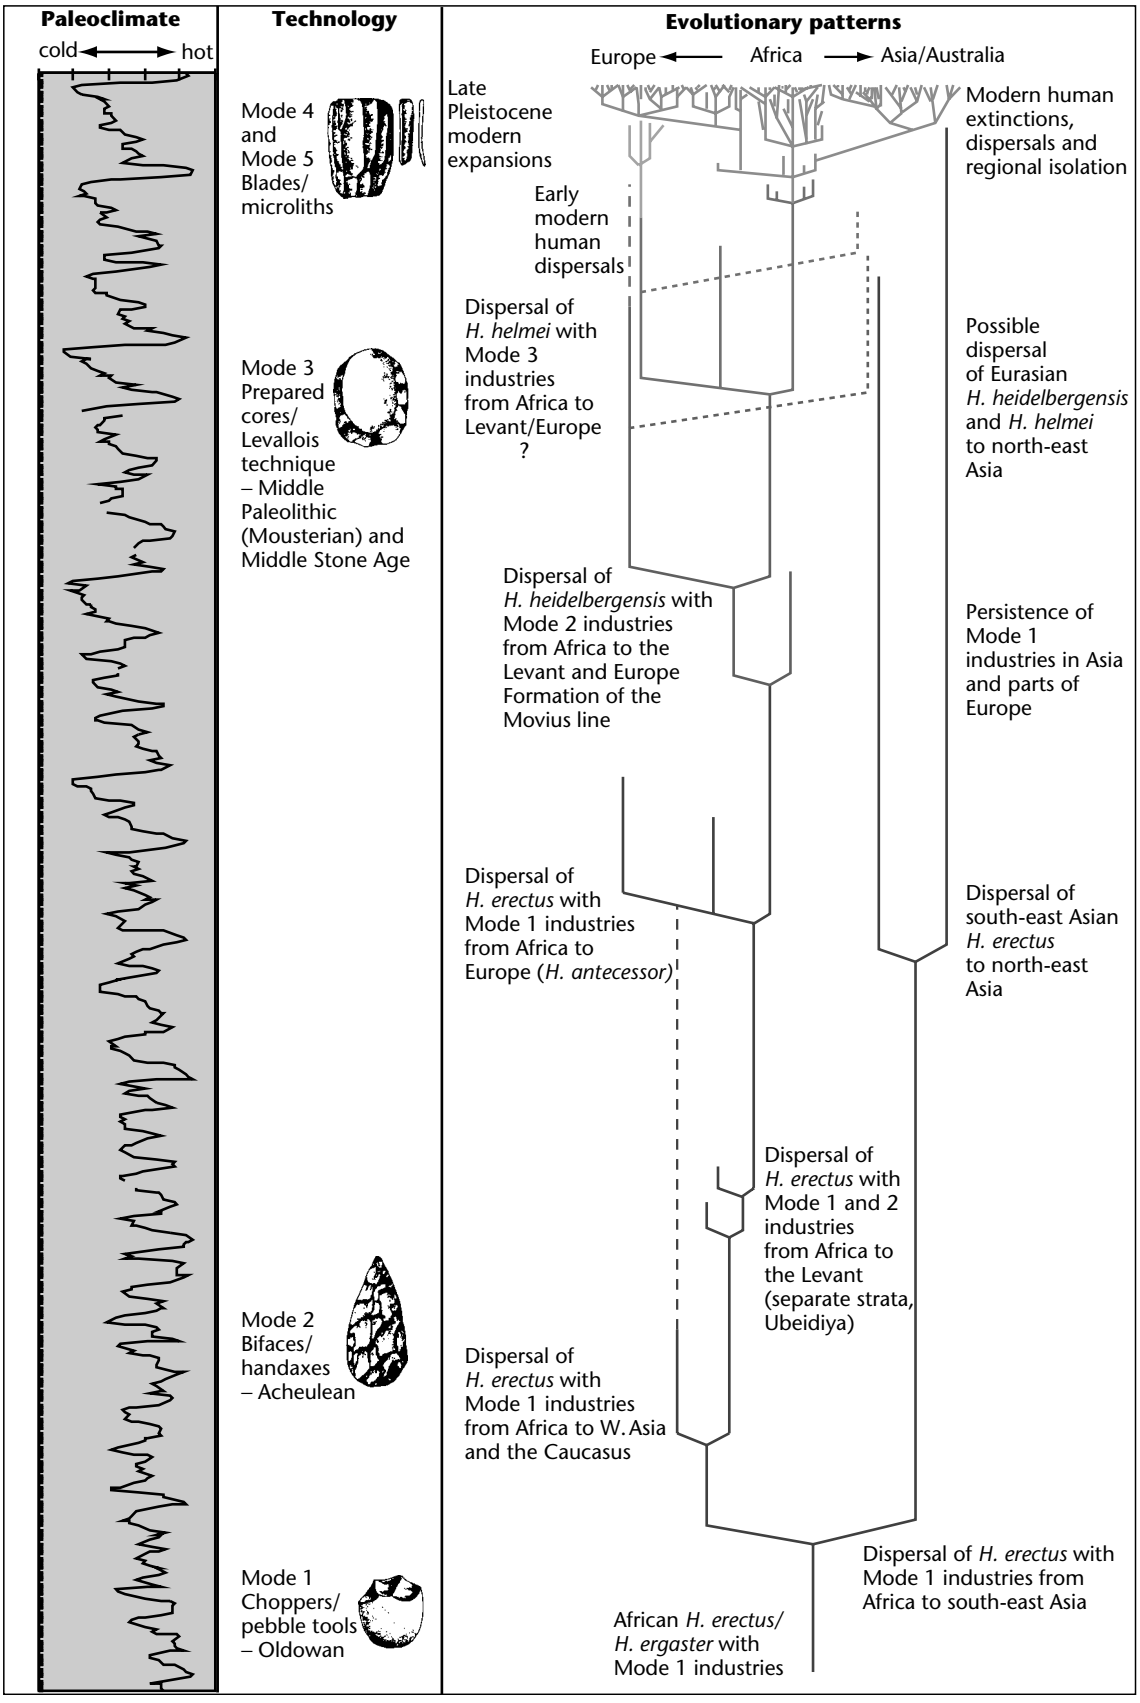

Figure 3. The record of human evolution in the Pleistocene.

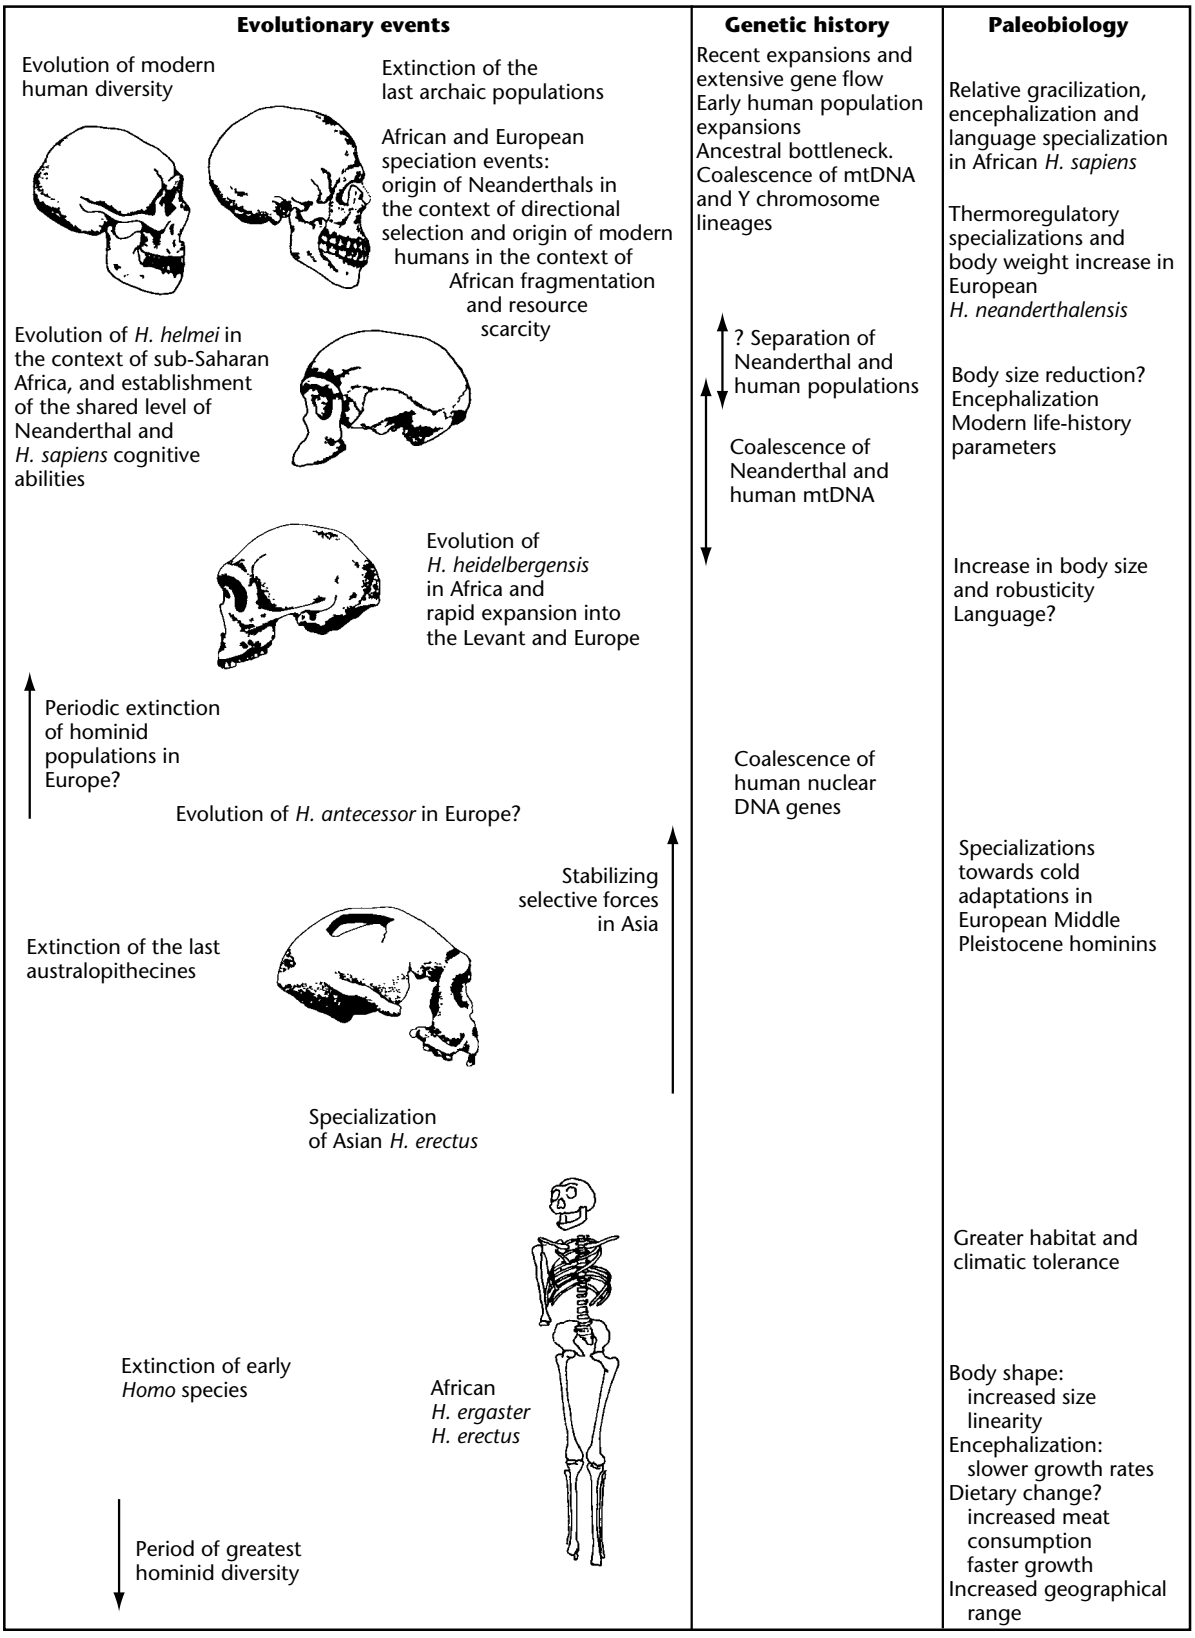
Figure 3. (*cont.*)



on the one hand, and Neanderthals on the other, are to be found. As mentioned above, different opinions exist as to when the African and European lineages exchanged significant genes for the last time, whether it was around half a million years ago in the form of *H. heidelbergensis*, or whether it was more recently, around 300 000 years ago, in the form of *H. helmei*. Independent of this, from around 130 000 years ago African and European fossils show modern human and Neanderthal features respectively.

The period preceding the appearance of Neanderthals and modern humans, 200 000--130 000 years ago, was one of extensive glaciation. These extreme climatic conditions would have generated different pressures on the populations of both continents. In Europe, thermoregulation would have been the main factor affecting survivorship, while in Africa the immediate effect would have been scarcity of resources because of aridity and ecological fragmentation. It is in response to these different selective pressures that researchers interpret the adaptive differences between Neanderthals and modern humans.

Many of the features of *H. sapiens* and *H. neanderthalensis* were inherited from their large›brained and large›bodied ancestor, who had a relatively long ontogeny, who manufactured complex tools, used a degree of planning and social organization in its strategy to exploit the environment, and most importantly, probably had some linguistic abilities. The differences between the two species thus reflect their modification of this ancestral heritage in order to meet the pressures posed by their respective evolutionary environments. In Neanderthals, these adaptations are represented by changes to the face, in particular how much it protruded and how large the nasal aperture was, together with a broad chest, and an overall dense and robust skeleton, with relatively short distal limb proportions. These changes are thought to reflect thermoregulatory adaptations to the warming of inhaled air and overall heat retention, as well as to a tough lifestyle that required extensive nomadism. In modern humans these differentiating features are more difficult to specify, largely because the history of the species is one of early geographical differentiation, thus making it difficult to identify the universal traits. However, a few can be described -- these are represented in the small size of a nonprotruding face with a chin in the jaw, in a differentiated cranial shape that resulted in a rounded head, and an overall gracile body. The increased aridity throughout Africa that led to increasingly scarce resources would also have led to demographic contractions, which might in turn have increased the role of genetic drift, as well as set new selective pressures. The changes observed in the evolution of a modern morphology, to a large extent associated with the gracilization of the skeleton, are consistent with selective pressures on resources, by which a cheaper skeleton would have been advantageous. Recent studies on the ontogeny of Neanderthal and modern human cranial growth suggest that the differences characteristic of both species were present at birth.

Genetic evidence has significantly increased our understanding of the evolution of these two lineages. Genetic studies have made a major contribution towards establishing a recent African origin for modern humans, and revealing their relationship to Neanderthals through the retrieval of ancient DNA. The genetics of living populations can be used to draw inferences about their past, in a similar way to the use of molecular clocks to understand the phylogenetic relationship between living apes and humans, and to infer, through genetic distances, the time lapsed since their divergence. The study of the genetic origins of modern humans is based on several genes and a range of different techniques.

For a long time geneticists used classical markers (polymorphic gene products) to study the variation among human populations. These are measured as percentages of different alleles in different groups, and their study has been championed by the Italian geneticist Luca Cavalli›Sforza. Classical markers are interesting, particularly because a large number of gene systems can be analyzed together to provide a tree of relationships of human populations. These are population trees, in the sense that they track the multivariate history of populations through the genetic expression of many systems. The results of studies of classical markers point clearly to an African origin of all modern humans, with the first branches of a human genetic tree taking place among African populations.

Since the 1980s molecular markers have been used to track the history of human populations. These studies were first developed using the mitochondrial deoxyribonucleic acid (mtDNA) genome, but are today based on a number of genes, including mutations on the Y chromosome. The advantages of the mtDNA and Y chromosome genomes are that they are inherited through only the maternal or the paternal line, and therefore do not undergo recombination during meiosis. Furthermore, most of these markers are believed to be selectively neutral, which means that not only does their distribution reflect history rather than

selection, but also they accumulate mutations faster than functional genes. Together, they provide the most powerful tool for the investigation of the evolutionary history of living human populations (of course, they cannot throw light on any group that has since become extinct, with the rare exception of the extraction of DNA from actual ancient remains). Their disadvantage is that they provide gene trees rather than population trees, and the history of any population is made up by the sum of each genes history. This is an important caution, as, for example, mtDNA and Y chromosome histories are not the same because men and women have had different histories determined by their patterns of mating and dispersal behavior. These single gene systems are analyzed in a variety of ways, the most important of which are based on coalescence theory and network analysis (Figure 4).

The results of these studies all point to an African origin of modern humans. Among the thousands of individuals sampled for either mtDNA or Y chromosome markers, Africans are the most diverse in having the greatest number of mutations. Furthermore, all the earliest branching events occur among African individuals. In other words, these data show that the last common ancestor of all living humans was part of a population from which Africans derive, and that only much later, other populations branched off this group. The application of a molecular clock to these various systems provides a range of dates for the last common ancestor of all humanity -- between 200 000 and 130 000 years ago, thus in full agreement with the paleoanthropological record.

Molecular data can also provide information on the demographic parameters of the ancestral population of any given species. The basis for these is the estimation of the effective population size of a given system, derived from the equation

$$F_{ST} = \mu 2N_e \quad (1)$$

Both F_{ST} (a measure of diversity in a gene) and μ (the mutation rate of a gene) are empirical observations, allowing the calculation of N_e, the effective ancestral population size. From such calculations, geneticists have suggested that the ancestral population of *Homo sapiens* underwent a severe demographic bottleneck before its diversification. Estimates of the magnitude of the ancestral bottleneck vary, ranging from 1000 to 10 000 individuals. Transforming these values into census values (i.e. the whole population), it is possible to estimate that the ancestral population of modern humans was at one point composed of 3000 to 30 000 people. The scar of this bottleneck is one of the main features of *Homo sapiens*. Although our species contains more than 6 billion individuals, we have a tenth of the diversity of any of our close primate relatives. From their African origin, modern humans underwent various periods of demographic expansion that led to multiple dispersals into Europe and Asia. A large proportion of the diversity among human populations can be related to this early fragmentation as small groups of hunter›gatherers dispersed and colonized the world. One such dispersal took modern humans into Europe around 40 000 years ago, into the Neanderthals homeland.

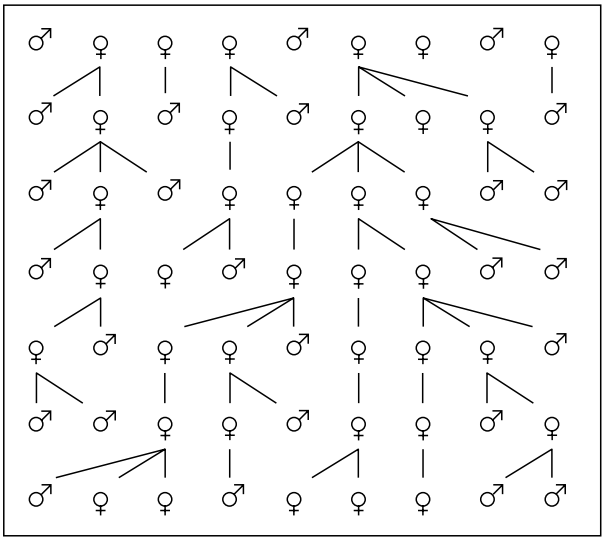


Figure 4. Basic principles of coalescence theory, showing as an example the coalescence of a maternally inherited gene.

The nature of the relationship between modern humans and Neanderthals has been much debated. After modern humans dispersed into Europe, Neanderthal fossil remains and their associated Mousterian technology disappeared from most of the continent. However, in certain areas these two hominins appear to have coexisted for some 10 000 years. Studies of Neanderthal mtDNA, obtained through the extraction of ancient DNA from three fossils, show that 600 000--500 000 years ago there lived a population from which both Neanderthals and modern humans descend, although not when this population separated into its European and African descendants. Furthermore, the absence of the particular mutations observed in the Neanderthal samples among the thousands of recent people studied indicate that Neanderthals did not contribute to the living mtDNA gene pool, offering further evidence for the extinction of Neanderthals, although whether small amounts of interbreeding took place 40 000 years ago cannot be ruled out. The last 30 000 years have been probably the first time in the last 5 million years in which only one species of hominin exists in the world.

HUMAN DISPERSALS

Dispersal is an essential element of the evolutionary process for all organisms. Most species start as small localized populations, and if successful spread more widely to fill up the available habitat. The rate and direction of any such dispersal are functions of the ability of the species to survive and thrive in the environments encountered, and of its own characteristics. Looking broadly across the animal kingdom, it is clear that not all species disperse to the same extent: some are much more widely distributed than others. Lions, for example, existed across the whole of Africa and Eurasia, whereas most monkeys are very localized.

Human evolution fits into this biogeographic pattern. From their localized African origins, humans have come to live all over the world, and that can only have happened as a result of dispersals. However, that pattern of colonization is a complex one, occurring irregularly over long periods. The first part of human evolution, that of the period 5--2 Mya, was dominated by australopithecines, and they never managed to disperse beyond Africa. In this sense they were much like the other anthropoid apes. With the emergence of *Homo* more extensive dispersals occurred. From 2--1.5 Mya *Homo ergaster/erectus* spread into the southern parts of Asia, becoming the first non›African hominin. After 1 Mya they gradually dispersed into the colder, more northerly latitudes of northern Eurasia. However, rather than this being a single continuous dispersal, it is probably best seen as a series of repeated events, probably interspersed with extinction of populations. The primary driving force of this process would have been the climate, particularly after the onset of glacial conditions.

The dispersal of modern humans is another of these events, beginning during the warmer phase of the last interglacial period, around 120 000 years ago. Again, the dispersal of modern humans was not a continuous single event, but is best described as a series of multiple dispersals. The major events in this process were the first dispersals out of Africa and along the southern rim of Asia, through to Australia, around 60 000 years ago; the dispersals into northern Eurasia from around 40 000 years ago; recolonization following the extremes of the last glaciation around 15 000 years ago, resulting in the first peoples in the New World; and, perhaps most important in terms of the current human population, the spread of the first farming peoples in the last 10 000 years. While archeologists and anthropologists have argued about the relative importance of migration compared with local development, it is becoming increasingly evident that the ability to migrate and colonize has been an important element of human evolution.

HUMAN TECHNOLOGIES

The archeological record represents the appearance and development of hominin technological abilities, and it extends to the last 2.5 million years. Stone tools are thus associated with the second half of hominin evolution, most markedly with species of the genus *Homo*, although tools in possible association with late australopithecines have been found. What is the importance of the archeological record?

- It provides very strong evidence of behavior in the past, ranging from use of the landscape, to subsistence strategies, to defense organization.
- It provides unique evidence of cognitive processes in extinct taxa, through the inferred thought processes required to produce either the tools themselves or their accumulation pattern.
- Owing to its durability, it provides the best evidence for the spatial distribution of populations in the past, allowing, in certain circumstances, paleodemographic inferences to be made.

The range of tools possible is unlimited to our minds, with new inventions appearing daily, but this was not so in the past. Several factors acted to constrain the range of tools earlier hominins made: manual dexterity, cognitive ability, and availability of raw materials. This has allowed archeologists to categorize stone tool traditions according to the shape of the tools produced or the methods by which they were made. Several such categorizations with different levels of detail exist (Figure 5). One of the most useful classifications of the archeological record is that developed by Graham Clark. He organized stone tools according to what he called modes, and the timing and distribution of these modes, as well as trends within the technocomplexes they define, have important consequences for our interpretation of hominin cognition through time (see Figure 3).

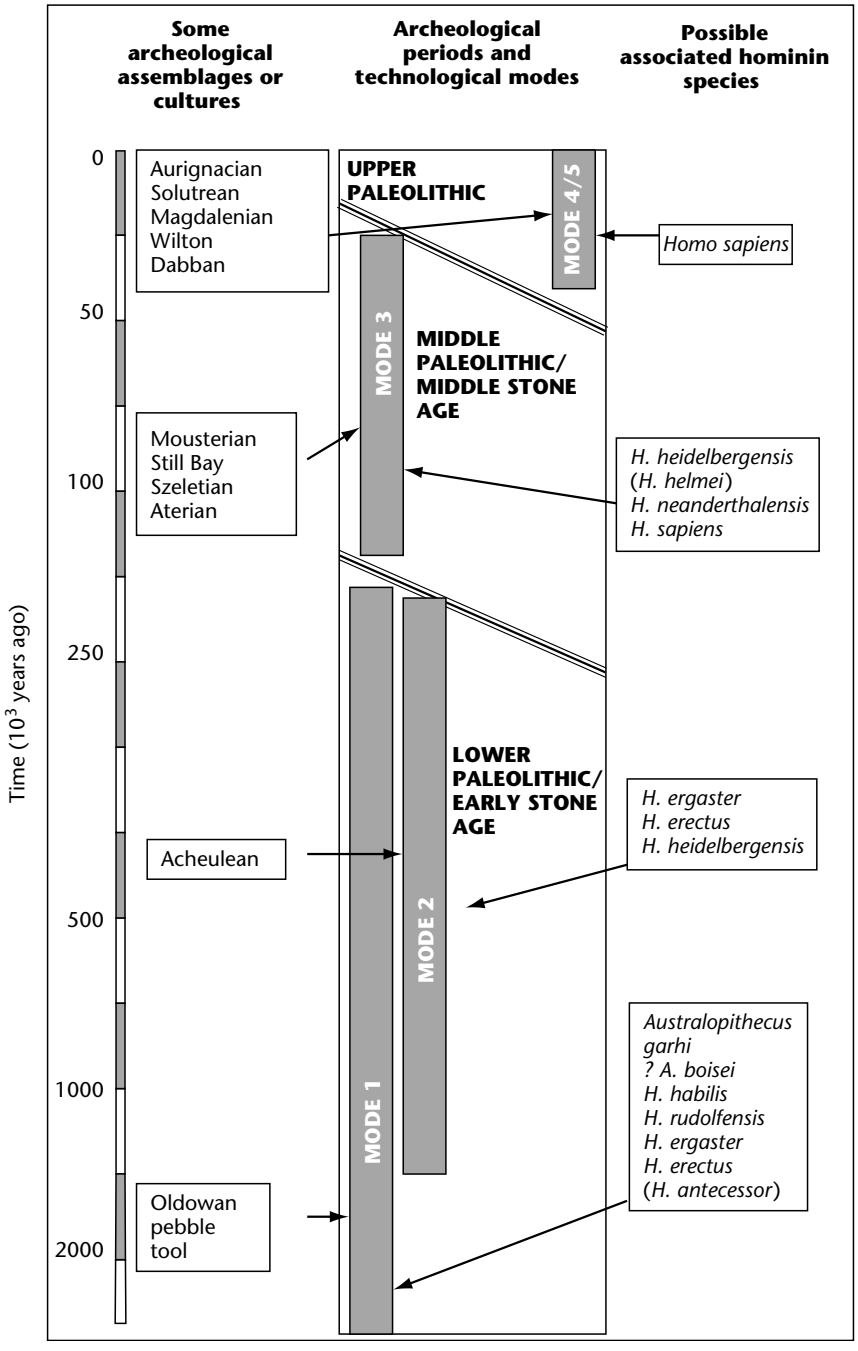

Figure 5. Temporal distribution of archeological assemblages and modes.

For those working within the framework of a recent African origin of modern humans, *Homo heidelbergensis* has been considered as the last common ancestor of Neanderthals and modern humans. This view argues that, some time between 600 000 and 500 000 years ago, during an interglacial phase, hominins dispersed from Africa to Europe, taking Mode 2 or Acheulean technologies to Eurasia for the first time. However, around 300 000 years ago, a new technology appears in Africa and soon afterwards in Europe. This technology, known as Mode 3, or Middle Stone Age (Africa) or Middle Paleolithic (Europe), has some striking features. Hominins were no longer turning stone cores into tools, but rather flaking them to obtain thinner, preshaped, and more abundant objects. In order to do this, hominins needed to prepare the cores prior to flaking, a step that required a level of mental abstraction. This technique of preparing the core before flaking, first observed within late Mode 2/Acheulean assemblages, is the technological background of both Neanderthals and modern humans.

Neanderthals and modern humans may have inherited this ability from a more recent common ancestor, known as *Homo helmei*. This would be consistent not only with the archeological record, but also with the little evidence there is for the evolution of language. Language is considered one of the key traits that define and to some extent structure human cognition and human behavior. However, the ability to speak does not affect the skeleton, and thus its origins cannot be traced in the fossil record. However, in recent years two indirect lines of evidence for linguistic ability among hominins have been explored -- one related to the expansion of the vertebral canal at the point of innervation of the diaphragm, and the other related to the size and shape of the hyoid bone. Both suggest that some of the anatomy that allows human speech evolved within the last half›million years, and that Neanderthals probably had some language ability. This would further reinforce the view that the two lineages share a recent common ancestor in the late Middle Pleistocene who had increased cognitive abilities.

HOMININ EVOLUTION: THE EVIDENCE

Paleoanthropology has recovered a rich record of the evolutionary history of humans. This record is made up of fossils and of the material culture left behind by various hominin species, integrated with the information derived from geology, paleontology, and paleoclimatology. It is further enriched by the evolutionary inferences possible from our own genetic diversity and that of our closest living relatives, the apes. Together, this information allows the reconstruction of a complex process, in which we recognize some broad patterns:

- Hominin origins, the divergence of our lineage from that leading to chimpanzees, date to 7--5 million years ago, and are based on changes in locomotive strategy.
- The first 3 million years of this history, during the Pliocene, are characterized by the diversification of bipedal apes within eastern and southern Africa, leading to the evolution of two separate lineages: one in which megadontic adaptations are associated with the consumption of large quantities of low›quality foods, the other in which encephalization, increased carnivory, tool use, and a longer ontogeny are associated with a more opportunistic exploitation of resources.
- The last 2 million years, the Pleistocene, are characterized by dramatic geographical expansions in the context of deteriorating climatic conditions, and the establishment of distinct regional trajectories expressed in both morphology and material culture.
- Neanderthals and modern humans represent the contemporaneous evolution, in Europe and Africa respectively, of large›brained and behaviorally complex hominins from a common ancestor who lived 500 000--300 000 years ago, and thus uniquely share a number of traits.
- From their African ancestral homeland, modern humans dispersed throughout the world by means of multiple events. These, together with the different selective pressures in the areas colonized and the effects of drift on small hunter›gatherer groups, shaped the diversity of the species.
- The extinction of the Neanderthals was probably associated with the migration of modern humans into Europe and the changes in the competitive environment caused by this influx of people.
- In recent millennia, and in association with the shift to an agricultural and sedentary lifestyle, humans have undergone a demographic revolution that took the species from a few thousand to over 6 billion individuals.
- When compared with other species, *Homo sapiens* shows a distinct lack of genetic diversity in spite of its current population size (the heritage from a recent ancestry as a very small population in Africa), and most of that diversity is to be found within, rather than between, populations.

In summary, humans are the result of the same evolutionary mechanisms that acted on other animal lineages. The history of their lineage is made up of the evolution, differentiation, and extinction of a large number of species during the last 7--5 million years. The history of the species is relatively recent and characterized by unpreced-

ented geographic and demographic success, one in which our unique cultural complexity and diversity played a major part.

Human Reproduction and Life Histories

Intermediate article

CONTENTS

Life history theory can explain varying patterns of human reproduction in different human societies given that organisms must allocate energy between the competing demands of growth, maintenance, and reproduction. One enigma to evolutionary theory is the demographic transition when humans began voluntarily to reduce fertility to what appear to be maladaptive levels.

THE USE OF LIFE HISTORY THEORY IN STUDIES OF HUMAN REPRODUCTION

To understand the reproductive strategies of species and even individuals within species, evolutionary biologists routinely use life history theory as an analytical tool. It is a way of understanding how organisms allocate available energy to growth, maintenance, and reproduction in order to maximize their fitness. Life history analysis therefore examines factors such as maturation rates, fertility, interbirth intervals, age at reproductive cessation, and maximum lifespan. The differential allocation of energy among growth, maintenance, and reproduction necessarily represents trade-offs – for example, allocating more energy to growth may mean postponing reproduction; allocating energy to produce a greater number of offspring may compromise the survivorship of these offspring or of the individual that produces them. Such trade-offs are usually dependent on the kinds of environments in which individuals live and the availability of sufficient resources.

Biologists also refer to species as having specific life history characteristics which can be used on a comparative basis and to acquire useful comparative information about adaptive strategies. For example, humans have long life spans compared to other similar-sized mammals; they usually give birth to one altricial infant; human offspring have a comparatively long period of juvenile dependency before being able to reproduce and become independent; adolescents in preindustrial societies become fertile between about 14 and 16 years of age; lactational periods average between 2 and 4 years; interbirth intervals in noncontracepting societies are about 3–4 years long; and the total fertility rates (TFRs) in such societies averages six. Understanding some aspects of the life history of species can also generate predictions about others. For example, large-bodied mammals generally have longer life spans and produce fewer offspring at slower rates compared to smaller mammals.

THE LIFE HISTORIES OF HUMAN FORAGERS COMPARED TO OTHER SUBSISTENCE GROUPS

Recently, anthropological demographers as well as evolutionary psychologists have suggested that we can only fully understand the adaptive significance of life history patterns in our species by studying those of foraging groups (Hill and Hurtado, 1996). The rationale behind this is that human physiological and cognitive evolution occurred under the constraints of a hunting and gathering way of life. In this case, studying the life history patterns of humans in modern, industrialized nations who are exposed to novel and sometimes unprecedented stresses may not be informative about potential adaptive responses. In addition, understanding the life histories of foraging groups may be helpful in attempting to reconstruct similar parameters for our hominid ancestors who, in turn, evolved from the common ancestor to modern apes. There is, however, no single characteristic suite of traits

that can be used to describe foraging societies, precisely because such traits are mediated by environmental conditions even within the same population. This is amply demonstrated by Hill and Hurtado (1996) for the Ache foragers of Paraguay. There are certainly generalities that one can make – for example, the maximum average number of offspring recorded for women in foraging societies is much lower than that of women in subsistence agricultural societies – but the patterns outlined below show considerable variation (Table 1).

Table 1 contains comparative data from three foraging groups for whom there exist probably the most reliable information on life history traits; even so, information for many aspects of interest is still missing. The !Kung san of Botswana are somewhat problematic since it is highly probable that many women in this population had been exposed to sexually transmitted diseases at the time of study. This would explain their low TFRs and very early average age at last birth. Despite this problem, the TFRs of the three foraging groups here range from five to eight children, the Ache producing almost twice as many offspring as the !Kung. That resource availability may be a factor explaining differential fertility is suggested by the average energy intake of the three groups (as well as energy spent in obtaining these resources) with the Ache having the greatest intake and also the highest TFR.

Many human life history characteristics, particularly those relating to fertility among noncontracepting societies, are shared with our closest primate relatives – the apes. They are similarly long-lived animals that invest several years in their single offspring. Chimpanzees and gorillas produce a total of about five offspring during their lifespans, females breastfeed their infants for up to 4 years, and have long interbirth intervals of approximately 5 and 4 years respectively. Chimpanzees and gorillas also have similar reproductive cycles and gestational lengths to humans (Bentley, 1999). The main features that distinguish us from other apes is a longer maximum life span, a longer period of juvenile dependency, and the potential for very short interbirth intervals. Human females are also distinguished by having a menopause.

Table 1. Comparison of life history traits among foraging groups

	!Kung[a]	*Agta*[b]	*Ache*[c]
Age at menarche	16.6	17.1	15.3
Period of adolescent subfecundity	2.19	3.01	3.2
Age at first birth	18.8	20.1	18.5
Interbirth interval	3.7	2.9	3.2
Age at last birth	34.4	NA	NA
Age at menopause	NA[d]	43.9	late 40s
Years of reproductive capacity	15.6	18.7	NA
Total fertility rate	4.7	6.5	7.8
Daily caloric consumption (kcal)	2,355	NA	3,827
Daily time spent in food acquisition (mins)	108	NA	79

[a]Howell, N (2000)
[b]Goodman *et al*. (1985)
[c]Hill and Hurtado (1996)
[d]Not available.

As mentioned above, the maximum TFR recorded for foraging societies is lower than for subsistence agriculturalists. The reasons for this disparity are linked to technological and environmental changes brought about by the development of agriculture and urbanization. These changes appeared to reduce interbirth intervals probably by improving maternal nutritional status rather than permitting earlier weaning. There were also significant socioeconomic changes that accompanied agricultural innovation and that permitted, for example, the permanent employment of wet nurses for individuals who could afford them.

In contrast, the average TFR of modern industrialized nations averages less than two. This translates into a rate of growth below replacement levels and, if it persists (as seems likely) population numbers can only be maintained in such countries through immigration. Humans in such societies are able to achieve and maintain this low fertility level through the extensive use of effective contraceptives. Tied to this are the economic and psychological pressures exerted on parents that motivate low fertility. The differences between the life history of reproduction between humans in noncontracepting, foraging societies, modern industrialized societies, and our closest primate relative, the chimpanzee, are exemplified in Figure 1.

ALTERNATIVE APPROACHES TO LIFE HISTORY THEORY

In many respects, life history characteristics are also studied by demographers who are generally trained in social sciences with little or no biological background. Demographers are interested in factors such as reproductive rates, patterns of mortality, interbirth intervals, and comparison of these rates between different groups. What demographers lack compared to biological practitioners is a higher-level body of theory with which to organize and understand their data. Integrating the two areas of research has become a goal for a number of

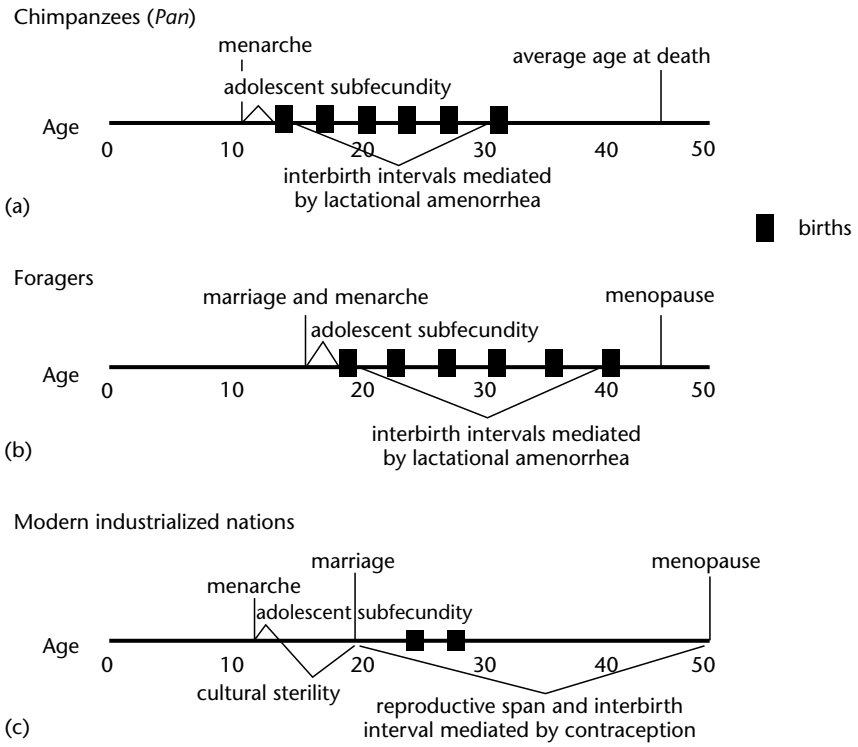

Figure 1. Life history traits of chimpanzees, human foragers, and humans in modern industrialized societies. Adapted from Lancaster and Hamburg (1986).

biological anthropologists and evolutionary ecologists interested in population issues and life history theory.

In addition, traditional demographers typically do not study populations such as foragers who live in remote and inaccessible parts of the world. Data from such groups have derived almost exclusively from anthropologists. In explaining factors such as the comparatively low fertility of many foraging groups, anthropologists have drawn on models from the medical literature, particularly those dealing with nutrition and energy expenditure (sports medicine). For example, the low fertility of the !Kung San of Botswana (with a TFR of 4.7) may be explained by the high levels of energy expenditure necessitated by their foraging lifestyle where women are responsible for most of the energy intake of the group. On the other hand, the !Kung San have also been exposed to sexually transmitted diseases which may have lowered their fertility, as outlined above. Other models refer to the importance of postpartum lactational amenorrhea and extensive birth spacing to explain low fertility among subsistence populations. Many anthropologists have studied the poor nutritional intake of foragers and horticulturalists who may live in marginal environments, and the impact of low energetic status on ultimate fertility. Reproductive ecologists are also using hormonal analyses to understand the mechanisms that govern the reproductive system and to explain patterns of low fertility among subsistence groups.

At the same time, all of these approaches within anthropology – in contrast to the demographic perspective – take a fundamental biological approach: namely, that achieved fertility conforms to life history expectations and is likely to be optimal for the individuals involved.

THE DEMOGRAPHIC TRANSITION

Despite the exhortation to study foragers, traditional demographers have spent much more time studying a phenomenon in contemporary human population history known as the 'demographic transition'. This refers to a historical (and still ongoing) process first described in the 1950s by demographer F. W. Notestein, whereby countries undergoing industrialization, beginning with Europe and North America about two centuries ago, gradually transform from high fertility and high mortality patterns to low fertility and low mortality. During this transition, countries generally experience very high growth rates when

fertility rates outstrip mortality rates. The drop in mortality rates is associated with improved nutritional and health conditions that accompany industrialization. The larger family sizes that result from a reduction in mortality eventually leads families to respond by decreasing family sizes. Populations after the demographic transition have many fewer individuals in the lower age classes than those that have not undergone fertility decline.

Although frequently called demographic transition *theory*, the traditional description of population events in Western Europe referred to a *process*, as opposed to an explanation, for what was observed and documented. In fact, demographic transition theory has been criticized on a number of grounds by behavioral ecologists including its lack of a theoretical framework. In addition, while demographers have frequently predicted a demographic transition for countries in Africa, South America, and Asia, it is by no means clear that similar processes are, or will, be operating there. Research into historical demography also paints a far more complex picture of events in preindustrial Western Europe than was previously thought. In particular, many areas had comparatively low fertility caused by voluntary abstinence and late ages at marriage well before the period of time that was traditionally assigned to demographic transitions. Yet there are sufficient similarities around the world to define a phenomenon in need of an explanation.

THEORETICAL DIFFICULTIES EXPLAINING LOW FERTILITY

As already stated, human behavioral and evolutionary ecologists have for some time argued that life history theory could provide an excellent and proven model with which to explain human demographic processes and behaviors, just as it does for other species (Hill and Hurtado, 1996). But, from this perspective, the human demographic transition to low fertility regimes remains a theoretical enigma. A primary tenet in evolutionary theory is that, where resources are abundant, organisms should opt to maximize their reproductive success by leaving as many offspring as possible in the expectation that more will survive to reproduce. This prediction appears to hold true for preindustrial human groups.

Humans have evidently evolved to enjoy and seek out sexual opportunities, and also to acquire resources to attract mates. Children would have been the inevitable consequence of these preferences in ancestral environments. Indeed, we still have such preferences, and there is evidence that wealthy men in modern societies do have a higher number of sexual partners. But, sexual activity does not necessarily translate into progeny if contraceptives are used. This raises the question of why people choose to use contraception, and why fertility started to decline in some European countries long before any modern methods of contraception were available. Reproductive decision-making is plastic in traditional and modern societies, and it is therefore interesting to examine how an evolved human psychology that favored reproduction could have produced such a consistent, modern trend towards small family sizes. An explanation for the demographic transition is therefore of particular interest to evolutionary anthropologists, because the reduction in family size generally occurs at a time of improving living conditions.

Various schools of thought have arrived at different levels of explanation for this apparently maladaptive fertility decline. One possible explanation is put forward by a particular school of theorists in evolutionary psychology who argue that many behaviors in our modern industrialized world are, in fact, maladaptive given the disjunction between this kind of environment and that of our human foraging ancestors in which we evolved. This is specifically referred to as the 'environment of evolutionary adaptation'. In this case, we need look no further for other explanations: low fertility rates are essentially maladaptive since the kind of environment in which we live is unprecedented and produces aberrant behaviors. This form of evolutionary psychology, however, has been criticized on several grounds. Of particular relevance here are critiques against the idea that humans have been unable to adapt to their environments since the Pleistocene period (e.g. Irons, 1998).

In fact, no simple biological, economic, or ecological correlate can predict the onset of the demographic transition across countries. Historical demographers tend to consider the demographic transition as an idea that is spreading around the world, using language rather similar to the meme concept, introduced by Richard Dawkins. France experienced the first and probably best documented demographic transition, starting in the eighteenth century. The prevalence of smaller families, presumably associated with higher parental investment in each child, spread from centers of sophistication over time. In remote areas fertility decline came later, but once it started, it proceeded more rapidly. One of the best predictors of the onset of the trend was simply distance from these epicenters.

Again, such findings describe rather than explain the demographic transition. More formal models of cultural evolution, in which units of culture are considered to evolve in ways similar to genes (but without the need to necessarily enhance biological success), have also been used to generate some explanations. Boyd and Richerson (1985) show that it is theoretically possible for a 'meme' for low fertility to spread in a scenario where we copy successful individuals. Since success is defined through wealth, when child rearing tends to compete directly with the ability to earn money, those with small families are more likely to be wealthy and to become role models.

GENETIC FITNESS VERSUS OTHER GOALS IN CONTEMPORARY SOCIETIES

All these explanations described above imply that the demographic transition is maladaptive. This could be taken to support the claims of some scholars that humans are different from other animals and that evolutionary theory has little utility when applied to our own species. Evolutionary ecologists, however, are familiar with the notion that fertility might be reduced by some quantity/quality trade-off (Lack, 1968), and hence have explored the possibility that very low fertility could indeed be adaptive in some circumstances. The best evidence for this comes from recent models that combine themes drawn both from economics and evolutionary ecology. For example, economists like the Nobel prize winner Gary Becker have long argued that it is the economic costs and benefits of children that influence fertility. Evolutionary anthropologists maintain that wealth actually always flows down the generations, even in traditional societies (i.e. children are nearly always net costs) and that, in any case, Darwinian fitness is the currency being maximized, not parental income.

There are empirical examples of almost instant shifts in fertility occurring when the economic costs and benefits relevant to raising children change. In societies such as hunter-gatherers where juvenile mortality rates cannot always be predicted but can assumed to be high, an optimal fertility strategy is to produce large numbers of offspring with the hope that some will survive to maturity. In such societies, the costs of offspring are relatively low, particularly once children are old enough to begin foraging for themselves (this will itself vary from society to society depending on the environment and difficulties of acquiring food resources). In agricultural societies, where children can perform agricultural labor and become producers relatively early, as well as become caretakers of the elderly at older ages, the costs of offspring can be even lower. Where resources and especially land is both heritable and in short supply, however, having too many children may not be optimal in the long term. In fact, women in such societies appear to approach an optimal and intermediate number of children compared to their theoretical maximum.

The costs of raising children in modern industrialized societies is, by almost any standard, relatively high, and estimated as approximately £350,000 in the UK including the cost of education, food, and clothing (McAllister and Clark, 2000). The returns on this investment are also relatively low compared to foraging groups – most offspring in modern industrialized societies eschew care of the elderly, who are often housed instead in specialized and segregated facilities. In addition, the chances of survival of offspring given the quality of modern medical care are excellent, reducing the need to produce surplus offspring. Producing low numbers of children in a highly competitive atmosphere may in fact be optimal for most parents. The evidence thus shows that parents have large families if children can generate income for their family. However, the logical consequence of this argument is that when children become a net cost, population fertility will decline to zero, which has never been observed. One argument advanced to explain this is that children fulfill an innate biological desire for nurturing that will tend to override other economic considerations (Foster, 2000).

Economic demographers have recently focused on the link between relative cohort size and fertility decline – the argument is that those individuals born in 'baby booms' face stiff competition, particularly when trying to find jobs and build families; economic hardship relative to expectations precipitates fertility decline. The political state of a population can sometimes have a surprisingly large influence on fertility. While government edicts often have no effect – as in Romania during the Ceaucescu regime of the 1980s – pro-natalist policies do seem to work when they occur during warfare or territorial disputes. One such example is Palestinians living in the Occupied Territories who have one of the highest TFRs anywhere. A political *volte face* in the government of Iran from pro-natalist policies to those encouraging family planning correlated with an unprecedented and dramatic decline in fertility in just 10 years during the 1990s.

Parental investment is the key to understanding fertility decline. In humans, parental investment

can include inherited wealth and education, and anything else that might enhance the long-term chances of gaining wealth or status. In hunter-gatherer populations, children still require some level of parental support until their late teens to survive, so a psychology of high parental investment is likely to extend far back in our evolutionary history. In farming populations, heritable resources like land and livestock become strong determinants of reproductive success.

A state-dependent, dynamic model that optimizes reproductive success over two generations has been used to predict both optimal family size and the optimal amount of wealth to allocate to each child at the end of the parents' reproductive lives (Mace, 1998). Wealth inherited from parents was assumed to be an important determinant of future reproductive success. When wealth is modeled as having the potential to generate more wealth, it can be shown that very small families can be optimal if the costs of raising children to adulthood are high. The models shows that the higher the cost of raising children, the more wealth it is optimal to allocate to each child rises, making the average family in such a population wealthier. In populations where the costs of raising children were low, higher fertility and lower levels of wealth inheritance were optimal, meaning the average family is poorer.

Such a model offers some insight into the paradox of the negative correlation between wealth and reproductive success that is commonly observed. Within each model population, wealth is positively associated with reproductive success, but those model populations that had the poorest families also had the largest family sizes. Homogeneous populations, such as those from traditional cultures usually studied by anthropologists, frequently show a positive correlation between wealth and reproductive success, as predicted from evolutionary ecological theory. However, the large, heterogeneous populations usually studied by demographers typically show a negative correlation between wealth and reproductive success. If heterogeneous populations represent a group of subpopulations, each experiencing (or believing they experience) different costs and benefits associated with investing in children, then a decoupling or even a negative relationship between wealth and family size might be observed.

Empirical evidence is mounting that many human populations are structured in this heterogeneous way. However, this does not explain directly why different levels of parental investment across subpopulations have arisen. Formal population genetic models, where the quality of offspring is assumed to have long-term consequences for their competition against others, and hence for their future reproductive success, are needed. It is from these models that an understanding of the evolutionary basis of high parental investment might emerge, although as yet this branch of life history theory is relatively underdeveloped.

Even if a plausible evolutionary model predicting the origin and maintenance of very high parental investment and/or low fertility can be built, the existing empirical evidence from modern populations suggests that, at least across two generations, contemporary low fertility is not adaptive. In a survey of New Mexican men conducted in the early 1990s, it was found that those born into smaller families had greater educational achievements and earning power, but this did not translate into higher Darwinian fitness (Kaplan *et al.*, 1995). However, these individuals lived in a period of economic and population expansion – extra parental investment might pay better fitness returns in a stable population where competition is more intense. It is possible that low fertility combined with high parental investment may yet prove a successful reproductive strategy over the very long term, but there is necessarily no reason to believe this will be so. From an evolutionary perspective, we appear to be overinvesting in children's education. Competition between children, and between children's parents, appears to be driving a form of 'runaway parental investment' that pays good financial returns to children, but not to their fitness.

Our psychology may simply not be adapted to the range of choices that we now have with regard to our fertility, and hence this new range of preferences is being exposed to strong selection for the first time. There is some evidence that number of own siblings is a good predictor of number of own children in postindustrial populations, and there is also evidence that this heritability has some genetic basis (Rodgers *et al.*, 2001). If this is true, it is possible that a low desire for children, which until the advent of contraception would not have been an achievable desire, will now be subjected to strong negative selection. Over the very long term, fertility may start to rise again in countries that have undergone fertility decline as a low desire for children is selected out.

SUMMARY

Life history theory provides a useful theoretical tool with which to explore human reproduction.

Its use is being advocated by a number of behavioral ecologists and reproductive ecologists, but is only just being realized by traditional demographers. Despite its utility, practitioners have difficulties in explaining why humans have recently opted for low fertility beginning with the demographic transition in industrialized Europe. However, models that take into account the trade-offs inherent to human reproduction are beginning to explain this enigma.

Material Culture

Intermediate article

Ofer Bar-Yosef, University of Harvard, Cambridge, Massachusetts, USA

CONTENTS

The evolution of human material culture over the past 2.5 Ma, as seen through the archaeological windows of tool use, the controlled use of fire, and prehistoric art, provides interesting clues about the parallel evolution of human cognition as both a cause and an effect of these cultural changes.

USE OF TOOLS

Since research into human prehistory began in the nineteenth century, stone tools have been considered the marker of human activity. During the twentieth century, investigations of primate behavior, and particularly of chimpanzee behavior, modified this view. Observations of chimpanzees and orang-utans in their natural habitats revealed how they make simple vegetal artifacts for instant use. An exception is West African chimpanzees, which employ naturally-shaped hammer-stones and large cobbles to crack nuts.

Experimental study of the bonobo (pygmy chimpanzee) Kanzi demonstrated that apes are not capable of the same degree of precision as humans in tasks requiring hand dexterity. The physical limitations in hand movements explain why non-human primates do not systematically chip stones as humans do. This difference between humans and non-human primates has been expressed since about 2.5 Ma ago in the archeological record by the consistency of humans in making and shaping stone tools. Owing to the uneven preservation of objects in most Pliocene and Pleistocene sites, wooden items, which were probably employed by humans, have only rarely been discovered in contexts dated to the last 0.4 Ma.

The basic method of making a stone tool is to break a nodule ('core') of rock by hitting it with another rock ('hammer'), and then to use the sharp edges of the detached piece ('flake'). When the action is repeated, additional flakes are chipped off the core. During the last 2.5 Ma various techniques for obtaining blanks with sharp edges were developed. Some of these are named after the sites where they were first discovered.

Owing to the poor preservation of human-made or human-used wooden objects, research into prehistoric material elements concentrates, for most of the earlier periods, on the study of stone tools. This research includes the reconstruction of the process of the actions required for detaching blanks from a nodule, known as the 'operational sequence' (chaîne opératoire). Effectively, this means the sequence of events involved in making (knapping) stone tools from a particular raw material in the form of a nodule or cobble, through the initial phases of decortication (the removal of the natural cortex of the nodule), and the detachment of the first blanks obtained by direct (hammer) or indirect (hammer and chisel) percussion. Subsequent flaking often requires the knapper to reshape the volume of the core. Hence, the detachment of the blanks is interspersed with chipping aimed at maintaining the desired form of the core. The products of core reshaping are known as 'core-rejuvenation pieces' or 'core-trimming elements'. The optimal situation for the prehistorian who is attempting to trace the decisions of a knapper is when all or most of the pieces can be fitted together to recreate the original nodule. Of course, the final products that were taken from the site to be used cannot always be found in the excavated site, but the general sequence of the core reduction can be analyzed.

Chronology of Human Tool-making

Early prehistoric times are subdivided into three major periods within the Old Stone Age (Paleolithic): Lower, Middle and Upper Paleolithic; or Early, Middle and Late Stone Age in Africa. These periods were in common use before the introduction of radiometric dating techniques. Geological and archeological research of the Late Pliocene and the Quaternary resulted in the establishment of a simplified sequence of stone industries. Thus,

the view that stone tools are chronological markers for each Stone Age period is now obsolete.

The first type of stone tools, uncovered in the geological contexts dated to about 2.5 Ma near Lake Turkana in Kenya and the Afar basin in Ethiopia, are classified as a 'core-and-flake industry'. The debate over whether these early stone tools were produced by the hominins known as *Homo habilis* or by *Australopithecus robustus* remains unresolved, but most scholars regard the early toolkits in stratified sites of the Late Pliocene and Early Pleistocene as manufactured by members of the *Homo* evolutionary line.

Oldowan assemblages

Cores and detached flakes from the early sites have been classified and given names such as 'choppers' and 'core-scrapers', and are all incorporated under an entity named the 'Oldowan' culture, after the extensive excavations in Olduvai Gorge in Tanzania. The Oldowan assemblages also contain other tool types, such as the spheroids, which resemble stone balls. Except for those that attained a rounded shape by serving as hammer-stones, their function is generally unknown. Other types include flakes whose sharp edges were reshaped by direct percussion (a process known as 'retouching') to create a desired form. Certain kinds of retouch could have been the results of use.

The Acheulian Industrial Complex

The next improvement, which did not require a cognitive change, was the modification of the shape of a cobble or a large flake by chipping both faces to create what we call 'hand-axes' or bifaces. Bifaces are associated with an entity known as the 'Acheulian Industrial Complex'. They exist in a variety of forms, including some that are almond-shaped and pointed and some that are oval and rounded. U-shaped bifaces, with what is considered a straight cutting edge opposite the rounded base, are called 'cleavers'. The production of Acheulian bifaces continued for at least 1.5 Ma. Most of the later ones are highly symmetric, indicating increased attention to and investment in chipping both faces. The appearance of symmetrical forms may have marked a greater efficiency of what is considered an 'all-task tool' and an evolving level of awareness of esthetics.

Acheulian tools are found in Africa, Europe (except for its eastern part), western Asia, and India. Only a few assemblages of bifaces have been found in eastern Asia. These tools are often considered to be the product of *Homo erectus*, with their spatial distribution supposedly reflecting the dispersal of *Homo erectus* from Africa into Eurasia. The discovery of early hominins in Dmanisi, in Georgia, with an Oldowan-type ('core-and-flake') stone-tool assemblage, may indicate that early hominins were able to adapt to new environments without bifaces. Furthermore, this tool form was probably invented more than once in the course of the Pleistocene period.

Fossil hominins from the Middle Pleistocene (780 000 to 130 000 years ago) display a physical and morphological variability across Africa and Eurasia. In Africa, Acheulian assemblages were the dominant kind, while in Eurasia both core-and-flake industries (such as the Clactonian, or the assemblages of Zhoukoudian in northern China) and Acheulian toolkits were spread in an uneven geographical distribution. In the well-preserved contexts of lignite deposits currently being quarried in Schöningen in Germany, a series of wooden spears have been uncovered in a site that dates to about 400 000 years ago. Similar isolated finds from the latter part of the Middle Pleistocene are already known from Lheringen in Germany and from Clacton on Sea in the UK.

Among the notable populations that emerged in the second part of the Middle Pleistocene, but are better known from the Upper Pleistocene (130 000 to 11 000 years ago) are the Neanderthals and the Modern Humans. Molecular and nuclear genetic evidence acquired from today's world populations indicate that Modern Humans emerged in sub-Saharan Africa between 300 000 and 100 000 years ago. Some Modern Humans colonized Australia, beginning about 60 000 years ago. Others, known as Cro-Magnons, later moved across Europe – perhaps originating in the Nile valley or the Levant – splitting the territories of the Neanderthals, in a process that lasted from about 40 000 to 30 000 years ago. The Neanderthals, a native population of Europe, emerged at least 300 000 years ago, and expanded from the western provinces to beyond the Caspian Sea. They were well adapted to a variety of periglacial, temperate, and Mediterranean environments of Europe and western Asia.

The Levallois technique

All late Middle Pleistocene humans, from about 300 000 years ago, employed a variety of operational sequences for producing stone tools. The best known is the Levallois technique, which required a new cognitive model. In this stone-knapping technique, the volumetric concept of the nodule and the desired design were predetermined. The clear goal of obtaining a series of useable

blanks (whether we define these as flakes, blades or points) was required before commencing the process of blank detachment. In the Levallois technique the form of the core was usually relatively flat. A series of different preparatory flaking stages was required before the desired blanks were produced. This could be from one primary knapping direction, or from others (identified as 'convergent', 'bidirectional', and 'radial'). So the blanks, and the scars left after the removal of the cortex (the natural face of the nodule), disclose the method preferred by the knapper.

Some tool types, such as Levallois points (often hafted as spear points), were manufactured without the need for secondary retouch. The edges of other blanks were shaped by retouch, and their most common form is classified as side-scrapers. Subsequent resharpening altered the form of the cutting or scraping edges.

Among the Middle Palaeolithic industries, several geographical varieties of stone tools should be mentioned. In northern Africa, the 'Aterian' entity is characterized by tanged Levallois points and scrapers, as well as bifacial leaf-shaped points. Similar bifacial points have been found across Africa, without evidence for continuous geographic spread in Europe in archeological entities such as the Szeletian.

Middle Palaeolithic humans were also able to produce blades, which are defined as flakes whose length is more than twice their maximum width. Blades are considered the cultural hallmark of the Upper Paleolithic cultures, and *Homo sapiens sapiens* the manufacturer. Research in the last two decades has demonstrated that blades, which were generally produced from cores with a semicylindrical volume, were manufactured in different regions at different times. Given the constraints on how an artisan can knapp stone cobbles, it is not surprising to find that blades were made in eastern Africa and the Levant some 250 000 ago, in north-western Europe some 100 000 years ago (by Neanderthals), in southern African humans some 80 000 to 60 000 years ago (in an archaeological entity known as the Howieson's Poort), and then in proliferation since about 50 000 years ago in western Asia, northern Asia, the Indian subcontinent, and Europe. In most of southern Asia, the simple core-and-flake industries predominated, and were produced by Modern Humans.

Stylistic variability

The Upper Paleolithic or Late Stone Age is traditionally considered the time when Cro-Magnons, or Modern Humans, expanded across Eurasia and Africa. In Africa, the change in material culture appears to have been gradual. However, in Eurasia, except in south-eastern Asia, the acceleration in lithic techniques, art, and the use of body decorations during the Upper Paleolithic is clearly reflected in the cultural remains. One of the traditional characteristics of the Upper Paleolithic is the production of blades from nodules where, following the process of decortication, the volumetric concept motivates the knappers to achieve cores with a semicylindrical to fully cylindrical shape. Blades were detached from these cores either from one striking platform or from two opposing ones.

One distinctive attribute of the Upper Paleolithic (and later) stone tools is the regional and relatively rapid shifts (within a hundred or a few thousand years) in artifact design, interpreted as reflecting stylistic variability. There is evidence of long-distance exchange networks in lithics and other raw materials ranging over several hundred kilometers. Improved hunting tools were invented, such as spear-throwers, and eventually bows and arrows and boomerangs. There was clearer spatial organisation within natural habitations and hunting stations. Pit-houses were constructed in open-air sites. The design of natural shelters changed: careful excavations at well-preserved sites uncovered the locations of human activities (kitchen areas, sleeping grounds, knapping floors, butchering stations, and the like). Storage facilities, often underground, were constructed. Bone and antler artifacts that served for daily and ritual uses were systematically produced. Body decorations made from marine shells, animal teeth, and ivory were made. There emerged also mobile imagery (human and animal figurines), decorated and carved bone, antler, ivory and stone objects, and representational and abstract images and signs, either painted, engraved or both, in caves and rock-shelters, as well as on exposed outdoor rocky surfaces.

During the several millennia of the Terminal Pleistocene, when the retreat of the glaciers led to environmental improvements, human populations expanded over the entire globe. This is the time when the Americas were colonized by groups coming from Asia, carrying their original lithic technologies. Subsequent human dispersals into these continents, and adaptation to the new environments, led to the emergence of particular local methods for making stone tools, characterized by the production of bifacial points such as the Clovis, Folsom, and others.

In Eurasia and Africa, the variability of lithic types, and the dominance of microliths, are well recorded, except for south-eastern Asia, where the old core-and-flake industries were maintained until adzes, bone and shell tools began to be produced.

The Terminal Pleistocene and Early Holocene are also characterized by the establishment of societies of complex hunter–gatherers, forming a social arena for the emergence of agriculture in certain areas (south-western Asia and China).

Tools and Human Anatomy

The relationship between human anatomy and the production and use of stone tools is difficult to trace. The size and shape of thumb joints in robust australopithecines and early *Homo* suggest that these hominins had the ability to grip objects both firmly and precisely. These abilities may be adaptations that permit the systematic detachment of flakes from a cobble, which characterizes the oldest stone tools. Thus, the earliest stone tools may have been fabricated by more than one species. Experiments with the bonobo Kanzi have demonstrated that chimpanzees lack these skills: in nature, chimpanzees sometimes use unmodified stones for nut cracking, but they do not detach flakes from a nodule.

Later in human evolution there is more abundant evidence for tool use. Middle Paleolithic hominins, especially Neanderthals, have upper-arm asymmetries indicating a 'dominant arm', and heavily-muscled shoulder joints that indicate extensive tool use, possibly throwing heavy spears. In addition, some differences in hand grip have been observed between remains of roughly contemporary Neanderthals and early Modern Humans (the Qafzeh-Skhul group), in spite of the archeological evidence that both taxa fabricated and used similar tool assemblages.

Finally, technological changes in food production and processing technologies may be related to decreases in both facial size and tooth size, especially since the end of the Pleistocene.

Tools and Human Cognition

The formal classification of prehistoric stone objects expressing variability was originally intended to identify the relative chronology within the Late Pliocene and the Quaternary. When radiometric dating techniques were introduced, tool forms and how they were obtained became the subject of a search for meaning. Assuming that stone tools were used for purposes similar to those of metal tools in hunting, fishing, trapping, food preparation, carpentry, basketry, and the like, it was natural to suppose that the different forms were determined by their functions. However, numerous replications and microscopic examinations of stone tools by researchers in several countries suggest that, while there is a certain correlation between form and function, many forms can serve for the same or similar tasks. Hence, the study of style, as reflecting the mental process of the human actor, was reintroduced into prehistoric research. Style is thought to reflect formal variation and communication. Because of the lack of organic remains (except for bones, antlers, and horn-cores) prior to the later historical periods (except for rare cases of waterlogged sites in which organics are better preserved), most of the debate concerning the meaning of style focuses on stone tools.

Early hominins produced simple stone tools, and although they were regularly obtained from nodules of pebbles, they did not exhibit the kind of symmetry found in the bifaces dated to the Middle Pleistocene. Cognitive models seem to have first appeared, as mentioned above, with the Levallois technique, which required a predetermined design. Blanks were selected for use, and in particular for secondary retouch, which shapes the active edge. However, continuous resharpening often creates variable forms, not necessarily predicted by the original design. Although not a global practice, during the Upper Paleolithic, knapping blades produced blanks that were shaped by retouch into various forms, such as points, burins (used for a variety of tasks), scrapers, and borers.

Interestingly, during the closing millennia of the Pleistocene, people in many regions of the world began to manufacture small tools, known as 'microliths'. These were shaped from small blades and flakes, and the pointed forms among them were hafted as arrowheads and barbs.

Hence, style reflects the particular design preferred by a social entity. Style is therefore an important social marker. The shift in design, when suitability for function overrides style, is better expressed in the following Neolithic period. At that time, when farming communities established themselves in a few areas and dispersed across the world, tool types such as sickle blades, perforators, adzes, and axes expressed the specific functions of the human actors. Thus, the style of stone tools in the last 50 000 years carries the social message more clearly than in any preceding period.

CONTROLLED USE OF FIRE

In terms of human evolution, the intentional use of fire is regarded as improving the nutritional values of vegetal and animal foods, as well as having implications for social organization (e.g., a place for focal gatherings). A few archeologists believe that the evidence for the use of fire begins with *Homo erectus*, some 1.5 Ma ago; but archeological contexts do not demonstrate the presence of hearths before 500 000 years ago, even though we find burned bones.

A certain set of visible features is considered direct evidence for the intentional use of fire. These features are (from lower to upper): the reddened soil produced by heat from the fire; the black layer of partially-burned substances; and ashes, which are white in color if well preserved. Frequently, however, post-depositional processes, such as leaching by water and burrowing by animals and insects, destroy hearths. Laboratory techniques, including mineralogical analysis of thin sections of artificially-consolidated blocks of the prehistoric deposits, have proved useful in recognizing the use of fire by humans. This technique, known as micromorphological analysis, can also identify the mineralogical elements of the ashes long after they change color and contextual appearance, and identify those blackened bones that have been next to a fire, rather than stained by manganese.

Caves located in the Mediterranean climate areas (including southern Africa) contain ample evidence for the use of fire by humans. Hearths for heating, cooking, and parching were built by humans everywhere even before the Middle Paleolithic, and around most of the well-preserved hearths there is evidence for collecting firewood, represented by the remaining phytoliths. The consumption of cooked food influenced the masticatory system of humans, and it has been proposed that the reduction in tooth size is related to this.

ART

Works of prehistoric art are seen today as variable expressions of the minds of their producers, users, and viewers. The symbolism of the images, whether painted, engraved, incised or carved, conveys various meanings depending on the social unit and the time of their creation. Art objects may indicate the evolving self-awareness of humans and their intricate relationships with their own selves and the outside world. Therefore the search for the earliest art is considered crucial for our reconstruction of the evolution of human cognition, and is a controversial issue.

The earliest manifestations include objects like the incised Late Acheulian figurine from Berekhat Ram in the Levant, and a few objects from Mousterian contexts. There is no doubt that the full bloom of imagery expressions began, as with the systematic use of body decorations, during the early millennia of the Upper Paleolithic period, although not in every region of the world. The Franco-Cantabrian region is the most famous and the richest, but somewhat similar phenomena are found in other areas such as Australia.

European cave and rock imagery was discovered in the nineteenth century, and the history of its study is an eventful story which is still unfolding, and often triggers rival interpretations. Scholars agree that the variability of the subjects (from portable human figurines to animals and schematic signs) conveys a set of symbols that reflect the beliefs of ancient populations. The topics under debate essentially concern the identity of the makers or wall painters, their position within their own society, and the occasions of the production and use of objects and rock art as daily, seasonal, or annual events.

A schematic classification suggests that all symbolic expressions can be divided in terms of material and size into: elements of personal jewelry (made from bone, teeth, ivory, etc.); portable objects (made from bone, antler, ivory, terracotta, and hard rocks); engraved and incised slabs ('plaquettes'); and finally parietal images carved, incised and painted on cave walls and open-air rocky surfaces, which could be in a living area or rock-shelter, or in deep, dark caves and narrow passages.

Portable objects – including functional tools such as spear throwers, shaft straighteners, animal and human figurines, decorated pendants, and other small objects – are geographically spread across all regions. These objects probably served the people on a domestic, family or band level, reflected social alliances, and were probably passed on through generations. The images reflect beliefs in human and natural powers and spirits, including those of fertility, recorded information, ownership, and hunting magic.

The dominant subjects of the painted, engraved open-air rock surfaces and cave walls are the animals. The most common ones are those that inhabited temperate and Mediterranean Europe. They include deer, horse, bison, aurochs, mammoth, rhinoceros, and carnivores such as cave bear, brown bear, and felines, as well as fish (mainly on portable objects), tortoise, birds (swan,

duck and heron), rare plants, and humans (commonly represented by hands).

Since the first discovery of rock art in western Europe, attempts to establish the relationship between the dated archeological cultures and the images have been connected with various interpretations. These include: the uncommon view of 'art for art's sake'; totemism and sympathetic magic as derived from ethnographic parallels; and the binary-structuralist analysis, opposing the most common two animals in each cave site (e.g., bison and horse), as male and female symbols.

In recent years, the empiricist approach, based on correlations between ethnographic reports of the San in southern Africa, from the nineteenth and twentieth centuries, and the rich recorded images from local rock-shelters, have demonstrated the association between the rock art and the cosmology, symbols and rituals of San shamanism. Shamans performed their spiritual 'duties', sometimes in altered states of consciousness. The responsibility of prehistoric shamans, and probably of other prominent leaders of hunter–gatherer bands, in creating and modifying parietal art, is generally accepted.

The role of shamans today includes facilitating connections with the spiritual world among foragers. It is therefore suggested that comparisons between the activities of recent shamans (and other members of their society) and the preserved historical 'art' may help investigators to achieve a better understanding of Upper Paleolithic imagery and of later prehistory.

CONCLUSION

Studies of the development of human material culture produce a wealth of evidence concerning the evolution of human cognition, although direct interpretation of this evidence is fraught with difficulty and likely to remain so.

Social Learning in Animals

Intermediate article

Bennett G Galef Jr, McMaster University, Hamilton, Ontario, Canada

CONTENTS

'Social learning' is a general term referring to several behavioral processes that allow social interactions to bias what individuals learn. Processes involved in social learning include 'local enhancement', when the normal activities of one individual simply focus attention of others on a particular part of the environment with which they then interact, and 'teaching', when a model changes its own behavior to facilitate learning by naive individuals.

INTRODUCTION

Understanding the behavioral processes that promote diffusion of behavioral traditions through animal populations, and comparing these processes with those that support culture in human societies, suggests important similarities as well as important differences in the processes that support social learning in humans and animals. This article discusses a variety of such social learning processes that are common to both humans and animals, and two of these processes, namely imitation and teaching, that may be used only by humans and their closest relatives.

WHAT IS SOCIAL LEARNING?

Understanding the role of behavior in promoting survival and reproduction is a goal of life scientists working in a variety of disciplines. Students of animal social learning are particularly interested in the question of how interactions among members of a species affect development of their behavioral repertoires. Social learning is only one of several factors that interact to influence behavioral development. For example, ethologists studied instinctive patterns of behavior produced by natural selection acting on heritable variation, whereas students of animal learning were and are interested in how individual experience of events in the physical environment shapes behavior.

EXAMPLES OF SOCIAL LEARNING

Contemporary interest in social learning arose from the observation that members of one free-living population of a species often behaved quite differently to members of other populations of the same species. For example, chimpanzees living to the west, but not to the east, of the Sassandra-N'Zo river on the Ivory Coast use stones to crack nuts (Whiten *et al*., 1999). Of course, population-specific behaviors such as nut cracking could reflect differences in either the genetic substrate of populations (i.e., different subspecies of chimpanzee might inhabit the two banks of the Sassandra-N'Zo river) or differences in the physical environments in which the two populations live (e.g., there might be no nuts on the east bank of the river). In fact, there are no known genetic differences between chimpanzees on the two banks of the Sassandra-N'Zo, and similar nuts and stones are found in both places.

The nut-cracking example is not unique. There are often systematic differences in the behavior of populations of a species even when there is no evidence of genetic or environmental differences between populations (Whiten *et al*., 1999). For example, chimpanzees living in Gombe National Park in Tanzania use twigs or blades of grass to feed on ants and termites. These implements are used to probe the passageways of insect mounds, and when the residents attack an intruding probe, the chimpanzees extract the probe and eat any termites that are clinging to it.

There is variation among chimpanzee populations not only in the species of insect preyed upon and the materials used as probes, but also in how probes are prepared for fishing and how insects are captured. For example, chimps at Gombe in Tanzania hold a long stick in one hand and use the other hand to wipe a ball of ants into their mouths. Chimps living in the Tai Forest on the Ivory Coast use a short stick to collect ants, and they place the

stick directly into their mouths, removing the ants with their lips and tongue. Chimpanzees at Assirik in Senegal usually peel bark from twigs before using them as probes, whereas chimpanzees at Gombe do not peel the twigs before using them. Such observations have led many scientists to conclude that at least some population-specific behaviors of chimpanzees are traditions learned by one individual as a result of observing the behavior of another individual (McGrew, 1992; Whiten *et al*., 1999).

It has been known for many years that some animals can learn complex patterns of behavior by imitating others of their species. 'Imitation' is a special type of social learning that has been defined in different ways by different scientists. For example, imitation has been defined both as 'copying of a novel or otherwise improbable act' (Thorpe, 1956) and as 'learning to do an act from seeing it done' (Thorndike, 1898). An example of the former is to be found in the songs that adult male songbirds produce both to attract conspecific females and to repel conspecific males. Males from different populations of many species produce different variants of a basic, species-typical song, and laboratory studies have shown that a 'song dialect' is produced only by males that, as juveniles, heard adults of their species sing that dialect (Marler, 1970).

Thus we know both that even birds (with their relatively small brains) can learn song dialects by imitation, and that chimpanzees from different populations engage in different feeding behaviors. Why should we not simply conclude that if a difference in the behavior of two groups of chimpanzees cannot be explained easily by reference to differences in either their genes or their ecology, the different behaviors have been transmitted by imitation among chimpanzees within each group?

Although birds learn their songs by imitation, as we shall see below, this may be a special case. More often, when a possible instance of learning by imitation observed in natural circumstances is brought into the behavioral laboratory for analysis, it is found that the learning depends on some social learning process that is not truly imitative. For example, rats living in the pine forests of Israel are unique in that they, and no other rats, survive by stripping the scales from pine cones and eating the pine seeds that the scales protect (Aisner and Terkel, 1992). It is difficult for rats to strip pine-cones in a way that allows them to get more energy from the pine seeds than is consumed in obtaining them. The rats must start by removing the scales from the base of a cone, and then take advantage of the cone's architecture by removing the remaining scales in a spiral from the base of the cone to its apex. A more direct method, which involves gnawing through individual scales to access seeds, is used by rats from populations that do not typically feed on pine-cones if given access to them. However, this method consumes more energy than it produces.

In the laboratory, rats born to pine-cone-stripping mothers grew to strip pine-cones in the efficient manner only if they were reared by adult rats that demonstrated pine-cone stripping, and not if they were foster-reared by adult rats that did not know how to open cones efficiently. Furthermore, even young rats reared by adults that did not know how to strip pine-cones became efficient strippers of seeds when provided with cones started appropriately by either an adult rat, or a human using a pair of pliers to remove scales from the base of the cones. Apparently, interaction with cones started in the right way guides the development of behavior in young black rats, making them efficient strippers of seeds from pine-cones. In nature, young rats probably snatch partially opened cones from adults, and by interacting with the cones learn how to finish the job.

The study of social learning in Israeli rats has yielded two important findings. First, complex motor patterns can be transmitted from one generation of animals to another. Second, the existence of a complex tradition of behavior in a population of animals cannot be used to infer that a complex social learning process, such as imitation or teaching, was involved in its transmission.

CLASSIFYING SOCIAL LEARNING

Some authors have suggested that describing a behavior as traditional is totally uninformative unless the spread of the behavior through a population can be attributed to a particular social learning process. This is almost certainly an overstatement. Referring to a behavior as traditional implies that the spread of that behavior through a population was facilitated by social interactions (i.e., that each group member did not learn the behavior independently). Still, the assertion that describing a behavior as traditional is uninformative raises an important issue. As we have already seen in the cases of bird-song learning and pine-cone stripping, animals may influence one another's behavior in quite different ways. Consequently, for those with an interest in understanding how behaviors develop, describing a population-specific behavior as traditional answers relatively few questions and raises many.

While almost everyone seems to find instances of traditional behavior in animals intrinsically interesting, many outsiders to the field of social learning find attempts to categorize the many ways in which social interactions affect the acquisition of behavior either boring or impenetrable. Admittedly, attempts to define various social learning processes have produced quite complex and not altogether satisfactory vocabularies describing the many ways in which social interactions can bias behavioral development (Whiten and Ham, 1992). However, such attempts at categorization are important because they make explicit the fact that social learning can occur in many different ways in both humans and other animals.

One rather simple way in which one animal can bias development of the behavior of others, thereby facilitating spread of the behavior through a population, is by focusing the attention of others on particular parts of the environment. For example, if one Norway rat sees others eating in a particular place, or smells rat odors left at a potential feeding site by other rats that have eaten there, that rat is much more likely to begin eating whatever food is at the socially marked site than to start eating at unmarked sites where different foods might be available. Because wild Norway rats are extremely reluctant to eat unfamiliar foods, anything that causes a rat to begin eating one food rather than another has a profound effect on the rat's subsequent food choices.

Such social biasing of learning by other individuals has been termed 'local enhancement', defined as 'apparent imitation resulting from directing the animal's attention to a particular object or to a particular part of the environment' (Thorpe, 1956). Local enhancement can be contrasted with imitation, defined as 'copying of a novel or otherwise improbable act' (Thorpe, 1956) or 'learning to do an act through seeing it done' (Thorndike, 1898).

In local enhancement, an animal learns only that it should interact with one part of the environment rather than with another. In true imitation, an animal learns directly about the behavior in which it should engage. The distinction is fundamental to all academic discussions of social learning in animals.

Are two terms – local enhancement and imitation – sufficient to enable discussion of all animal social learning? Unfortunately this is not the case. Humans and other animals can learn from the behavior of others, either directly or indirectly, in more than one way. For example, if a chimpanzee watches another of its species use a rake to pull in food items that would otherwise be out of reach, the observing chimp learns to use the rake to pull in food faster than it would if it had never seen another chimp use a rake (Tomasello *et al*., 1987). However, observer chimps failed to imitate in the sense of copying the particular actions used by the demonstrator to obtain food. Rather, observers developed their own techniques for using the rake. Observers seemed to learn that a rake was useful for acquiring food, but did not learn much about the actual behavior that a model uses when raking and, as noted above, what is meant by imitation is 'learning to do an act'. Tomasello *et al*. (1987) proposed that the observers were not so much copying the model's behavior as attempting to create the results of the model's efforts, a process that they termed 'emulation.'

Finally, consider teaching, an activity which contributes to social learning and that is common in our own species. In local enhancement, imitation or emulation, the model is essentially passive. The observer extracts information from a model engaged in activities it performs without reference to the observer. In teaching, according to the most widely used current definition (Caro and Hauser, 1992), a model modifies its behavior in the presence of a pupil, often leading to some reduction in the efficiency of the model's performance. Furthermore, the model either encourages or punishes the pupil, or provides the pupil with examples of behavior or experiences so that the pupil acquires information or skill more rapidly than it otherwise would.

The important elements of this somewhat complex definition, distinguishing teaching from other activities that play a part in social learning, involve potentially costly modification of the teacher's normal behavior, resulting in accelerated learning by pupils. Surprisingly, given the importance of teaching (at least in modern Western societies), there are few plausible examples of teaching in the animal world, and even those few instances are hotly debated. Feline mothers may meet the definition by delaying their killing and eating of prey and providing their young with incapacitated, live prey on which to practice predatory behavior. However, there is contradictory evidence as to whether experience with incapacitated prey facilitates the development of hunting behavior in young cats. Some authors have suggested that killer whales teach their young to hunt seals, although this view is not generally accepted (Rendell and Whitehead, 2001). Chimpanzees may teach juveniles how to crack open nuts using a stone hammer and anvil (Boesch, 1991).

It is worth quoting verbatim Boesch's (1991) descriptions of one such instance, as they provide

a fine indication of both the strengths and the weaknesses of unusual field observations. Ricci's 5-year-old daughter Nina is trying without success to crack open nuts using an irregularly shaped hammer. Ricci joins Nina, and Nina gives the hammer to Ricci.

> Then with Nina seated in front of her, Ricci, in a very deliberate manner, slowly rotated the hammer into the best position with which to pound the nut effectively. As if to emphasize the meaning of this movement, it took a full minute to perform this simple rotation. (Boesch, 1991, p. 532)

Ricci then cracks 10 nuts with the hammer in the correct position, and leaves. Nina then picks up the hammer, adopts the same grip that her mother used to crack nuts successfully, and she opens four nuts in 15 minutes. According to Boesch:

> In this example, the mother corrected an error in her daughter's behaviour and Nina seemingly understood this perfectly, since she continued to maintain the grip demonstrated to her. (Boesch, 1991, p. 532)

Some authors accept Boesch's interpretation of his observations, while others do not. The fact that such complex interactions between an apparent pupil and teacher have been seen only twice in many years of field study surely makes them difficult to interpret with certainty. Indeed the issue of whether animals teach is only one of a number of questions that are being actively debated by researchers who are interested in social learning in animals.

DISPUTES ABOUT SOCIAL LEARNING

For more than a century, two central questions have motivated much of the research on social learning in animals.

1. Which non-human animals, if any, imitate?
2. What is imitation and how can it best be distinguished empirically from other forms of social learning, such as local enhancement?

Can Animals Imitate?

The discovery over decades that many different types of social learning can bias behavioral development has made it increasingly difficult to determine whether any given case of social learning is a product of true imitation or of some other less cognitively demanding process. Why should anyone care enough about the types of social learning that animals employ when using one another as sources of information about the environment to actually argue about it? Many believe that understanding similarities and differences in social learning processes in humans and other animals will provide insight into similarities and differences in their mental processes. Indeed, the first laboratory investigations of social learning in animals were undertaken in order to determine whether, like humans, non-human animals had access to mental representations that they could manipulate in order to solve problems (Thorndike, 1898).

To imitate the behavior of a model, an imitator must store a visual image of the model's behavior and then match its motor output to that stored representation. Earlier we considered the learning by birds of song dialect as a result of hearing the song of adults belonging to their social group. Such learning might be described as 'learning to sing a song from hearing it sung'. This is somewhat different from 'learning to do an act from seeing it done', which some hold to be the definition of imitation.

Why should a distinction be made between seeing and hearing when defining imitation? The task of learning to sing a song by listening may be far simpler than that of learning to do an act by seeing it. In order to learn to sing like another, all the singer needs to do is to match the sounds it produces when singing with a stored representation of the sound of the song of another. Thus song imitation can occur within a single modality, namely audition. On the other hand, when learning to perform an act by seeing it done, a match has to be made across modalities, between a stored representation of a visual stimulus (the sight of another performing a behavior) and kinesthetic feedback from a motor act. Such cross-modality matching is necessary because even if an observer perfectly imitates an act performed by a model, the visual input to the observer while imitating is quite different to the visual input that the observer received when observing the model perform the act. For example, when I see someone bow, what I see is very different from what I see when I bow myself. On the other hand, when I whistle a song, what I hear is very similar to what I heard when someone else whistled the same song (Heyes, 2001). So when we are discussing imitation in animals, should we be limited to instances where overt motor patterns are copied, or should we include bird-song learning? Most authors think that we should not include bird-song learning.

There is even controversy about whether, in order for a behavior to be considered a result of imitation, the imitated behavior has to be new to the imitator and, if so, how one knows whether a motor pattern is really new. With regard to the first

point, how can you tell if an individual has learned to perform an act by seeing it done, if it has previously performed the act? With regard to the second, an individual may never have used a rake to pull in food before, but it has grasped objects, used objects to move other objects about, sought food, etc. An apparently novel act may be nothing more than a combination of acts that are already in an individual's repertoire. Perhaps all a subject does when it imitates a familiar act is to use the behavior of another as a cue as to which elements of its own behavioral repertoire it should try in the situation that it now faces. If you are interested in imitation as a tool for exploring the cognitive capacities of animals, then cases in which observers simply use others' actions to cue their own behavior are not very informative.

What is the Best Empirical Method for Discovering Imitation?

For many decades the predominant strategy for demonstrating imitation learning was first to determine whether watching the performance of a task allowed observers to learn to perform that task faster than animals that did not have the observational experience, and then by conducting additional experiments, to attempt to exclude all explanations of the accelerated performance other than imitation. As the number of alternative social learning processes described by scientists increased, the strategy of excluding alternatives became increasingly cumbersome. For example, if kittens are allowed to watch a demonstrator cat press a lever to obtain food, they subsequently learn to press the lever faster than kittens that do not see a cat receiving rewards for pressing the lever. To determine whether this accelerated acquisition of lever pressing was due to imitation of the cat by the kittens, one would have to exclude, among other things, the possibility that lever pressing is facilitated by either local enhancement of the lever or observing others eat. In general, such attempts have produced no convincing evidence of imitation learning in any animal.

At present, the 'two-action method' is the preferred laboratory procedure for discovering imitation in animals. In the two-action method, each subject sees a demonstrator receive rewards for manipulating an object in one of two ways. The observer is then given access to the object, and it is determined whether observers tend to manipulate the object in the same way as the demonstrator did. For example, chimpanzees first watch a human demonstrator either pull or twist bolts in order to open a closed box containing fruit, and they are then given a closed box. The most recent evidence suggests that chimpanzees tend to use the same action that they saw demonstrated to open the box (Whiten, 1998). Surprisingly, the two-action method has also produced evidence of apparent imitation in Japanese quail, starlings, pigeons, grackles, and budgies (Heyes, 2001), although other methods for demonstrating imitation have not provided evidence of the latter, even in animals as sophisticated as monkeys (Visalberghi and Fragaszy, 2002).

Perhaps more fundamentally, there is even a question as to whether evidence gathered in the field or evidence collected in the laboratory is more suitable for determining whether members of a species can imitate. Laboratory workers feel that the social learning mechanisms responsible for apparent imitation of one animal by another can be analyzed satisfactorily only in the controlled environment of the laboratory. However, some field workers suggest that the sterile environment and abnormal social conditions of the laboratory result in systematic underestimation of the imitative abilities of complex animals such as chimpanzees (McGrew, 1992).

Just How Important is Social Learning to Animals?

Recently, several students of animal behavior have argued in book-length monographs that social learning is central to the development of adaptive behavioral repertoires in a variety of animals (Avital and Jablonka, 2000; Dugatkin, 2000). These authors argue that social learning and natural selection are practically co-equals in producing adaptive behavior in animals, and that social learning of one type or another is necessary for animals to maximize everything from selection of a mate to avoidance of potential predators. Although social learning has been demonstrated to play some role in the mate choices of guppies and quail, and in the avoidance of predators by blackbirds and monkeys, claims of a major role for social learning in the evolution of behavior are relatively recent, and have yet to be evaluated. Still, the issue of just how important social learning is to understanding animal behavior is an open one, and is sure to be contentious.

THE ROOTS OF CULTURE

An intense area of debate concerns the degree of similarity between 'traditions' of animals and

'cultures' of humans. As is often the case in discussions of the relationship between human and non-human animals, some authors emphasize apparent similarities and others highlight apparent differences. The former group suggests, for example, that if an anthropologist were to describe populations of humans whose technologies and social customs varied as much as do those of well-studied populations of free-living chimpanzees (Whiten *et al*., 1999), the anthropologist would surely refer to the human populations as having different cultures. Therefore it is foolish to deny culture to chimpanzees (McGrew, 1992).

Those in the opposing camp look at the same data and focus on apparent differences between chimpanzee and human social learning. They argue that differences in the behavioral repertoires of various groups of chimpanzees tell us nothing about the processes responsible for the development of those differences. Moreover, if you are interested in discovering true precursors of human culture, you should look for behaviors that are transmitted from one generation to the next by the same processes that support human cultures (Galef, 1992). Humans can teach one another; they do learn by imitation. As we have seen, generally animals do not teach, and they rarely learn by imitation. Consequently, most instances of human culture and animal tradition may depend on rather different behavioral processes.

The type of culture that animals which do not teach or imitate could produce would be severely restricted. In human cultures, techniques or behaviors often become increasingly complex over generations. Youngsters learn from elders what the elders know. The young can then spend a lifetime improving on what they have learned socially, and then transmit those improvements as the starting point for the next generation. Such 'ratcheting' can occur only if social transmission involves learning directly about behavior, as in imitation or teaching, not when social transmission involves changes in attention to environmental stimuli, as in local enhancement or emulation.

A local enhancer only increases attention to some aspect of the environment. A model for emulation merely indicates that a tool can be used to achieve a goal. Consequently, in each generation, naive individuals whose learning was shaped by local enhancement or emulation must learn for themselves how to behave with respect to the part of the environment to which their attention was directed, and no ratcheting across generations can occur.

The argument goes on. Many, perhaps the majority, of those who study apes in their natural environments are convinced that these animals exhibit something quite similar to human culture. Many, perhaps the majority, of those who study social learning processes in animals in the laboratory believe that the differences between human culture and animal tradition are sufficiently great to require different terms to describe them. They often want to restrict use of the term 'culture' to humans, and to refer to 'animal traditions' when discussing population-specific behaviors of non-human animals.

Is There Anything Worth Arguing About?

At first glance, such arguments over terminology may seem arcane or even useless. However, our language both reflects and influences the way in which we think about the natural world. Those who believe that it is appropriate to discuss 'culture' in animals generally differ from those who prefer to talk about 'animal traditions' in their views of how similar the behavioral and mental capacities of human and non-human animals may be.

Understanding how we humans both resemble and differ from other animals is neither arcane nor useless. It is a basic part of our effort to discover what we are as a species, and to define the ways (if any) in which we are unique among animals. Thus unraveling the processes involved in social learning in animals, whether they are living free in their natural habitat or maintained in the more restricted laboratory environment, is but one of many ways available to us to increase our understanding both of ourselves and of our place in nature.

Sociobiology

Intermediate article

Ullica Segerstråle, Illinois Institute of Technology, Chicago, Illinois, USA

CONTENTS

Sociobiology, the study of animal social behavior, is represented by a number of approaches, and scientists who practice sociobiology may call themselves by other names. Central sociobiological ideas include inclusive fitness, kin selection, the gene's eye view, reciprocal altruism and mutualism, and game theory.

INTRODUCTION

Sociobiology is part of modern evolutionary biology. It is concerned with explaining such things as the evolution of altruistic behavior, the regulation of animal conflict, and the differences in male and female 'strategies' (unconscious behavior patterns). The reasoning in sociobiology can often be expressed exactly in the mathematical language of population genetics and tends to be of a game-theoretical nature.

A central concept is that of 'inclusive fitness' associated with William D. Hamilton (1964). This concept explains why from a 'gene's eye' point of view it can make sense for an animal to behave altruistically towards others (who are typically relatives). Altruism is here defined in a behavioristic way, strictly focusing on the outcome of a behavior, not ascribing conscious motives. An altruistic act is an act where the donor incurs a considerable cost while helping a beneficiary. The ideas behind sociobiology were popularized by Edward O. Wilson (1975) in *Sociobiology: The New Synthesis* and Richard Dawkins (1976) in *The Selfish Gene*.

The Varieties of Sociobiology

There are important differences between the types of sociobiology introduced by Wilson and Dawkins. In his book Wilson defines sociobiology as 'the scientific study of the biological basis of social behavior in all kinds of organisms including man' and presents a broad synthesis of existing theories and research, including ecological considerations. His aim is to establish a new comprehensive discipline of comparative study of behavior. Dawkins's focus in *The Selfish Gene* is much narrower. He is firmly grounded in the population genetic tradition and limits himself to explicating the mechanisms of evolution in the light of the new ideas of Hamilton, George Williams, Robert Trivers, and John Maynard Smith, using a novel 'gene's eye' view of evolution. Wilson presents altruism as the central problem of sociobiology, but Hamilton's theory is introduced together with a number of group selectionist models. Dawkins limits himself to animals, but Wilson extends sociobiology to include the human species.

Currently the term 'sociobiology' is used to refer to a number of different things: (1) Wilson's view of sociobiology as a broad, comparative discipline, (2) the more narrow focus on a gene selectionist explanation of evolutionary mechanisms associated with the theorists presented by Dawkins, (3) a new version of sociobiology seen as a co-evolutionary process between genes, mind, and culture introduced by Wilson and Charles Lumsden in 1981, and (4) popular theorizing about human behavior. Scientific research in sociobiology often goes under the name 'behavioral ecology' or 'functional ethology'. Human sociobiology is often called 'evolutionary psychology' or 'Darwinian anthropology'.

SOCIOBIOLOGY'S ORIGINS AND ANTECEDENTS

At the time of Wilson's synthesis, the term 'sociobiology' was already in use in a division of the Animal Behavior Society led by John Paul Scott and others. Important earlier synthesizers in the field of animal ecology were Warder C. Allee and

Alfred E. Emerson (1949). The idea of comparative study of animal societies, again, goes back at least to the early nineteenth-century Swiss entomologist Pierre Huber. The most important antecedents of sociobiology are to be found in ethology on the one hand and the Neo-Darwinist or Modern Synthesis on the other.

Sociobiology and Ethology

Ethology, the study of animal behavior in natural environments, comes from the tradition of Konrad Lorenz and Niko Tinbergen. Ethology asks questions not only about function (adaptive value) but also phylogeny (evolutionary origin), ontogeny (development), and mechanism (proximate cause) of a behavior (Tinbergen, 1963). Sociobiology focuses on ultimate, genetic explanations. Many see sociobiology as 'functional ethology'. Wilson, in contrast, regards ethology as a subfield of the more encompassing discipline of sociobiology.

The Modern Synthesis

The Neo-Darwinian or Modern Synthesis, taking place between 1920 and 1950, aimed at integrating the various fields of biology within a common framework of mathematical population genetics, where evolution was expressed as the change of gene frequencies in a population. This international endeavor happened in two major steps: first the unification of Mendelian genetics with Darwinism, and second the extension of the synthesis to the rest of biology.

The problem of the seeming incompatibility between Darwinism and Mendelism was solved when it could be shown that continuous Darwinian variation could be expressed mathematically in particulate form, and that mutations were typically small and could serve as needed 'raw material' for evolution. The scientists making this first step, who worked out the translation of the various evolutionary forces into the new language of population genetics in the 1920s and 1930s, were Ronald A. Fisher and J. B. S. Haldane in the United Kingdom and Sewall Wright in the United States. Prominent architects of the second step of the synthesis were Theodosius Dobzhansky, Ernst Mayr, Julian Huxley, George Gaylord Simpson, Ledyard Stebbins, Bernard Rensch, and S. S. Chetverikov, who demonstrated that fields such as systematics, paleontology, and botany were compatible with Neo-Darwinist assumptions. Embryology (developmental biology), physiology, and morphology, however, still remained outside the synthesis. The extension of the synthesis to behavior came in the 1960s with Hamilton.

There were already conflicting views of the meaning of the Modern Synthesis among the original architects: there was a population genetic and a more holistic view. The former regarded the synthesis as completed following the work of the population geneticists. This opposition was later reflected in Dawkins's and Wilson's different conceptions of sociobiology. Harvard's Ernst Mayr (1963, chap. 10) set the tone for the 'holists' by dismissing what he called 'beanbag genetics' in favor of 'the unity of the genotype'. The resistance to talking about genes as if they were freely moving beans in a bag was to continue in the next generation with holistically oriented critics of sociobiology, such as Stephen J. Gould, Richard C. Lewontin, and Niles Eldredge.

INCLUSIVE FITNESS

Inclusive fitness is the key concept in sociobiology. The idea of inclusive fitness solves the long-standing mystery of how it is possible for altruistic behavior to evolve. It was this concept that Hamilton developed mathematically in his trailblazing 1964 paper, 'The genetical evolution of social behaviour'. Inclusive fitness has been typically used to formalize the reasoning about natural selection in kin groups (kin selection), but Hamilton himself intended that the concept have a broader application (see below).

Hamilton's Rule

Altruistic behavior can be favored by natural selection if the donor and recipient share a sufficient number of genes. Therefore, by helping relatives, an individual is actually helping the survival and propagation of its own genes (including the gene that promotes altruism). The coefficient of relatedness between relatives can be exactly calculated for various relationships. It is, for instance, ½ between siblings, ½ between parent and offspring, and ⅛ between first cousins.

'Hamilton's rule' (Hamilton, 1963) postulates that altruism can evolve if the reduction in fitness (number of offspring) of the donor is more than made up for by the increased fitness (number of offspring) of the recipient. It is simply expressed in the formula $k > 1/r$, where k is the cost–benefit ratio of the behavior, and r is the coefficient of relatedness between two individuals.

Technically, inclusive fitness of an organism is rather complicated to measure. It is typically

measured as the organism's own fitness plus the effect of its behavior on its relatives' reproduction minus its relatives' effect on its own reproduction, multiplied by its genetic relatedness to each related organism (Dawkins, 1982, chap. 10; Grafen, 1982)

The Case of the Social Insects

An illustration of the principle of inclusive fitness is the evolution of social behavior in *Hymenoptera* (bees, ants, and wasps). Here female workers are sterile and help raise their sister's (the queen's) offspring instead of their own. This makes evolutionary sense because of the unusual coefficients of relationship in a haplodiploid species like *Hymenoptera*. Here the female workers are related more closely to their sister, the queen, than to their own (potential) daughters.

The females are diploid, having two sets of chromosomes (they come from the queen's fertilized eggs). One of them will later become a queen. The males (drones) are haploid, having only one set of chromosomes (they come from the queen's unfertilized eggs). In diploid species for two sisters on average half of the mother's genes and half of the father's are the same. In haplodiploid *Hymenoptera* the haploid father (a drone) has only one set of genes to transmit. As a result, *Hymenoptera* sisters end up sharing three quarters of their genes. Meanwhile each sister's relationship to any potential daughter would be only the standard one-half. It therefore 'pays' for a female worker to forego reproduction and help raise her queen sister's offspring instead.

Expanding Inclusive Fitness

Hamilton intended 'inclusive fitness' to be a broader concept than 'kin selection', 'group selection' or even 'reciprocal altruism'. The basic requirement for inclusive fitness is that the benefits of altruism fall on individuals who are likely to be altruist rather than on random members of the population. These may be relatives (kin selection) but do not have to be. Altruists may live with altruists simply because they have never parted, or because they are able to recognize fellow altruists (what Dawkins has called 'the green beard effect'), or even because of some pleiotropic effect of the gene on habitat preference. This is why Hamilton later recommended a flexible use of terms, depending on the actual case: kin selection, group selection, kin-group selection, low migration, assortation, or other alternatives, as appropriate (Hamilton, 1975).

KIN SELECTION

Kin selection is often the way in which inclusive fitness has been understood in practice: as natural selection acting on the family or kin group instead of the individual. The case of *Hymenoptera* is a good example of kin selection. Another example is the assistance that group-living animals (flocks, herds) give one another.

Kin Selection and Group Selection

'Kin selection', Maynard Smith's (1964) term for the process of inclusive fitness maximization, is often contrasted with the idea of 'group selection', natural selection working on groups rather than individuals. Group selection was an earlier explanation for animal altruism, where individuals were seen as sacrificing themselves for 'the good of the species' or group. The Scottish zoologist Vero Wynne-Edwards (1962) was the first to explicate the possible mechanisms involved. Many evolutionists believe group selection is unlikely in nature. The problem is how altruism might initially arise in a group of individuals with regular, selfish genes, without individuals possessing mutant, altruistic genes getting outreproduced. Some evolutionists, however, consider group selection a real phenomenon in nature, among others E. O. Wilson. Elliott Sober, and David Sloan Wilson (1998) have reintroduced group selection as 'trait group' selection, invoking Price (1972) and Hamilton (1975).

Kin Selection in Practice

Early critics of kin selection wondered how a gene can calculate coefficients of relationships and make cost–benefit analyses (e.g. Sahlins, 1976). The answer lies in the existence of (subconscious) behavioral rules. Individuals act as if they are following such rules (Dawkins, 1979). A rule of this type for a bird might be: feed gaping mouths in your nest! This rule may not be specific enough to identify a cuckoo chick. Another perceived problem was kin recognition. Later research has shown that various kin recognition mechanisms do exist, such as smell (Fletcher and Michener, 1987).

THE GENE'S EYE VIEW

Inclusive fitness and other theories in sociobiology are often best understood by taking a 'gene's eye' view. This means regarding a gene causing an individual to behave in a particular way as a strategist interested in its own survival and

propagation. This view is associated with William Hamilton (1963), George Williams (1966), and Richard Dawkins (1976). According to Hamilton (1963), if there is a gene G that causes its carrier to act in an altruistic way, 'the ultimate criterion which determines whether G will spread is not whether the behaviour is to the benefit of the behaver, but whether it is to the benefit of the gene G'. Williams (1966) introduced the gene-selectionist approach as a methodological device, famously suggesting that in evolutionary explanation no higher level than necessary be invoked. Dawkins showed the fruitfulness of the new approach with imaginative explications of 'the selfish gene' causing its carrier to behave in ways that promote its own interest, including acting altruistically towards relatives carrying copies of itself.

The Gene's Eye View as a Tool for Thinking

The gene's eye view is a particularly useful tool when it comes to thinking about behavioral strategies (that is, behavioral patterns) adopted by interacting animals. An example is mating strategies. Depending on what type of body the gene is in (male or female), a gene will cause its vehicle to adopt a different strategy depending on the particular investment its carrier has in its offspring. A male typically invests little beyond the act of mating itself, while the female invests a lot. For a male it is often advantageous to mate with as many females as possible to maximize reproductive success. For a female, in contrast, it pays to be choosy, finding the best father for her offspring and making him help rear it. This argument was developed in detail by Robert Trivers (1972) in his paper on parental investment, drawing on Darwin's theory of sexual selection.

Replicators and Vehicles

Some early critics of the selfish gene idea believed that the gene was now claimed to be the true unit of selection (e.g. Gould, 1977; Wright, 1980) and protested loudly that other levels of selection existed. Dawkins, in response, made an important distinction between 'replicators' and 'vehicles' (Dawkins, 1978). A replicator needs to last long enough to produce additional replicators which retain their structure largely intact; it needs to possess the characteristics of 'longevity, fidelity, and fecundity'. A gene fulfills these criteria, making it a replicator. In contrast, individual organisms, groups, and so on are not replicators but vehicles.

Dawkins's argument was a logical one about the workings of evolution, not a factual statement about the vehicles that actually exist in nature. This misunderstanding was to persist throughout the so-called sociobiology debate. Dawkins emphasized (1982) that a gene could physically be any piece of DNA – as long as it was small or stable enough to have a 'frequency' that could be changed by natural selection. He also noted that genes are selected for their capacity to cooperate and that we call the result of this cooperation 'an organism'. However, the cooperation may not be perfect, as indicated by free rider effects and other phenomena.

RECIPROCAL ALTRUISM

Reciprocal altruism is altruism that occurs between unrelated individuals when there will be repayment (or at least promise of repayment) of the altruistic act in the future, and where the cost incurred by the altruist is smaller than the benefit of the beneficiary (Trivers, 1971). This principle of 'I'll scratch your back, you'll scratch mine' can be found in many bird and mammal species, where individuals clean one another of pests. Another example is blood-sharing in vampire bats. A successful vampire bat will share the blood it has swallowed during the night with less fortunate fellow bats. Later on, the recipients repay the favor. Further, animals (e.g. chimpanzees) may form alliances and coalitions with nonrelatives. An animal offering help can expect assistance itself in the future. Reciprocal altruism is an example of game theory (see below) where two (all) parties cooperate and both (all) can win.

Mutual assistance between members of different species is called 'mutualism' or 'symbiosis'. Here both parties derive an immediate benefit. An example is the lichen, a symbiosis between a fungus and green algae. Another is the aphids (greenfly) kept as 'milk cows' by ants. The aphids process plant juice, which the ants then 'milk' from them, while protecting the aphids and their offspring in return. Finally, there are the cleaner fish which get food by cleaning the mouths and gills of larger fish, which in turn refrain from eating them.

One perceived problem is that of individual animals recognizing each other later. This in fact often happens. Another problem is cheating: taking advantage of a benefit offered but not paying back. Trivers (1971) suggested that many human psychological characteristics may have evolved for us to be able to cheat, to detect cheaters, and, if cheating, to avoid being detected. The idea of cheater

detection has become one of the cornerstones of evolutionary psychology.

GAME THEORY

The basis for much sociobiological reasoning is in game theory, an approach originally developed in the 1940s and 1950s by the mathematician John von Neumann and the economist Oskar Morgenstern. Game theory captures much of social life, because here often the best course of action for one actor is dependent on what others do. Note that one individual's gain does not necessarily mean another's loss. In zero-sum games, one's gain is the other's loss. In non-zero sum games, both (all) parties can win.

The Prisoner's Dilemma

The prototypical two-person game is the famous Prisoner's Dilemma. This model illustrates how each individual's perceived self-interest typically wins out over a solution which would have been in the best interest of both. Two prisoners are arrested for a crime for which there is no good evidence. Each one is now invited to confess ('defect') against a greatly reduced prison sentence. If both keep quiet ('cooperate'), there is little evidence to keep them in prison. If both confess, both will get a severe penalty. The maximum penalty, however, will result from one keeping quiet while the other one confesses. Assessing the options, each typically reasons that he is better off defecting – and so both end up worse off than if they had cooperated. This outcome is typical in laboratory-type Prisoner's Dilemma games played only once with participants who do not know each other. In so-called iterated Prisoner's Dilemma games individuals meet again and again (which is often the case in social life). Under this condition reciprocal altruism may develop.

Evolutionarily Stable Strategy (ESS)

An important concept in game theory applied to animal social life is that of an evolutionarily stable strategy (ESS). This is a pattern of behavior (strategy) which when it is the dominant one in a population will prevail against any alternative 'mutant' strategy. The idea of ESS was developed by John Maynard Smith and George Price in their work on animal signals (1973), and later by Maynard Smith (e.g. 1982). An early version was Hamilton's 'unbeatable strategy' (1967). ESS was initially developed to explain the regulation of aggressive behavior; it was sociobiology's answer to the ethologists' question of why animals which are in principle able to kill one another do not actually fight to the death. In natural populations ESS often takes the form of stable polymorphisms (an evolutionarily stable ratio of 'hawk' to 'dove' genes, say, where 'hawk' and 'dove' represent different patterns of behavior).

Winning Strategies

Using iterated Prisoner's Dilemma games Hamilton together with political scientist Robert Axelrod (1981) explored the possible evolution of cooperation between unrelated individuals. An early winning strategy was Tit for Tat. Here an individual starts off by cooperating, is 'nice' as long as the other cooperates but responds to defections with immediate retaliation. Examples of later successful strategies are Generous Tit for Tat, which occasionally reponds to defection with cooperation, and Pavlov, a 'nasty' strategy whose 'win–stay, lose–shift' approach makes it defect even against a cooperator. Note that 'winning strategy' here means that it won in computer tournaments against other strategies: Tit for Tat, for instance, won because a number of 'nasty' strategies all eliminated one another.

Applications of Game Theory

Game theory can be employed to explain a variety of phenomena, for instance why animal formations are often small and circular. Every individual in a 'selfish herd' wants to protect itself against a predator by having other animals around itself (Hamilton, 1971). Game theory has also been used to explain why sex ratios are typically 50:50 and not otherwise (Hamilton, 1967). Trivers (1974) used game theory to develop his theory of parent–offspring conflict. A mother may wish to wean her offspring in order to continue reproducing, while her present offspring wants to enjoy continued feeding. Moreover, game theory can be used to model intragenomic conflicts, for instance genomic imprinting, in which a gene is expressed differently depending on whether it derives from the father or the mother. Still, the existence of seemingly stable genomes indicates that evolutionarily stable strategies may also exist at the genomic level (Haig, 1997).

THE SOCIOBIOLOGY DEBATE

The sociobiology controversy started in 1975 around E. O. Wilson and his book *Sociobiology*: *The New*

Synthesis, whose last chapter applied sociobiology to humans. Among the most active critics were Wilson's own Harvard colleagues in evolutionary biology, Stephen J. Gould and Richard Lewontin, members of a Boston area group who accused sociobiology of supporting a conservative political agenda and legitimizing racism and sexism. After the initial upheaval, including an incident in 1978 where a pitcher of ice-water was poured into Wilson's neck at the American Association for the Advancement of Science conference in Washington, DC, followed a more scientifically oriented critique of the adaptationist program (Gould and Lewontin, 1979). Human sociobiology meanwhile continued being attacked for biological determinism and reductionism (e.g. Gould, 1981; Lewontin *et al*., 1984).

While Dawkins (e.g. 1982) tried to clear up apparent misunderstandings, Wilson, with the help of physicist Charles Lumsden (1981), responded with a new model of sociobiology, now based on gene, mind, and culture co-evolution. Gould continued working on alternatives to adaptation, such as 'punctuated equilibria' (Eldredge and Gould, 1972; Gould, 1980), 'exaptation' (Gould and Vrba, 1982), and contingency (Gould, 1989).

The controversy soon became one chiefly between Dawkins and Gould, who for over two decades in popular books continued attacking each other while promoting their own views. (Wilson had moved on to biodiversity.) Dawkins showed how adaptation can give rise to complex design while Gould argued for chance and contingency in evolution. While Dawkins explained the mechanisms of evolution, Gould treated these as statements about the real world.

Scientifically, the sociobiology debate can be seen as the next round in the ongoing conflict about the Modern Synthesis and the true meaning of Neo-Darwinism. It was a continuation of the protest against reducing everything to 'beanbag genetics' and an attempt to reopen the debate about the relationship between micro- and macro-evolution (e.g. by bringing in punctuated equilibria), and about phylogeny and ontogeny (e.g. by emphasizing the role of developmental constraints and interaction effects).

An indication of this continuing conflict is Niles Eldredge's (1995) and Gould's (1997a,b) division of the Darwinians into 'ultra-Darwinians' (who try to explain everything in terms of relative gene frequencies) and 'naturalists' or 'pluralists' (who accept the existence of multiple forces in evolution and multilevel selection). While Eldredge admits that both sides 'agree on the rudiments of evolutionary change: adaptative modification through natural selection', Gould is less conciliatory. His magnum opus (2002) is an anti-adaptationist manifesto against those who claim the triumph of sociobiology (e.g. Alcock, 2001).

But the sociobiology controversy has also had a moral/political dimension. Learning from the sociobiology controversy, the new field of evolutionary psychology has tried to avoid political traps. It self-consciously deals with the evolved architecture of the human mind rather than with 'genes for behavior' and emphasizes human universals rather than individual differences. Still, because the field employs adaptive explanation, it has inherited the adaptationist critique of sociobiology. The critics seem convinced that claims about a biologically constrained human nature will inevitably be used as justification for social inequality or immoral behavior, while an anti-adaptationist stance is connected to progressive politics and human liberation.

Although often presented that way, the sociobiology debate was not a feud between the political left and right. It was rather a conflict between a new brand of academic activists who wanted to weed out seemingly dangerous ideas from science before these could do social harm and traditional scientists who believed in the benefit of knowledge and trusted the democratic process (Segerstrale, 2000).

Development

Introductory article

Nora S Newcombe, Temple University, Philadelphia, Pennsylvania, USA

CONTENTS

Development refers to the acquisition of mature knowledge states and cognitive capabilities. Cognitive scientists seek to characterize initial knowledge states and cognitive capabilities, and the processes involved in their transformation into adult competence.

BACKGROUND

Babies do not appear to think or act like adults. Thus, there seems to be a self-evident problem of development. How does the helpless infant change into the competent adult? Answers to this question have both practical and theoretical implications. On the practical side, knowledge about when and how children change can help parents to be aware of their children's capacities and sensitive to their needs. Understanding cognitive development can also help educators to work with children to learn optimally, and can help clinicians asked to deal with a variety of challenges to learning. On the theoretical side, the study of development is one of the crucial aspects of cognitive science. No theory of knowledge or skill would be complete without an approach to how the knowledge or skill is acquired. Indeed, thinking about acquisition can place important constraints on the theoretical enterprise and strengthen or rule out specific approaches.

Consideration of the nature of cognitive development predates psychology. Philosophers pondering the matter generally argued for one of two answers tothe question of how the baby becomes the adult. The first kind of answer was to suggest that infants are molded into adults by the influence of the world in which they live. There are various versions of this kind of theory, generally known as empiricism and most famously associated with the name of the English philosopher John Locke. Empiricists postulate a baby born with very little knowledge or capability – Locke spoke of a 'tabula rasa', or blank slate – for whom responses are shaped by the associations of certain sensations in time and space with other sensations, and by reward and punishment.

The second kind of answer to the problem of development is to argue that infants know more than they may seem to know at first sight. Although they appear helpless, they may be endowed with capabilities and categories of thought that allow them to apprehend a world governed by immutable laws of space, time, and causality. Such a theory, emphasizing the importance of the human mind in creating the reality of the world around us, is most famously associated with the German philosopher Immanuel Kant. Kant's theory of knowledge has not one but two modern descendants. It can, in fact, be seen as leading to two quite different approaches to development within cognitive science: constructivism, as originally proposed by Jean Piaget, and nativism, as originally proposed for the case of language development by Noam Chomsky.

Philosophers discussed the nature of infants', children's, and adults' knowledge without actually observing any infants, children, or adults in the process of thinking. When the science of psychology began in the second half of the nineteenth century, it gave rise almost immediately to the empirical study of babies and young children and to theorizing about the nature of development based on observation. Some investigators, working in the empiricist tradition, emphasized the role of the environment in development. For example, John S. Watson made studies of conditioning that he argued showed the origins of certain thoughts and fears. B. F. Skinner analyzed language development as the product of contingencies in the world. Other investigators, working in a biological tradition that can be seen as an early version of nativism, portrayed development as the maturational unfolding of a preprogrammed biological being. For instance, Arnold Gesell and G. Stanley Hall created tables and charts showing just what children at typical ages could be expected to do and think, implying that functioning would be in

a constant relation to chronological age. Some thinkers emphasized the Kantian theme of an active mind that structured understanding of the world. James Mark Baldwin and Heinz Werner are early examples of this type of constructivist thinking.

During this early period, it is interesting to note, writing about development already had a property that is still true today: it was seen to have relevance for thinking about applied problems of child rearing and education. Hence, for example, Edward Thorndike was simultaneously a learning theorist and a founder of the field of educational psychology.

CLASSIC APPROACHES

Prior to the 'cognitive revolution' of the 1960s, comparatively little was known about cognitive development, in large part because comparatively little was known about the nature of mature cognitive functioning. Psychological science, especially in the United States, was dominated by the view that there were universal laws of learning that applied equally to all animal species including humans. Therefore the problem of development tended to be conceptualized as the simple accumulation of learning achieved by means of the operation of the universal laws of learning (B. F. Skinner's cumulative record), or, slightly more developmentally, as the problem of learning to learn in an adult way. An example of research in the latter tradition would be experiments designed to examine exactly what children learned when they learned that a response to a particular stimulus was rewarded. For instance, children might learn that a reward would follow pressing a square of a particular absolute size that was also the middle-sized square of three. There was interest in determining whether there was a developmental change in children seeing the absolute size as controlling the reward as opposed to seeing the 'middle' relation as controlling the reward. Work by Jean Piaget and Lev Vygotsky was published in Europe in the first half of the twentieth century, but their writing was not widely appreciated when it first appeared.

The cognitive revolution led to a radical change in this situation. There were several events central to this revolution, many of them with developmental aspects. Chomsky's writings on language in the 1950s and 1960s led to a rethinking of the psychology of language by figures such as George Miller, and also to work on children's acquisition of language led by the pioneering investigations of Roger Brown. This research emphasized children as active constructors of a child grammar, in the Kantian tradition. Simultaneously, building on his earlier work on the constructive nature of perception and on the nature of adult concepts and thinking, Jerome Bruner started a research program on children's cognition that emphasized children as theorizers. Bruner's work, along with John Flavell's introductory writing on Jean Piaget, led to widespread interest in the United States in Piagetian research. By the mid-1970s, research on cognitive development was dominated by a focus on Piaget's theory and hypotheses. (*See* **Piagetian Theory, Development of Conceptual Structure**)

The cognitive revolution put an end to simple empiricism as an approach to development. Almost from the start, however, there were controversies between developmental theorists who emphasized the Kantian idea of the developing mind as an active constructor of knowledge and those who focused on the equally Kantian idea of innate capabilities. Piaget was the central example of the constructivist approach. But his theory quickly came under fire for several reasons. One criticism was that his thinking seriously underestimated the initial capabilities of infants. Piaget postulated that infants are born with only simple sensorimotor capabilities – they can see, hear, feel, taste, and smell the world, and they are also equipped with stimulus-response reflexes and other, less patterned motor exploration patterns. A large amount of research during the 1980s and 1990s showed, however, that infants and young children had far more substantial abilities than Piaget had seen. A second criticism was that various capabilities did not cohere in the way that Piaget's stage theory had envisioned. Piaget postulated that development consists of qualitative transformation through four distinct stages of thinking ability: sensorimotor, preoperational, concrete operational, and formal operational. Research on the abilities said to characterize these four stages showed, however, that children frequently achieved competence in some of the relevant tasks while lagging behind on others said to be characteristic of the stage, often for protracted periods of time. A third problem was that Piaget talked in general terms about the process of developmental change as being the operation of equilibration, a process of achieving cognitive equilibrium either by seeing the environment in terms of existing cognitive structures (assimilation), or, if needs be, changing cognitive structures in order to make sense of observations of the environment (accommodation). Many investigators argued that a more

detailed specification of the mechanisms of change was needed.

The waning of support for Piagetian theory led to an increased interest in nativism as a solution to the problem of development. Nativism had long been espoused as a theory of language development, because Noam Chomsky had argued strongly that there must be an innate language acquisition device. Otherwise, he said, it would be impossible for children to learn language from the impoverished and error-laden speech sample that they would obtain from listening to adults. Beginning in the late 1970s, nativism also became popular when considering domains of cognitive development in addition to language, including understanding of the Kantian aspects of the world, such as causality, space, time, and number. Nativism was also applied to other aspects of cognitive development, such as the acquisition of categories, or the possibility of imitation of the actions of adults. In addition, many investigators who were not strict nativists became very intrigued by the demonstration of the surprising early competence of infants, such as their memory abilities.

A different response than nativism to the waning of support for Piagetian theory was to champion approaches that more strongly emphasized the role of the environment in development. Vygotsky's writings underwent a revival because their focus on cultural transmission through language and teaching seemed to emphasize the role of the environment in development, without representing a retreat to pure empiricism. Information processing approaches to development also stressed the role of the environment in development but conceptualized it somewhat differently than Vygotskyan theory, as a provider of informational feedback. Information processing theory melded a focus on environmental feedback with a developing part of the emerging field of cognitive science, namely computational modeling. Many information processing theorists also incorporated biological thinking in their models by using parameters in the models that could be conceptualized as changing maturationally, notably short-term memory and processing capacity. (*See* **Categorization, Development of**; **Memory, Development of**; **Culture and Cognitive Development**)

RECENT INFLUENCES

As the field of cognitive science developed during the 1980s and 1990s, in conjunction with the development of cognitive neuroscience during roughly the same period, the study of cognitive development changed concomitantly. The use of computational models expanded. In addition, the style of modeling changed from the predominant use of production systems, written line by line by modelers with certain assumptions about relations between input and processing, to an increasing use of parallel distributed processing (PDP) models, set up with fewer content-related assumptions. PDP modelers postulated a cognitive architecture and made assumptions about the nature of environmental input and feedback, but they then needed to run their systems as experiments to see what they actually did. Modeling in this tradition has led, in some hands, to a view of development as the self-modification of systems that can be identified as constructivist. However, in other models, there are *tabula rasa* assumptions and decisions about the nature of environmental feedback that bring the models close to old-fashioned empiricism. (*See* **Cognitive Development, Computational Models of**)

A second change in thinking about cognitive development in recent times has been the increasing attention given to the role of the neural substrate in thinking. The advent of developmental cognitive neuroscience has added new techniques and dependent variables to the armamentarium of investigators, as well as renewing interest in developmental disorders. In addition, neuroscience has been the source of certain broad insights about the probable nature of development. One important example is the attention received by Peter Huttenlocher's research on synaptogenesis in different areas of human cortex. Huttenlocher has shown that increases in synaptic connections occur during the early part of life, probably in a maturational way. When connections reach a critical level, one often sees the advent of new forms of functioning. From a peak far above the levels typical for adults, synaptic connections seem to be eliminated, or pruned, in a way that is dependent on environmental input. (*See* **Neural Development**; **Neuropsychological Development**; **Developmental Disorders of Language**)

Newer approaches to cognitive development are not only the products of modeling and the use of neuroscience – they have also been driven in traditional ways by the rethinking of existing data and the acquisition of new data. There are three theories that attracted much attention in the 1990s. Dynamic systems theory was developed in other areas of investigation, such as characterization of motor behavior and it has been productively applied in thinking about motor development. However, Esther Thelen and Linda Smith have argued that

it can also be very useful in thinking about development in many other domains as well. In brief, this approach suggests that behavior is complexly determined by contextual variables, so that thinking about development as the acquisition of specific static competences is liable to be misleading and unproductive. Variation-and-selection theory is an updated version of information processing theory proposed by Robert Siegler. Siegler argues that various strategies for dealing with cognitive problems co-exist, with development consisting of the relative predominance of these theories at different points in time. Domain-specific interactionism is a constructivist approach to development that recognizes the fact that the initial starting points for cognitive development are often quite strong and specific, and that development proceeds in a way that is not strongly stagelike. Many key domains have been investigated from this point of view. (*See* **Motor Development**; **Lexical Development**; **Causal Perception, Development of**; **Intermodal Perception, Development of**; **Naive Theories, Development of**; **Object Concept, Development of**; **Space Perception, Development of**; **Speech Perception, Development of**; **Object Perception, Development of**)

SUMMARY

The central problem addressed by research on cognitive development is the issue posed philosophically as the opposition between nativism and empiricism. A wide variety of theories and research has addressed the question, and we have moved beyond the most extreme versions of the debate to consider more integrated and balanced solutions. In the course of this research, we have also learned a great deal about the nature of development in various domains and at various ages. Much of this knowledge is now mature enough to be useful in a variety of applied areas, such as designing intervention and remediation for children with developmental disabilities, or improving the effectiveness of education for normally developing children. In addition, from a theoretical point of view, the field of cognitive development is a vital part of cognitive science. Because no cognitive model can be considered complete if it cannot be acquired by human children, given sensible assumptions about the nature of their learning, developmental thinking offers both constraints on theories and opportunities for theory testing. (*See* **Early Experience and Cognitive Organization**; **Language Development, Critical Periods in**)

CONTENTS

Agreement in linguistics is a relationship of matching or systematic covariation of the features of constituents of a syntactic construct. All major syntactic categories and many minor categories can entertain agreement relationships of a variety of different kinds, typically involving subject–verb or modifier–head configurations.

AGREEMENT: GENERAL PROPERTIES

Agreement (or concord) is a relationship of matching or systematic covariation of the features of constituents of a syntactic construct. The constituents are said to agree in features: ϕ-features (where 'ϕ' is a cover for person, number, gender); case (e.g., Latin *ill<u>arum</u> du<u>arum</u> bon<u>arum</u> femin<u>arum</u>* – 'of those two good women', with genitive feminine plural marked throughout); noun class (e.g., Bantu); or some other properties (e.g., categorial features, as in Chamorro complementizer agreement; or tense).

All major syntactic categories can entertain agreement relationships with other constituents. In many languages, finite verbs agree with their subjects ('subject agreement'), and there are also languages in which finite verbs can agree with one or more of their objects ('object agreement'), or with *wh*-extracted constituents ('*wh*-agreement' as in Bantu, Palauan, Chamorro); nonfinite verbs can also show agreement with their dependents (past participle agreement in Romance languages; inflected infinitives in Portuguese, Hungarian). Predicative adjectives can agree with their subjects, attributive adjectives with the head noun. Predicate nominals often agree with their subjects as well; and possessed nouns may show agreement with their possessors. Finally, prepositions can agree with their objects (e.g., Celtic, Hungarian, Abkhaz).

Minor (or closed-class) syntactic categories may also show agreement. Determiners (articles, demonstratives) typically agree with the head noun of a complex noun phrase. Complementizers (subordinating conjunctions) may bear agreement inflection for either the subject of the clause they introduce (as in varieties of the Germanic languages) or a *wh*-phrase extracted out of that clause (as in Irish; cf. also relative clause constructions featuring inflected relative complementizers).

HEAD AGREEMENT AND DEPENDENT AGREEMENT

An important typological distinction between languages is that between head-marking and dependent-marking languages (Nichols, 1986). Head-marking languages are rich agreement languages; dependent-marking ones express relationships between heads and their dependents in other ways (typically with case-marking on the dependent). Abkhaz, a typical head-marking language, shows agreement inflection on the verb for several of its arguments, and possessive inflection on nouns and prepositions. Languages may combine a rich head-marking agreement system with a system of morphological case-marking on dependents (e.g., Hungarian); languages showing neither type of marking also exist (e.g., Chinese).

Agreement can be classified along head/dependent lines as well. We define head agreement as involving agreement marking realized on the head, not on the dependent. Interpretively, in a sentence with an overt subject and an inflected verb, the expression of ϕ-features on the subject is meaningful (the difference between singular and plural noun phrases is semantically significant) while that on the finite verb is not (it is merely the reflection of the agreement relationship with the subject). Thus, we may call the ϕ-features on the subject interpretable and those on the verb uninterpretable (cf. Chomsky (1995) for a theory in which this distinction plays a major role). In languages in which nominal arguments may remain unexpressed in the presence of ϕ-feature inflection

on the head (so-called pro-drop languages), the inflection on the head may itself be taken to be meaningful – the inflection would be the argument of the head ('pronominal argument languages'; Jelinek, 1984). The pronominal agreement approach bears a strong relationship to analyses of clitic constructions; indeed, the dividing line between clitics and agreement is often difficult to draw and remains a contentious issue.

Agreement may also be marked on the dependent. The quintessential example of dependent agreement is the inflection of attributive adjectival modifiers of noun phrases, where the head noun determines the form of the modifying adjective. Another possible case of dependent agreement is that between anaphoric expressions and their antecedents (*They like themselves*); agreement here is not always strictly grammatical agreement, though (*Everybody thinks they are smart*). Both these dependent agreement cases can be reanalyzed as involving head agreement (Abney, 1986; Kayne, 2001); whether the theory needs to recognize two separate agreement types is not immediately obvious, therefore.

In addition to the above agreement patterns, in which one member is the dependent of the other member of the pair, we find agreement relationships between items where neither is a direct dependent of the other. We will encounter some of these in the next section; they may be assimilable to the head/dependent pattern in ways sketched in the last section.

INTRICACIES OF AGREEMENT

Agreement in ϕ-features exhibits a complicated distribution when it comes to the subset of features picked out. Number shows up cross-linguistically in all types of head agreement; person is frequently marked in finite verb agreement but not all languages having past participle or adjective agreement express person there (cf. Romance); gender, on the other hand, is much less commonly marked in finite verb agreement than in adjective agreement. Animacy and definiteness are two other major agreement features.

The question of whether we find agreement or not may be influenced by complicated syntactic factors, especially in the context of subject agreement and extraction. The position of a noun phrase *vis-à-vis* the agreeing verb may affect agreement possibilities: thus, in Arabic, prenominal subjects agree in all relevant features while postnominal subjects trigger person agreement only. In Berber and varieties of Celtic, *wh*-extracted subjects fail to agree with the verb except if the clause is negated, in which case subject agreement does show up (Ouhalla, 1993). And regular subject agreement can be suspended in sentences in which the finite verb agrees with a *wh*-constituent – as in Bantu (Kinyalolo, 1991) and varieties of American English (Kimball and Aissen, 1971: *the people who John think are in the garden*) – or with a subconstituent of the subject ('agreement attraction': *The identity of the participants are to remain a secret*).

Such 'overruling' tends to be skewed with respect to number: plurals can supplant regular singular agreement, but the opposite is much less common (cf. the frequently occurring *the key to the doors are missing* versus the much rarer *the keys to the door is missing*). This points towards number involving a privative opposition, with plural as the marked member. 'Overruling' of regular subject agreement also tends not to occur when the subject is pronominal. There is a robust cross-linguistic tendency for agreement between a head and a pronoun to be richer and more persistent than that between a head and a full noun phrase. Thus, in Welsh VSO sentences the verb does not show number agreement with full-nominal subjects, but subject pronouns must agree for number; *mutatis mutandis*, the same is found in Hungarian possessed noun phrases.

Within the realm of pronouns, first and second person pronouns often behave differently when it comes to agreement-related phenomena than do third person noun phrases (whether full-nominal or pronominal). Hungarian definiteness agreement between finite verbs and their objects yields straightforward results with third person objects, but first and second person object pronouns surprisingly trigger indefinite agreement on the verb. Splits between first and second person on the one hand, and third person on the other, characterize many so-called split ergative languages as well. The Mayan language Mocho, for instance, exhibits such a split. Other Mayan languages show split ergativity conditioned by tense, aspect, or clause type (main versus subordinate; Dixon, 1994, p. 201 and sections 4.3–4.4). Many morphologically ergative languages (e.g., Warlpiri) exhibit a nominative–accusative verb agreement pattern in tandem with an ergative–absolutive case system, showing that case and agreement patterns need not coincide.

Hybrid agreement patterns manifest themselves in a variety of forms. In French *Vous êtes loyal* [you-2PL are-2PL loyal-M.SG], the second person plural pronoun *vous* is used as a polite form with a

singular referent, in which case it triggers second person plural agreement on the verb but singular agreement on the predicate; similarly, in Spanish *Su Majestad suprema está contento* [your supreme-F.SG Majesty-F.SG is happy-M.SG], *Majestad* triggers femine agreement on the attributive adjective regardless of the referent but has predicate agreement determined by the gender of the referent (here, masculine).

These kinds of hybrid agreement may also be classified as semantic agreement, with the ϕ-feature composition of the head being determined by the referent of the dependent rather than by the morphosyntactic features of the dependent *per se*. Semantic agreement seems to be confined to head agreement.

AGREEMENT IN CURRENT GRAMMATICAL THEORIES

Semantic agreement is the cornerstone of Dowty and Jacobson's (1988) theory of agreement, in which agreement relationships are given a semantic explanation. In Reed's (1991) functional approach to verb number in English, meaning is also the epicenter: for Reed, what is generally referred to as an agreement relationship between the subject and the finite verb is not a case of agreement at all; instead, the number specification of each is chosen independently of that of the other, with each contributing independently to the message the speaker seeks to convey. Naturally, the emphasis in this work is on lack of agreement.

A semantic theory of agreement faces difficulties wherever semantic factors fail to have the final say. Thus, while *the dog* can be pronominalized with either *it* or *he*, in a sentence like *That dog is so ferocious, it/he even tried to bite itself/himself*, the assignment of gender to the subject pronoun and the object anaphor has to be uniform: the combinations *it* + *himself* and *he* + *itself* are impossible. This uniformity is not semantically determined; instead, it cues the need for a morphosyntactic theory of agreement.

Pollard and Sag (1994), who contributed this argument against semantic approaches, offer a theory of agreement built on the feature-based formalism of head-driven phrase structure grammar but allowing agreement access to semantic and pragmatic information as well. In this theory, ϕ-features are taken to be part of the internal structure of referential indices, the latter being the key notion of their theory. Indices in this theory make both a semantic and a syntactic contribution; they are vital in the analysis of agreement phenomena and referential dependencies.

A unified approach to agreement and referential dependencies in terms of indices is found also in the early principles-and-parameters literature (Chomsky, 1981, 1986; Borer 1986). In more recent principles-and-parameters work (Chomsky 1995), however, indices are assumed not to play a theoretical role. Instead, agreement is represented in terms of a local structural configuration ('specifier–head agreement') or is established under a (potentially long-distance) Agree relationship (Chomsky, 2001). Of these two options, the former represents theories in which agreement is a combination of feature matching and a specific structural configuration under which such matching is 'checked' – the spec–head structure (see the next section for more discussion), or Chomsky's (1995) 'checking domain' (see Chung (1998) for a different approach, cast in terms of the Associate relationship). The more recent Agree approach reduces agreement strictly to feature matching, with specific structural configurations resulting not from the need to establish agreement but from other, unrelated requirements.

Agreement as feature checking is essentially a symmetrical relationship; the Agree approach, by contrast, conceives of agreement as an asymmetrical relationship between a 'probe' and a 'goal'. Early generative approaches to agreement were asymmetrical as well, with transformations copying ϕ-feature specifications from one member of the agreeing pair to the other. Asymmetrical agreement also characterizes Keenan's (1979) approach to agreement in terms of the function–argument relationship. In the framework of Generalized Phrase Structure Grammar (Gazdar *et al*., 1985), agreement relations are likewise encoded asymmetrically, but in the more recent Head-Driven Phrase Structure Grammar (Pollard and Sag, 1994) agreement is treated in symmetrical terms.

AGREEMENT AS EVIDENCE FOR STRUCTURE

Agreement relationships are severely restricted: though there may be a variety of noun phrases present in the domain of a head, this head establishes agreement with only a narrow subset of those noun phrases. Thus, in *John ate Bill's cereal this morning*, there are four noun phrases surrounding the verb, but in no language will the verb agree with all four at the same time; at most, the verb agrees with the subject and the object.

While the possessor can agree with the verb under special circumstances ('possessor ascension to direct object'), bare NP adverbs never agree.

There are structural reasons why agreement relationships are so restricted. Agreement can be established in specific structural configurations only, of which the subject or specifier relationship seems to be the canonical case. If all agreement relationships are taken to involve such a structure, the occurrence of agreement between any two constituents is evidence for a structure in which these constituents are in a specifier–head relationship. In the principles-and-parameters theory of generative grammar, this hypothesis has led to the introduction of agreement phrases (AgrPs) for objects of verbs and prepositions and in the complementizers system. Agreement thus plays a pivotal role in the establishment of syntactic structures in some theories.

Agreement between complementizer and *wh*-extracted constituents and between possessors and possessed nouns is readily recast in these structural terms. When the possessed object itself incorporates into the verb, the possessor in a sense becomes a derived specifier of the verb; similarly, when the finite verb is incorporated into the complementizer position, the subject becomes a derived specifier of the complementizers (Zwart, 1997). In this way 'possessor ascension' and complementizer–subject agreement may be captured. Kayne (1995) shows that a similar treatment is available for cases of agreement in which the finite verb of an embedded clause agrees not with the subject but with an extracted nonsubject (*the people who John think* are *in the garden*). More 'exotic' cases of agreement (like that between a subconstituent of a complex subject noun phrase and the finite verb in English 'agreement attraction' constructions like *The identity of the participants are to remain a secret*) may, when assimilated to specifier–head agreement, provide evidence for syntactic constituency or derivation as well (cf. Kayne, 1998; Den Dikken, 2000).

Often harder to recast as a specifier–head relationship, long-distance agreement between the matrix verb and an argument of the clause it embeds (as found in Daghestanian, Indic, and Finno-Ugric languages) is restricted in ways which likewise provide highly specific evidence for syntactic structure (see, e.g., Polinksy and Potsdam, 2001). Throughout, agreement is a key diagnostic in the syntactician's toolkit.

INTRODUCTION: REFERENCE AND REFERENTS

Whenever a speaker utters a sentence, he or she has a particular message in mind, which the utterance conveys to the listener. An ongoing aspect of communication is the act of pointing out to the listener what objects in the world the speaker is trying to talk about. The speaker chooses certain words and phrases, and uses them to indicate to the listener what thing or things are being described. When a *phrase* of language is used to pick out a *thing* or *entity* in the world (more precisely, either the real world or the inner world of our thoughts), we say that the phrase *refers* to the thing or entity, and that the thing or entity is the *referent* of the phrase. Reference to objects in the world is one of the most fundamental, and common, things we do with language. Virtually every sentence, in any language, contains phrases that refer to things in the world or in our thoughts.

There is a fundamental distinction to be made between *directly referring* and *indirectly referring* phrases. The first type consists of a phrase whose lexical content – the meanings of the word(s) of the phrase – contains sufficient information to allow the listener to understand what entity is referred to. The phrase by itself carries enough information to refer to, or 'pick out', the entity. Typically, a directly referring phrase contains a noun (which describes the kind of entity being referred to) together with various modifiers the speaker might use to further specify the referent. (In this discussion, we use 'speaker' to mean whoever is producing the utterance, and 'listener' to mean whoever is trying to comprehend the utterance, independent of the medium of expression.) Because the phrase is built around the noun, we call it a Noun Phrase, or NP. For example, each of the italicized expressions below is an NP, and in each case it refers to an entity or group of entities:

The fat dog is barking. (1)

The fat dog that lives next door is barking. (2)

Dogs are barking. (3)

These phrases refer to their referents directly, independently of any other words in the sentence (thus the term *independent reference*). If you know what 'the', 'fat', and 'dog' all mean (i.e. if you are a speaker of English), you will know what is being referred to in sentence (1).

DEPENDENT PHRASES AND INDIRECT REFERENCE

The second type of reference, *indirect reference*, works differently. It always involves a pair of NPs. One will belong to a small class of semantically incomplete NPs, called the *proforms*, which includes the personal *pronouns* (English pronouns are listed in (4)); *reflexives* (listed in (5), which always consist (in English) of a personal pronoun plus the suffix '-self' (in the singular) or '-selves' (in the plural)); and *reciprocals*, seen in (6).

English personal pronouns (4)

	First person	*Second person*	*Third person*
Singular	*I, me*	*you*	*he, she, it, him, her*
Plural	*we, us*	*you*	*they, them*

English reflexives (5)

	First person	*Second person*	*Third person*
Singular	*myself*	*yourself*	*himself, herself, itself*
Plural	*ourselves*	*yourselves*	*themselves*

English reciprocals: *each other; one another* (6)

The other NP in the pair is the *antecedent* of the proform, the phrase that the dependent element

'looks back to' to determine its reference. Antecedents will typically be independently referring NPs. Proforms are nouns that are scaled down in meaning and, in English, convey information about person and about number, gender, and humanness. In other languages, proforms may convey additional information, including the familiarity of the speaker and listener, whether the listener is included or excluded, and information about fundamental aspects of the antecedent, such as its orientation in a plane, or whether it is flat. Regardless of the internal information expressed by the proforms, they are typically used in a sentence to 'echo', or repeat, the reference established by using the antecedent. For example, in (7), the reflexive 'themselves' and reciprocal 'each other' refer again to the dogs down the street:

a. The dogs down the street are looking at *themselves*.
b. The dogs down the street are looking at *each other*. (7)

The term *anaphora* refers to this pairing-up of a proform and its antecedent. As an aside on terminology, we note that the ancient Greek grammarians distinguished between cases where the antecedent preceded the dependent element, as in (7), which they termed 'anaphora', from cases where the antecedent followed the proform, which they termed 'cataphora', as in, for example, 'His mother talked about John'. In most modern literature the term 'anaphora' is used to cover both cases, and we follow that convention here. (Cases of the latter type are statistically very infrequent in written and spoken English, a fact which might follow from the increased processing burden placed on the language comprehension system by receiving the proform in advance of its antecedent.)

For the discussion below, it is crucial to keep in mind that sentences such as (7) contain two separate references to objects: the antecedent (e.g. 'the dogs down the street') refers directly to the referent; and then the proform connects back to the antecedent, and refers to whatever the antecedent did. Thus, in (7a), there is no way to determine what 'themselves' refers to without first figuring out what the antecedent is; the reference by the word 'themselves' to the dogs is indirect, mediated by the connection of the reflexive to its antecedent phrase. Proforms are also called *dependent expressions*. The two NPs are said to co-refer when they have such a dependent connection. Anaphora, then, is the link between a proform and its antecedent, which establishes co-reference. Figure 1 illustrates this graphically.

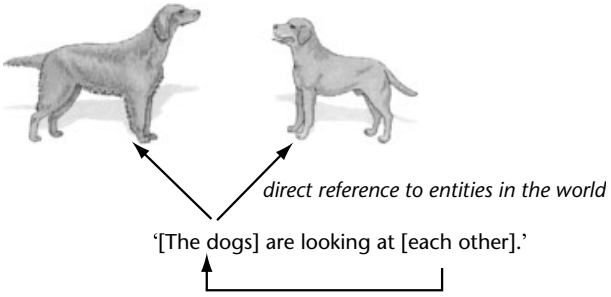

Figure 1. The antecedent–proform relation, creating indirect reference to the dogs.

CONSTRAINTS ON ANAPHORA

There is a major contrast between the pronouns in (4) and the reflexives and reciprocals in (5, 6). Typically, reflexives and reciprocals appear only in very limited positions within a sentence, and pronouns typically appear in cases of anaphora where a reflexive would be unacceptable.

The antecedent of a reflexive or a reciprocal will usually be structurally close to the proform, typically occurring as the subject of the sentence in which the reflexive occurs (square brackets are used here to mark the boundaries of propositions or clauses; '*' indicates that the sentence with the intended interpretation is not grammatically acceptable):

a. [John thinks that [Mary admires herself]].

b. *[John thinks that [Mary admires himself]]. (8)

By contrast, the antecedent of a personal pronoun has a different distribution, and cannot be in the same position as the antecedent of a reflexive or reciprocal:

a. *[John thinks that [Mary admires her]].

b. [John thinks that [Mary admires him]]. (9)

Notice the complementariness of the distribution of proform–antecedent pairs. (8b) is ungrammatical because the antecedent, 'John', is structurally too far away from the reflexive. This then permits the use of a pronoun to co-refer with 'John', as in (9b). By contrast, in (8a), the antecedent is close enough to the proform to permit use of a reflexive. This consistently blocks the use of a pronoun: (9a) cannot be understood to mean co-reference between 'her' and 'Mary'.

Consequently, in the course of understanding language, the listener must keep track of (1) the type of proform being used (pronoun versus reflexive/reciprocal), (2) where it occurs in the sentence, (3) the position(s) in which other NPs, which are candidate antecedents, occur, and (4) the person, number, and gender features of each NP (including the proform), which further constrain the pairing up of a proform with an antecedent.

Above we noted that a proform and its antecedent must match in person, number, and gender. Notice that (10a) is ambiguous (since both NPs match the pronoun in features), while (10b) and (10c) are unambiguous, since only one NP matches:

a. The boy told the man that [he was lucky].
b. The girl told the man that [he was lucky].
c. The boy told the woman that [he was lucky]. (10)

There are some cases in which feature mismatch is permitted. One is the use of the genderless, normally plural 'they/them' as an indefinite singular pronoun, when the speaker does not wish to seem gender-biased in using the singular (English contains no singular, gender-unmarked pronoun), as in (11a):

a. Every student must make sure they check in with the nurse.
b. Every student must make sure he checks in with the nurse. (11)

A second case is the use of the normally second-person pronoun to mean 'one', 'anyone', in casual speech:

a. You shouldn't do that.
b. One shouldn't do that. (12)

(12a) is ambiguous. It may be understood as directed at the listener(s), in which case the second-person feature is required. But it may also be taken as a casual variant of (12b), in which case the reference is generic, and not restricted to the listener(s).

In general, these mismatches can be seen as a type of compromise: a way of avoiding gender commitment or formal register.

THE PROCESSING OF ANAPHORA

The term *processing* refers to how the human mind registers and makes sense of sensory information over time. Cognitive processes, such as language production and comprehension, are largely unconscious and automatic. When listeners hear a sentence, they must first recognize the words contained in the sentence. For instance, for the sentence 'The dogs are looking at the mail carrier', the listener first must determine that the words 'the' and 'dogs' occurred, then figure out what the words mean, and then combine the meanings. Word meanings seem to just pop into mind: when we hear the words 'the dogs', we automatically think of the concept DOG. This process – of identifying words, thinking about their meanings, and combining meanings together – occurs over and over in the course of communication. One might wonder what happens to all this information: if the DOG concept is in mind, what happens to it when 'mail carrier' is uttered? Clearly, a listener would have to keep both concepts (THE DOG and THE MAIL CARRIER) in mind simultaneously (along with the LOOKING concept) in order to understand the sentence. And, of course, the concepts must be kept separate, so that we do not think of the dogs as being mail carriers, or the carriers carrying both mail and dogs. There is some evidence that words and their meanings are kept in mind until the end of a proposition (usually the end of a sentence), and then they are converted into a less detailed memory representation.

The presence of anaphora complicates matters considerably. In a sentence such as 'The dogs are looking at each other', what meaning 'pops into mind' when 'each other' appears? Do listeners automatically think about 'the dogs' again? Or does it require time and effort to make the connection between 'each other' and 'the dogs'? Before we address this question, we will describe how research on the processing of anaphora has been conducted.

Methods

There have been three basic approaches to the study of how proforms are interpreted. (1) Ask people. The most direct approach is to have people read sentences and then ask them about their

interpretations (e.g. presenting a sentence like 'John told Bill that Frank admired him' and asking 'Who does *him* refer to?'). The trouble with this approach is that it does not reveal anything about the process over time; it probes only the final interpretation of the sentence, and so does not answer any of the questions raised just above. There are two types of methods that do provide information about how a listener or reader understands a sentence as it unfolds.

(2) Probing word meanings. One variant of this method probes the activation of word meanings by having people listen to sentences and simultaneously make judgments about items they see on a computer screen. Here is how it works. Listeners hear the phrase 'The dog' at the beginning of the sentence. Then immediately they see (on a computer monitor) either a related word such as 'cat' or a completely unrelated word such as 'pen'. They are asked to simply decide whether the word they see is a real word of English, and press one button if it is and another button if it is not. The logic is this: if they see the word 'cat' while they are thinking DOG, then listeners will be quite fast to respond, faster than if they see 'pen' while thinking DOG, because the concepts CAT and DOG are connected in our word system, and PEN and DOG are not. By measuring the time it takes listeners to respond, experimenters can get some idea of what people are thinking about. Now suppose that listeners hear the sentence 'The dog down the street hurt itself yesterday'. If we probe what listeners are thinking about when they hear the word 'itself', we should be able to tell whether they are thinking about the concept DOG. If they are, this means that the connection between the reflexive 'itself' and the antecedent 'the dog' is established very quickly indeed. Another variant on this technique simply repeats the antecedent, and listeners or readers must decide if the word appeared in the sentence or not. The logic is similar: if people are thinking about DOG after the reflexive 'itself', they should be relatively fast to indicate that the word 'dog' was in the sentence.

(3) Measuring reading. Another approach has been to have people read sentences and to determine at what points in the sentences they slow down. In one variant of this approach, researchers construct sentences that have a 'surprise' ending IF the reader has adopted a particular interpretation. For example, given the sentence 'The actress liked the queen because she thought the queen did a good job', readers could initially assume at the point where 'she' occurs ('The actress liked the queen because she…') that 'she' co-refers with 'the queen'. Such an assumption is reasonable because an explanation for the proposition that 'the actress liked the queen' is likely to involve something that the queen did. If readers do make this assumption when they read the pronoun 'she', then they will be surprised when material after the pronoun reveals that 'she' is really 'the actress'. What happens when readers are surprised by how a sentence unfolds is a slowdown in reading (compared to the reading of a sentence that does not contain a surprise ending, for example 'The actress admired the queen because she thought the actress did a good job'). Reading time can be measured with the use of a device called an *eye tracker*, which, when it is linked to a computer, determines where on a computer screen the eye fixates and for how long (and whether the reader backtracks in order to re-read a section of text). A simpler way to measure reading time is to (have a computer) present pieces of a written sentence in sequence, in such a way that only one section is visible at a time. The reader controls the presentation by pressing a designated key on a computer keyboard. The key press makes the current sentence fragment disappear and the next fragment appear. The time between key presses provides a measure of reading time.

The Experimental Findings

Experiments that have focused on the questions raised above suggest that listeners do automatically think about the antecedent of the proform – immediately, or very soon after the proform appears – if they are reasonably attentive to what they are hearing. Hence, it appears to be automatic that proforms serve to reinstantiate their antecedents. Such findings raise a number of questions: does the information about sentence position have an effect on what people think about when they encounter a proform? What happens when there is more than one possible antecedent for a proform? Must a single antecedent be selected right away, or does a whole set of possible antecedents get computed, awaiting final narrowing down? What sources of information enter into the process? We will consider each of these questions in what follows.

First, recall the facts about the complementarity of the distribution of antecedents of pronouns on one hand and reflexives/reciprocals on the other. Examples are shown in (13).

a. The actress thinks that the queen admires her.
b. The actress thinks that the queen admires herself. (13)

In (13a), 'the queen' cannot be the antecedent of the pronoun 'her', but 'the actress' can be. In (13b), 'the queen' must be the antecedent of the reflexive 'herself' and 'the actress' cannot be. Some research suggests that knowledge about these restrictions constrains the process: listeners and readers think about only those antecedents that are 'allowed'. Further, they think about only those antecedents that agree in number and gender (this point is discussed in greater detail below).

Now consider the case in which there is more than one possible antecedent for a proform, as in the following examples.

The actress told the queen that the director wanted to meet her after dinner. (14)

The actress told the queen that she would be sitting next to the director. (15)

In (14), both 'actress' and 'queen' are possible antecedents of the pronoun 'her'. It might be slightly more likely that the director would want to sit with a queen rather than an actress (this is information about how the world works, or information about *plausibility*), or people might tend to think that since 'her' is the object of a verb (the verb 'meet'), an object ('the queen' in the first clause) is a better antecedent (this is called the *parallel function* interpretation). These kinds of information do matter, but evidence from word-probe experiments suggests that they do not come into play immediately. That is, listeners think about both 'actress' and 'queen' after hearing 'her'. Then they might use a variety of cues to settle on one antecedent or the other. (Typically, listeners do attempt to link proforms with antecedents right away; it would be difficult to follow a conversation without doing so.)

In (15), again, both 'actress' and 'queen' are potential antecedents of the pronoun, and both would come to mind after the occurrence of 'she'. Then other cues would be used to narrow down the set: parallel function would dictate that since 'she' is a subject, another subject ('the actress') should be the antecedent. Another factor that appears to affect pronoun interpretation is the order of potential antecedents: the first NP in the sentence has a sort of privileged status, and, given a choice, people are more likely to fix on that NP as the antecedent. A third factor has to do with plausibility: the likelihood that an actress would inform the queen about where the queen would be seated at dinner; the likelihood of the queen being seated next to the director, and so on. Again, it appears that such information acts to eliminate antecedents from a candidate set: the proform makes a listener think about a number of antecedents, selected via inspecting just the sentence structure, and other information acts later on to eliminate potential antecedents from the set.

It should be emphasized here that such instances of antecedent ambiguity are far from uncommon. This is because speakers are unaware when they say a pronoun that it may not be clear who the antecedent is; after all, for the speaker, there is no confusion at all. (Sometimes they do catch themselves, and identify the antecedent: e.g. '… and then she… that is, Susan, disappeared…'. Other times a listener might ask 'she, who?'.)

Now consider example (16).

The actresses told the queen that they were going to be late. (16)

Here there are also multiple antecedents for the pronoun 'they': just the 'actresses' or both 'the actresses' and 'the queen'. Research shows that listeners consider just 'the actresses', which matches in number with 'they'. When a matching antecedent is available, as it is here, listeners tend not to consider a joint referent consisting of both the actresses and the queen. (Note that, in contrast, a sentence such as 'The actress told the queen that they were going to be late' requires the listener to infer that 'the actress' and 'the queen' together constitute the antecedent of 'they'. It is not known at present whether or not this inference takes additional time.)

The examples above contain nouns that are gender-specific: 'actress' and 'queen' are both feminine. What happens when a gender-neutral noun appears, as in the following?

The supervisor warned the actress that she was going to be late. (17)

Only a handful of English nouns are specified for gender. These include kinship terms (e.g. 'aunt, grandfather, daughter'), royal titles (e.g. 'king, princess, duchess'), and miscellaneous others, many of which are disappearing from English (e.g. 'aviatrix, murderess'). Of the miscellaneous set of feminine-marked forms, the male counterparts are not clearly marked for gender: although 'aviatrix', 'murderess', and 'actress' must refer to women, 'aviator', 'murderer', 'actor' can be applied to both men and women. In general, most occupation nouns are gender-neutral: e.g. 'doctor, nurse, lawyer, director, president, manager, supervisor, teacher, professor, student, programmer, architect, gardener, coach'. Of this set, there is considerable variation with respect to the probability with which a term is likely to refer to a man or a woman. While 'student' seems to be equally likely

to refer to a male or a female, some nouns are more likely to refer to men (e.g. 'astronaut') and some to refer to women (e.g. 'nurse'). How does this type of information affect the processing of anaphora? There is not much research in this area, but the research to date suggests that listeners initially consider as a potential antecedent for a proform any noun that does not actually clash in terms of gender. Given a sentence like (17), and no additional information about the gender of the referent of 'supervisor', both 'actress' and 'supervisor' would initially be considered potential antecedents. Then the gender-probability information, along with information about real-world plausibility, parallel function, and order of mention, are all likely to come into play to guide the selection of a single antecedent. In a sentence such as (17), there will be conflicting information: parallel function and first-mention weight 'the supervisor' more heavily. But gender marking favors 'the actress'. Pragmatics arguably favors both equally, since the plausibility of 'being late' applies equally to both. The processing of sentences such as this should be slower than for sentences in which all the information favors the same antecedent.

Overall, the research suggests that the processing of anaphora involves a number of stages. First, the occurrence of a proform evokes a candidate set of antecedents. This set includes only those antecedents that are grammatically allowed, and only those that are not incongruent with respect to gender and number. Next, other types of information (about order of mention, sentence function, gender-probability, and plausibility) act to eliminate nouns from the candidate set.

Actually, the picture is more complicated than this because sometimes potentially helpful information about the identity of the antecedent is not available until later in the sentence. Take a sentence such as 'The director told the actress that she couldn't recommend her for the role'. At the point in the sentence at which 'she' occurs, it really is not clear which is the correct antecedent. Competition of the other types of information could lead the listener to settle on 'actress' (possibly because there are many more male directors than female ones). But the appearance of 'her' throws this interpretation into question: if 'she' co-refers with 'actress', and if 'her' cannot co-refer with 'she', then 'her' co-refers with 'director', and here's where the sentence goes awry. It is unlikely (but not impossible) that someone would tell someone else whom he or she could recommend. So, 'she' ought to co-refer with 'director', and 'her' with 'actress'. And when it is revealed that the recommendation is for a role, then this confirms the revised interpretation.

Given that late-occurring material can inform the interpretation of proforms, it might make more sense for listeners to postpone co-reference until the end of the sentence. Listeners and readers could simply take the information conveyed by a proform (e.g. third person, female, plural, subject) and plug that into the ongoing meaning of the sentence. But it appears to be the case that, as in language comprehension in general, a 'wait-and-see' approach carries too high a cost. The cost is that we might forget some of the critical details of an utterance and lose track of what the sentence is conveying. After all, for the most part, human beings talk about people and things. During a discourse, a speaker and listener both construct a *mental model* of the participants and events being discussed. In order to follow a discourse listeners and readers must figure out who is doing what to whom, and it appears that they make these calculations quickly, lest they forget.

Anaphora

Advanced article

Gregory Carlson, University of Rochester, Rochester, New York, USA

CONTENTS

Anaphora refers to referentially dependent expressions in natural language which contribute their meaning by identifying another expression to give them their semantic value.

INTRODUCTION

Anaphora, in its primary instances, is the establishment of a referential dependency between two (or more) expressions. The pronoun 'him' in (1) below is one such instance of anaphora:

Mark felt that there was someone watching *him*. (1)

On the understanding that 'him' refers to Mark, the pronoun is the *anaphor* and the expression 'Mark' is the *antecedent*. Both expressions refer to the same individual. The relationship between these expressions is not an equal one, however, since the reference of the pronoun is dependent upon the reference of its antecedent, whereas the reference of the antecedent is established by virtue of its meaning alone. The term 'co-reference' is often used to describe this referential connection between anaphor and antecedent. But anaphor–antecedent relations must be distinguished from the phenomenon of *accidental co-reference*. This occurs when two independently referring expressions happen to refer to the same individual. So, for instance, in (2) the two italicized expressions will be co-referential, 'accidentally', only when the president of the company is also the company's best employee:

The president of the company rewarded *the best employee*. (2)

This requires an understanding where the company has a self-rewarding president, but there is no anaphoric connection established between the expressions. Thus, anaphora is a matter of co-reference, and something more.

ANAPHOR–ANTECEDENT RELATIONS

Anaphors depend upon their antecedents to determine their referential content. One reflection of this referential dependency is that in many instances an anaphor cannot be interpreted as co-referential with another noun phrase (NP). For instance, in the following examples, the pronouns cannot be construed as non-accidentally having the same reference as the italicized NPs:

Bob was nominated by him. (him $\neq$ Bob) (3)

She hoped that *Mary* would win the contest. (she $\neq$ Mary) (4)

This is because an anaphor cannot receive its reference from another NP if that NP does not have an appropriate syntactically defined relationship to the anaphor. This relationship is not simply one of linear precedence, as in many instances an anaphor may precede its antecedent (a phenomenon which is occasionally called *cataphora*, though more commonly *backward anaphora*):

Near *her*, *Jill* saw a snake. (5)

If *he* wins the race today, *Bret* will be a hero. (6)

Much research has focused on the question of the precise nature of this syntactic relationship. The research is detailed and extensive (for example, research on *Binding Theory*). Most agree that the notion of *c-command* is crucial (Langacker, 1966; Lasnik, 1976). In general, an anaphor cannot c-command its antecedent, and in examples such as (3) and (4) above where the two designated NPs cannot be interpreted co-referentially, the pronoun would c-command its antecedent, and a referential connection cannot be established. The reference for the pronoun in these instances needs to be determined by other means, such as finding another, appropriate antecedent for it, or by providing it

with a *deictic* interpretation (discussed further below). (*See* **Binding Theory**)

One class of pronouns that has also received extensive attention is that of *reflexive pronouns*, exemplified below:

We found *ourselves* with too much to do. (7)

The professor taught *herself* French. (8)

These differ from the other personal pronouns in important respects. Primarily, the syntactic relations to their antecedents are much more limited. In general, reflexive pronouns may only have antecedents within the same clause, though the precise conditions remain a topic of detailed investigation. In the following examples, the reflexive pronoun may not be construed as co-referential with the italicized NPs:

We thought that [$_S$Jim liked ourselves] (9)

The professor remembered when [$_S$herself lived in Paris] (10)

As there is no appropriate antecedent for the reflexive pronoun within the same clause in these instances, the sentences are not grammatical.

Pronouns not only may find their reference by identifying an antecedent and using the reference of the antecedent as its own value, but they may function as *bound variables* as well. In such instances, the 'reference' of the pronoun is not determined by the reference of its antecedent NP, but rather by the assignment of values to variables that is determined by the quantifier, as in first-order logic. A representation of a sentence such as (11), with 'Every man' construed as the antecedent of 'he', would be as indicated:

Every man thinks that [*he* deserves a raise]
$\forall x$ [man(x) $\Rightarrow$ x thinks that [x deserves a raise]] (11)

Bound variable pronouns and their antecedents are syntactically more constrained than identity of reference pronouns and theirs. In the following examples, (12a) precludes any bound variable reading; this is despite the fact that a natural identity of reference reading is available when the antecedent NP has a clear referential value, as with proper names (12b):

a. The dean who placed *no student* on probation told *her* to check back in the fall.
b. The dean who placed *Hillary* on probation told *her* to check back in the fall. (12)

(12a) has no bound variable interpretation, because the antecedent is in a syntactic position which precludes this possibility. The relation that must hold, in the case of bound variable readings, is for the antecedent NP to c-command the pronoun.

The phenomenon of anaphora is much broader than the personal pronouns discussed thus far. One form of anaphora that has received much attention is *temporal anaphora* (Partee, 1984). This applies not only to pronouns referring back to time NPs,

The mail arrived *this morning*. I was at home *then* (= this morning) (13)

but also to the time introduced by the *tense* of a sentence:

Ali woke up. It was cold *then*. (14)

The study of temporal anaphora includes a wide variety of forms which are used to coordinate the time in one sentence with that of another. Beyond 'then', expressions such as 'when, before/after, until, as, while, since, immediately thereafter', and many others fall within this domain. Perhaps most significantly, tenses themselves appear to function anaphorically. In the examples below, the tense in the second sentence is understood as coordinated with the time reference in the first:

Samantha opened the door. She *had been* repairing the car. (15)

Daryl fell down. He *was* drunk. (16)

Our understanding that the repairing occurred prior to the door opening, or that the falling occurred while Daryl was drunk, is often attributed to temporal anaphora.

A wide variety of other anaphoric forms, beyond personal pronouns and temporal anaphora, make reference to an extensive array of other types of things. These include the demonstratives 'this' and 'that' (with or without a following noun), and epithetics such as 'the fool' or 'the bastard'. Other forms take as antecedents phrases that are not NPs. 'So' may take a verb phrase as an antecedent; 'such' takes a modifier; 'there' may take a locative prepositional phrase; 'one' may take a noun:

a. Sam tried to *win the race* before Al could do *so*.
b. If *intelligent* students attend college, *such* students usually do very well.
c. Everyone who was *at the party* had a good time *there*.
d. I own a big *car*, and you own a small *one*. (17)

In many cases the anaphor is expressed as null: that is, the anaphor is indicated by having some

constituent missing from the sentence. The following sentence is missing a noun plus its modifying adjective at the point indicated by the blank:

Jack owns three *large dogs*, and I own two____. (18)

In this case, the 'blank' takes as its antecedent the portion of the NP italicized. It functions as an anaphor in the same way as a pronoun.

Null anaphora extends well beyond nouns and NPs. Verb phrases (VPs) can function as antecedents for null VPs (known as *VP ellipsis*):

If you want to____, we can *take a break.* (19)

Verbs, and verb complexes, can serve as antecedents in the *gapping* construction:

Joseph *ate* a bagel, and Samuel, ____ a grapefruit. (20)

Null complement anaphora takes complement sentences as antecedents:

Kevin claimed *that our television was broken, but I'm not so sure*____. (21)

This by no means exhausts the range of anaphora expressed by null expressions.

DISCOURSE ANAPHORA

'Discourse' is the normal mode of communication: the use of more than one independent sentence or utterance put together in a way that 'makes sense'. The discussion above was limited to those instances of anaphora that take place within the boundaries of a sentence. Anaphora takes place across sentence boundaries as well. Many instances of anaphora that appear within sentence boundaries take place as well in discourse:

Several team members were suspended. Reportedly, *they* had missed a practice. (22)

Most people want to *win a million dollars.* Doris doesn't____. (23)

Certain cases of anaphora that occur within the boundaries of a sentence do not function as discourse anaphors. For instance, the phenomena of reflexive pronouns, gapping, relative pronouns, and bound variable anaphora do not appear to be able to function this way.

One treatment of discourse anaphora is to treat all such pronouns as *free variables*, which are assigned a reference independently by an *assignment function*, which designates a referential value for any free variables within its domain (e.g. Cooper and Parsons, 1976). It becomes co-referential with a NP in a previous sentence by virtue of being assigned the same reference. (*See* **Semantics, Dynamic**)

So, in (24), if a function assigns the same referential value as the proper name 'Leonard' has, to the pronoun 'he' in the following sentence, then a co-referential reading arises:

Leonard is a famous composer. *He* writes operas. (24)

On the other hand, if 'he' is assigned a different value (e.g. Fred), then the discourse will be understood as saying that Fred writes operas, and no co-referential reading will occur. All phrases with which the pronoun is co-referential must have a reference value in the first place, if this is to be the appropriate analysis. The case of indefinite NPs in discourse raises questions, though. Indefinite NPs are those which appear with a number of different determiners, most prominently the indefinite article 'a(n)'. Such NPs can be 'referred back to' by anaphors in discourse:

A man walked into the room. *He* sat down. (25)

Most researchers, however, question whether an indefinite NP should be properly assigned a reference value (Kamp, 1981). This is because the reference value determines the truth-conditions of the sentence, and if one assigns a certain individual as the reference of 'a man' in a sentence such as (25), then it would be true if that *particular* man walked into the room, and false if he did not (regardless of whether any other man walked in). However, these are not the truth-conditions for such a sentence, since (an utterance of) the sentence will be true if any man whatsoever walked into the room (and false only if no man at all did). If one assigned a reference for 'a man' as some particular man, one could not characterize these truth-conditions. It appears that the truth-conditions of the sentence are best represented quantificationally, with an existential quantifier binding a variable:

$\exists x$ [man(x) & x walked into the room] (26)

This treatment raises some problems, however, when we turn to discourse anaphora. The representation of the two-sentence discourse in (25) would have the existential quantifier binding the instance of 'he' in the subsequent sentence:

$\exists x$ [man(x) & x walked into the room & x sat down] (27)

Since anaphors referring back to indefinites are both very common and natural, unlike those functioning as bound variables with their antecedent quantified expressions in another sentence, one would need to make a separation between classes of quantifiers, some of which could bind variables in other sentences, and others which could not. This has proven an unsatisfactory analysis of the phenomenon, however, for both syntactic and semantic reasons. One of the main issues has centered around the treatment of *donkey sentences* (or, *donkey anaphora*). Such examples are so called because of the example below, commonly cited in the literature:

Every farmer who owns *a donkey* beats *it*. (28)

These sentences pose a problem of logical representation that has been known since medieval times. The problem is this. If one were to take 'it' in this sentence to be a free variable assigned the same reference as 'a donkey', there is, very clearly, no particular donkey which this sentence is in any way 'about'. The other, more attractive, possibility is that the pronoun is functioning as a bound variable, bound by an existential quantifier that is taken to be the meaning of the indefinite article. However, the only consistent representation available is essentially as follows:

$\exists x$ [donkey(x) & Every farmer who owns x beats x] (29)

The truth-conditions of this (which are directly reflective of the meaning), however, are very different from the truth-conditions of the sentence itself. This formula is true only when there is some donkey or other that every owner of it beats, which is far from the meaning of the sentence itself. There is no consistent way of representing the meaning by treating the indefinite article as an existential quantifier which binds the pronoun in the predicate of the sentence.

Replacing the quantificational analysis is one where indefinites are treated as contributing no existential meaning on their own, but only a free variable and a property ascription; so indefinites have neither inherent reference nor inherent quantificational force. The free variable implicitly contributed by the indefinite is bound by an operation of *text closure*. This is where the existential force arises. So, a single sentence such as the following has the representation given immediately below it, and then text closure operates to bind the variable as indicated:

A man walked into the room.
man(x) & x walked into the room
$\Rightarrow$ Text closure
$\exists x$ [man(x) & x walked into the room] (30)

Text closure is formulated in such a way that it operates over stretches of discourse, as more sentences are added. So a two-sentence discourse would be represented and operated on by text closure as follows:

A man walked into the room. He sat down.
man(x) & x walked into the room & x sat down
$\Rightarrow$ Text closure
$\exists x$ [man(x) & x walked into the room & x sat down] (31)

This analysis allows us to distinguish quantified NPs from indefinites, on the one hand, and allows us to treat the pronouns as free variables at the same time. Also, though not presented here, it offers a solution to the donkey sentences problem.

This approach raises issues of its own, as illustrated in the following sentence:

There is a man in the garden. The dog is barking at *him*. (32)

The 'There is …' construction in English quite plausibly introduces an existential quantifier of its own, rendering the variable contributed by 'a man' unavailable for binding by text closure. But the pronoun in the second sentence could be bound by text closure. If this is so, then the text would have the meaning 'Some man is in the garden. The dog is barking at someone'. Another problem with text closure is that the representation

$\exists x$ [man(x) & x is in the garden & the dog is barking at x] (33)

will be true also in cases where there are more men in the garden than just one. However, the original text means – or possibly strongly implies – that there is one and only one man in the garden.

Evans (1980) has argued that there is a need for still another category of pronoun, which he calls *E-type pronouns*. These pronouns, like the bound variable and co-referential pronouns, share all the same forms, but function differently: they are disguised definite descriptions, picking out a unique individual given the information present in the context. Informally, the analysis of the pronoun 'him' in (32) would be:

There is a man in the garden. The dog is barking at him (= *the man that is in the garden*). (34)

Since these descriptions can contain pronouns, or variables of their own, one can obtain solutions to problems like the following (an example that is often called a *pronoun of laziness*, a term coined by Peter Geach since it was a 'lazy' way to avoid repeating an entire NP):

The woman who deposited *her paycheck* in the bank was wiser than the woman who gave *it* to her teenage son. (35)

In this case, analyzing 'it' as meaning 'her paycheck', with 'her' in this instance assigned the same value as the second woman rather than the first, will give the right reading. However, on a co-referential reading (or a bound variable reading) the paychecks would have to be one and the same.

IDENTITY OF SENSE AND IDENTITY OF REFERENCE ANAPHORA

A traditional distinction is made between what are called 'identity of sense' and 'identity of reference' anaphora. The distinction between sense and reference goes back to the writings of the philosopher Gottlob Frege. In the case of NP meanings, this distinction concerns whether the individuals designated by the antecedent and the anaphor must be interpreted as identical. So, in (36a) the cars driven by Lyle and Maria must have been the same; however, in (36b) they need not:

a. Lyle drove *a car*. Maria drove *it*, too.
b. Lyle drove *a car*. Maria drove *one*, too. (36)

The difference between the anaphors 'it' and 'one' (the latter taking a noun meaning as its antecedent) would seem to suggest that anaphors themselves fall into these two classes. While this is so to a certain extent, many instances of anaphora can be identified in which the same form can play both roles. Consider the following:

a. *The President* (of the United States) walked off the plane. *He* waved to the crowd.
b. *The President* is elected every four years. *He* has been from a southern state ten times. (37)

The *reference* of the phrase 'The President' is whoever happens to be in that office at the time – currently it is George W. Bush; the *sense*, on the other hand, is that which picks out the president at the time, whoever it may be. In (37a), 'he' refers to a certain individual – Bush, for instance. The sentence 'he' appears in would be synonymous with saying 'Bush waved at the crowd'. In (37b), 'he' is anaphoric to the sense of the term, not its reference. It does not follow that any particular president, such as the current one, has been from a southern state ten times. Rather, this instance of the pronoun is talking about the presidents of the USA across time, regardless of who that individual may currently be. That is, it refers to the sense of the antecedent, not its reference.

When we turn to other types of anaphora, it is more difficult to make this sense/reference distinction. Consider null VP anaphora:

Zelda will *get up early* if Harry does____. (38)

The question that arises in this case is whether VPs themselves have a sense/reference distinction in their meanings to begin with. If, for instance, VPs have individual events as their reference, and have classes of events as their sense, then VP anaphora would be sense anaphora (as presumably Harry waking and Zelda waking would be distinct events). One can make reference to individual events by using the pronoun 'it', as exemplified below, but VP anaphora does not appear to ever make reference to events in this particular way:

The train blew its whistle. *It* (= the blowing of the whistle) was heard for miles. (39)

A similar situation holds for anaphora to sentence meanings. In a Fregean analysis, the sense of a sentence is a proposition, and its reference is a truth-value (T or F). However, with Null Complement Anaphora, which takes sentences as antecedents, the proposition rather than the truth-value is clearly the value assigned to the anaphor, as any other proposition with the same truth value (e.g. 'Grass is green') does not yield a synonymous sentence:

Bruno was selling drugs. When the FBI found out____, he was arrested. (40)

Thus, the sense/reference distinction is most useful in describing anaphora to NP meanings.

PRAGMATIC ANAPHORA

Pragmatics, that is knowledge of how the world works and what it contains, the circumstances under which a sentence is uttered, and of how language is used, is crucial for the study of anaphora. In most instances, a pronoun or other anaphor could, in principle, find more than one unique antecedent in the sentence or discourse, as in the following:

Mary told the *woman* talking to *her sister* that *Lesley* was sick today. *She* then turned and walked away. (41)

While 'she' could, in principle, find any of the previous NPs as its antecedent, in practice only one 'makes sense' and so is the one that is readily understood (in this instance, Mary). *Centering Theory* is one proposal that attempts to deal with this phenomenon (Grosz *et al*., 1995).

Another area requiring pragmatic knowledge to resolve reference of anaphora is *bridging inferences* (Clark, 1975). The listener or reader must make use of real-world knowledge to interpret a definite NP appropriately. For example:

John bought *a new car*. *The engine* was painted bright red. (42)

Here, one knows that the engine is the engine in the car that John bought, making use of real-world knowledge that cars have engines.

Much work in pragmatic anaphora focuses not on the process of selecting an appropriate antecedent from candidates given in the text or discourse, but on instances where the sentence or discourse itself provides no possible antecedents for an anaphor. For instance, imagine I was standing on the street with someone else when a man walks by very abruptly. Under these circumstances I can say:

He appears very upset. (43)

In so doing, I refer to the man that just walked by even though there is no expression within the previous discourse to serve as an antecedent for the pronoun. The man himself, in some sense, provides the 'antecedent' for the pronoun. When elements themselves in the real-world context of use provide the values for anaphoric expressions, they are said to be *pragmatically controlled*.

The example above might suggest that perceptual evidence establishes possible antecedents for *deictic* uses of pronouns. However, having the referent perceptually available is not always necessary. Consider the case where I am walking down the hallway at work, and a student is knocking on the door of the office of another faculty member. I can say, under the circumstances:

I haven't seen *her* today. (44)

even though the professor is not perceptually available for reference at the time. Thus, some contexts are 'rich' enough to support pragmatic control even in the absence of who or what is being referred to.

Most (but not all) instances of anaphora may be pragmatically controlled, including certain instances of reflexive pronouns and *logophoric* pronouns. These are pronouns, indicated by specialized forms in some languages, which are canonically used in indirect discourse to make reference to the person whose speech is reported (e.g. 'Ariel said that *he*[logophoric] was going to write a paper'). Below are instances of other types of anaphora that may be controlled pragmatically:

a. [Picking up a coat from the coat-check attendant] '*This* is torn!'
b. [Pointing through the glass at the candy counter] 'A green *one* and a red *one*, please.'
c. [Sally hides cigarettes in her room. Her sister, seeing this, says:] 'Better hope our parents don't find out____.'
d. [Trying on suits, and the salesman says:] '*Which* appeals to you most?' (45)

Certain instances of anaphora cannot be pragmatically controlled (Hankamer and Sag, 1976). These are the instances of *surface anaphora*, which, unlike *deep anaphora*, require a specifically linguistic antecedent. The distinction between deep and surface anaphors hinges not only on whether they may be pragmatically controlled, but also on whether, when there is a linguistic antecedent, the syntactic details of the antecedent determine the possibility of it serving as an antecedent, regardless of what meaning is expressed (which applies to surface anaphora but not deep).

Gapping, null anaphora to a verb or verb complex, requires an explicitly (surface) linguistic antecedent, even in very clear contexts, and cannot be pragmatically controlled; the example below is not felicitous:

[Bob throws a baseball] '. . . and Cary, a basketball.'
(Contrast with: 'Bob threw a basketball, and Cary, a baseball.') (46)

Sluicing likewise requires a linguistically introduced 'surface' antecedent, so the following too sounds strange:

[From outside, a scream; a shot is fired; and a thud] 'I wonder who____?' (47)

Similarly, the phenomenon of bound variable pronouns is not amenable to pragmatic control.

Articulation: Dynamic Models of Motor Planning

Advanced article

Kevin G Munhall, Queen's University, Kingston, Ontario, Canada

CONTENTS

The complex muscular system of the human vocal tract changes states rapidly and flexibly during fluent speech. The planning and control system responsible for this remarkable behavior must coordinate the spatial and temporal aspects of movement for a large number of independent articulators. Current models suggest that detailed representation of vocal tract movements and the acoustic consequences of those movements is required.

INTRODUCTION

All human cultures communicate primarily by using spoken language, and the children of these cultures acquire a remarkable level of articulatory skill by their second birthday. Although talking may thus be the most common and natural of human activities, it is still very much a scientific mystery. The linguistic, cognitive, motoric and neural mechanisms responsible for talking have remained beyond the grasp of a multidisciplinary research effort. As Gallistel (1999) has stated, there appears to be an inverse relationship between the apparent ease of performing an activity and the computational apparatus required to account for the behavior.

It is now clear that a complete analytic understanding of the production of speech will require the solution of a number of general motor control problems, as well as some problems that are relatively unique to oral language production. These problems include accounting for the mapping between a symbolic linguistic representation and a biomechanical system, the learning and production of sound categories, the coordination of a large number of movement systems so that the temporal and spatial requirements of articulation are met, and the accomplishment of this complex movement in real time. This article briefly summarizes articulatory phonetics and then considers current views of the way in which the nervous system solves the speech motor control problem.

ARTICULATORY PHONETICS

Articulatory phonetics is traditionally defined as the study of the way in which the sounds of a language are physically produced. This includes a description of vocal tract acoustics and the key aspects of sound production for consonants and vowels. Briefly, speech production involves the generation of sound (e.g., by the vocal folds) and its filtering by the acoustic properties of the vocal tract (size, shape, wall characteristics, etc.). This separation of source and filter has been the standard model of speech research since the middle of the twentieth century (Chiba and Kajiyama, 1941/1958; Fant, 1960), but the precise details of the process are still being elucidated.

SOURCE CHARACTERISTICS

During speech there are a number of different sources of sound. The primary source of sound is the vibration of the vocal folds. Through the activity of a complex muscle framework, the frequency, amplitude and mode of vocal fold vibration can be controlled. The muscular control of voicing has been reviewed elsewhere (Honda, 1995), as has the laryngeal anatomy and physiology (Titze, 1994). These attributes of laryngeal behavior produce the perceived pitch, loudness, and quality of voicing, and are used to signal segmental, prosodic, and paralinguistic information.

Our understanding of this subsystem of speech has depended on converging evidence from different experimental techniques and approaches. Electromyographic studies of humans during voicing (Honda, 1995), animal and cadaver studies of vibration (Kakita *et al*., 1981), photographic and

imaging research during speech (Hirose, 1988), and sophisticated biomechanical models (Titze, 1973, 1974) have revealed a vocal articulation system the behavior of which results from tuning the patterns of muscular tension to control the tissue biomechanics of the vocal folds themselves.

In addition to vocal fold vibration, sound is produced at a number of locations in the vocal tract above the larynx. This mainly occurs during consonant production (e.g., stop consonants and fricatives), and it involves sound being created through the manipulation of the air flowing through the oral cavity. The sudden release of air during the production of stop consonants produces an acoustic burst that varies depending on the air pressure, position of constriction in the vocal tract, and release movements. Frication is generally produced by air rushing though a small opening.

The characteristics of fricative sounds are similarly determined by the air pressure and position of constriction, but also by the details of the small channel through which air rushes, and whether or not the air jet strikes an obstacle such as the teeth. The articulatory conditions that are required for producing these sounds have been studied using a range of different techniques, such as electropalatography (Hardcastle and Hewlett, 1999), physical and computational models (Shaddle, 1985), electromyography, and kinematic measurements of articulator movement (Löfqvist and Gracco, 1997).

FILTER CHARACTERISTICS

The sounds that are produced in the vocal tract are modified or filtered by the acoustic properties of that structure. These filtering characteristics are known as the transfer function of the vocal tract, and include the cross-sectional area, length, and wall characteristics. Although there has been a general understanding of both vowel and consonant production for more than 100 years, the details of the filtering aspect of articulation are still being revealed. This slow progress is partly due to the relative inaccessibility of the speech articulators, as most of the determinants of the vocal transfer function are internal and not directly accessible to measurement without invasive recording techniques.

According to the simple textbook view, vowels are distinguished by a small number of articulation parameters (e.g., tongue height, front–back location of the constriction, lip roundedness) and consonants by a different but similarly small number of articulation parameters (e.g., place of articulation, manner of articulation, voicing). However, this textbook view significantly under-represents the full complexity of articulation. At least two aspects of this simplification should be noted. First, vowel and consonant acoustics are determined by the shape of the entire vocal tract. The gross details of this have been known since the first X-ray studies of speech (for a summary of these studies see Moll, 1960). Figure 1 shows two-dimensional magnetic resonance imaging (MRI) views of the three English vowels /i/, /u/, and /a/. As can be seen, the surface of the tongue, lips, jaw, pharynx, velum, and larynx changes position for each vowel to produce a unique transfer function. New developments in imaging of the vocal tract have revealed intricate three-dimensional shape changes associated with different phonemes (for a review of progress in imaging the shape of the vocal tract, see Munhall, 2001). Secondly, speech sound production involves movements, not a sequence of vocal tract configurations. According to the textbook

Figure 1. Mid-sagittal view of the vocal tract during vowel production. The vocal tract shapes for the vowels (a) /i/, (b) /u/, and (c) /a/. Figure provided by M. Tiede.

view, the position of a few key articulators at one point in time is used to describe the sound. In contrast, what really characterizes fluent speech is the seamless flow of gestures of the entire vocal tract.

Both of these factors contribute to the difficulty in mapping between traditional phonetic descriptions of speech and the reality of articulation. During speech the vocal tract is continuously changing in many dimensions, with the articulations for a given sound varying according to the context. However, the traditional phonetic description depicts speech as a series of static, invariant postures where only a few key dimensions are essential. An account of articulatory phonetics that recognizes its dynamic nature must depict speech as a motor skill.

Timing and Coordination

In order to control the vocal tract during speech, the nervous system must pattern the muscle activations of a large number of articulators so that the resultant movement paths shape the vocal tract properly. Because of the large number of degrees of freedom of the vocal tract, the spatial paths in articulation can be complicated. Figure 2 shows a mid-sagittal view of movement paths of the jaw and three points on the tongue. The speaker is uttering the following phrase: 'the oleander is a flower'. As can be inferred from the changes in articulator positions, the vocal tract shape is changing continuously.

The timing of muscle activations required to produce speech such as this also requires precise

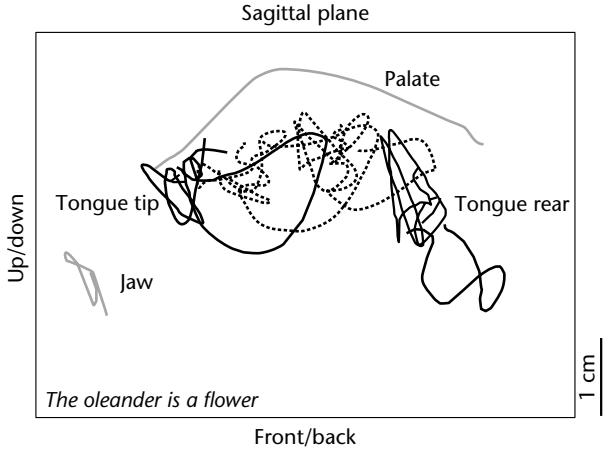

Figure 2. The movement paths of the jaw and three positions on the tongue during production of the utterance 'the oleander is a flower'. Figure provided by V. Gracco.

control, and the muscle activation generates patterns at many temporal scales. During the production of consonants and consonant clusters, coordinated movements between articulators can occur within tens of milliseconds, and even within a single articulator such as the tongue tip, successive movements can be coordinated to occur within 50 ms (Kent and Moll, 1975). At the syllable level, there is evidence of temporal organization that spans hundreds of milliseconds (for a recent example see Shaiman, 2001). At longer temporal spans there is a tradition of characterizing languages based on their rhythm class. For example, Japanese is classified as a mora-timed language in which strings of equal-duration mora are considered to be produced. However, Warren and Arai (2001) have recently published a critical review of mora timing.

Explanations for this complex behavior have been hindered by high levels of variance in the measured data. For both temporal and spatial descriptions of speech, the consistent impression is one of coordination but also of variability from one trial to another. The potential sources of such variance are manifold, including biomechanical, social, linguistic, and environmental contexts. Speaking rate, lexical and emphatic stress, and syllabification can vary from one repetition to another. In natural conversation the talker's mood, intent and social attention, as well as the conceptual and emotional meaning of a message, are all transmitted in parallel with phonetic information by subtle differences in the way in which words are spoken. These subtle differences are produced by systematic modifications to the movement timing and paths of the oral articulators. This variability that characterizes natural speech suggests that the control system must be programming articulation in real time and balancing many simultaneous requirements.

MODELING SPEECH PRODUCTION

In order to understand such complex behavioral organization as that of the speech motor control system, both experiments and sophisticated models are required. A common strategy is to identify the significant behavioral patterns and then decide how best to account for those patterns. Part of the difficulty that faces researchers is knowing what parts of behavior should be attributable to what parts of the planning and production process. Language planning involves many different stages and processes (e.g., semantic, syntactic, lexical, phonological; for one account of these stages, see Levelt, 1989), and speech motor control involves

additional stages of planning (Munhall *et al*., 2000; Perkell *et al*., 2000). Any single observation about articulation could thus be attributed to many parts of this complex chain of events. For example, context sensitivity or coarticulation in speech has been attributed to serial planning processes that take into account upcoming phonemes in order to plan smooth trajectories (Henke, 1966). However, David Ostry and his colleagues (Ostry *et al*., 1996; Perrier *et al*., 1996) have demonstrated that kinematic patterns due to speaking rate changes and coarticulatory context could, in principle, fall out from the physiology of the articulators. In their simulations, apparent context effects can be reproduced by modeling realistic physiological structures such as the jaw. The input to their jaw model does not take context into account, but the output is a smooth trajectory in which the articulator and muscle dynamics significantly shape the movement form to reproduce coarticulation effects.

The success of the research by Ostry and his colleagues depended on their dynamic modeling of the jaw and its muscle system. The term 'dynamics' is used here in a number of senses. First, it is used to refer to the general study of movement. Secondly, the term is used to refer to a subcomponent of the general study of movement that deals with forces (as opposed to kinematics, which deals with spatial descriptions of movement). Finally, it is used to refer to the behavior of complex nonlinear systems (so-called dynamical systems). A dynamic model of the vocal tract in all of these senses is necessary to test linguistic models of timing, phonological organization, etc. This model would represent the 'plant' or the physiology and biomechanics that are actually being controlled. It would also represent the complex interactions of control signals, biomechanics, and reflex coupling that are a part of stable movement. Unfortunately, such a complete model is currently beyond the scope of the field. To model the plant alone accurately is a daunting task. Histological, kinematic, dynamic (force), and myoelectric parameters are required for all of the musculoskeletal systems in the vocal tract, as well as good estimates of the three-dimensional morphology of the articulators. Many of these parameters are not available at present, and some are difficult if not impossible to acquire using current technology.

Models of individual articulators such as the vocal folds (Titze, 1973, 1974, 1994), the tongue (Wilhelms-Tricarico, 1995), the jaw (Laboissièrre *et al*., 1996), the tongue–jaw complex (Sanguineti *et al*., 1998; Dang and Honda, in press) and the face (Lucero and Munhall, 1999; Pitermann and Munhall, 2001) have been constructed with simulations of the tissue biomechanics (e.g., mass, stress/strain characteristics), muscle physiology (e.g., length tension characteristics of force development) and morphology. Although these simulations all involve some simplification of the articulator being studied (e.g., simplified geometry or finite element approximation of tissue structure), the models have played an important role in advancing the study of speech motor control. They have revealed the extent to which articulatory phonetics can be influenced by the physiological and biomechanical substrate of the vocal tract (Shiller *et al*., 1999). Furthermore, they have indicated that issues such as force, stability, and feedback processing are central problems for articulatory phonetics.

More global models of articulation have been proposed, which involve even more extensive simplifications of the oral motor mechanisms than the individual articulator models. However, these models address more complex phonetic output by controlling the vocal tract as a whole over time.

Saltzman's task dynamic model (Saltzman, 1986; Saltzman and Munhall, 1989) controls a set of stylized model articulators in a mid-sagittal vocal tract. The model describes the behavior of a set of 'tract variables' that refer to constrictions along the longitudinal axis of the vocal tract. The behavior of these tract variables is determined by a number of influences on the model articulators associated with the constrictions. For example, the behavior of the lip aperture tract variable is determined by the manner in which the lips and jaw are coordinated, as well as by the sequence of movements involving those articulators. The strengths of this model include its explanation of the coupling between articulators during articulation, and its focus on a task-level frame of reference in motor planning. The model can account for a number of important articulatory phenomena, such as some aspects of coarticulation and compensation following unexpected perturbations. When loads are applied to the lips or jaw, compensation from other articulators to achieve a goal at the task level is observed. For example, loads applied to the lips result in compensatory changes in the lips and jaw (Abbs and Gracco, 1984; Gracco and Abbs, 1985, 1988) as well as in the larynx (Munhall *et al*., 1994). The task dynamics model reproduces these findings and others. However, the model's vocal tract and articulator degrees of freedom are greatly simplified, and the articulators themselves are massless, with no physiology or biomechanics represented.

Another global model has been proposed by Guenther (Guenther, 1994; Guenther *et al*., 1998). The DIrections in auditory space to Velocities in Articulator space (DIVA) model represents a series of mappings between different frames of reference in speech motor control (e.g., auditory to articulatory mapping, articulatory to auditory mapping, phoneme to auditory mapping). These mappings are learned using neural networks trained in a 'babbling' phase in which random settings are applied to the articulator system and the acoustic consequences are used as feedback (for a similar approach, see Bailly *et al*., 1997). Like the task dynamics model, a series of key speech motor control phenomena are accurately replicated by the model. For example, when subjects are asked to speak with a bite block between their teeth, they are quickly able to produce normal vowel acoustics, even though the configuration of individual articulators may be unique. The DIVA model can reproduce this finding.

The DIVA model has a number of important features. It includes mappings between perceptual and motor systems as well as kinesthetic and acoustic feedback representations of speech. It involves learning, and it has been extended into a developmental model (Callan *et al*., 2000). Finally, it is consistent with current views on the detailed representations required for motor control (Wolpert and Kawato, 1998; Wolpert *et al*., 1998). Perkell *et al*. (2000) have described these detailed representations in DIVA. However, like the task dynamics model, the DIVA model is not controlling a realistic vocal tract. The work to date has used Maeda's articulatory synthesizer (Maeda, 1990), which is a two-dimensional mid-sagittal representation with stylized articulators that have no biomechanics or physiology.

An ambitious statistical approach has been developed by researchers at Advance Telecommunications Research (ATR) laboratories (Kawato, 1989; Hirayama *et al*., 1993, 1994; Vatikiotis-Bateson *et al*., 1993, 1994; Wada *et al*., 1995; Yehia *et al*., 1998, 2000). This model differs in many ways from existing models of speech motor control (Saltzman, 1986; Saltzman and Munhall, 1989; Guenther, 1994) in that it attempts to take into account the dynamics of the actual articulatory system and the fact that all parameters are derived from observed data. Briefly, the current model attempts to simulate the complete process from linguistic primitives to the dynamics and kinematics of the articulatory system, and finally to the output acoustics. The computation of motor commands (and thus movement trajectories) is constrained by global settings of the speech apparatus that last for a number of segments (e.g., for speaking rate). Linguistic units are provided as input to the speech-planning system and converted to a sequence of targets in vocal tract, acoustic, and articulator planning spaces.

The actual computation of the trajectories requires a knowledge of the physiological and biomechanical structures of the vocal tract in order to deal with the complex and nonlinear mappings between muscle activity and force, muscle force and movement, movement and speech acoustics, etc. It has been postulated that the control system builds up this knowledge though experience during speech development. In other words, the nervous system learns dynamic models of its own motor system as an aid to controlling the complex dynamics of articulation. The ATR group was among the first to recognize the importance of these 'internal models' of the articulator system as a major component of the control system in speech. An internal model is a neural representation of the spatial (kinematic), force (dynamic), and feedback (e.g., acoustic, proprioceptive) characteristics of movements that could be used by the nervous system to predict movement outcome (Miall and Wolpert, 1996; Kawato, 1999).

Like Guenther's model, the structure of the ATR model is composed of a series of learned mappings, and the plausibility of this statistical mapping has been demonstrated for a number of different dimensions and articulator systems (Yehia *et al*., 1998). This is a complex modeling program, but one that is addressing the full complexity of the articulation process (for an overview of the approach, see Munhall *et al*., 2000).

CONCLUSION

The speech motor system is one of the most complex human movement systems. The study of its control requires detailed models of the articulators in action, including simulations of their physiology and biomechanics. Surprisingly, recent studies suggest that the nervous system itself requires models of its own articulator system to accomplish trajectory planning. Research progress in this area will depend on the integration of detailed individual articulator models into global models of the full articulation process.

Binding Theory

Intermediate article

Eric Reuland, Utrecht University, Utrecht, The Netherlands

CONTENTS

Languages contain elements such as pronouns and anaphors or reflexives, which lack lexical/semantic content and may or must depend on another element for their interpretation. These dependencies cannot always be established freely, but are subject to structural conditions.

INTRODUCTION

In any language, distinct expressions may be used to refer to the same object. For instance, English 'morning star' and 'evening star' both refer to the planet Venus. Such expressions are said to *co-refer*. Here, co-reference holds on the basis of an empirical fact discovered by astronomers. In other cases speakers' intentions suffice to establish co-reference. The pronominal 'he' can be used to refer to any object that is linguistically classified as masculine and singular, as in 'John's mother thought he was infallible'. Here, 'he' may refer to John but also to some other masculine individual. However, in 'no one believes he is infallible' there is no individual such that both 'no one' and 'he' refer to that individual. Yet under the most salient interpretation 'he' does depend on 'no one' for its interpretation: the interpretive dependency is linguistically encoded, and instantiates *binding*. Binding is subject to constraints which cannot be explained on the basis of logic alone. Rather, they provide us with a window into the computational principles underlying language.

THE BINDING CONDITIONS

The theory of A(rgument)-binding explains the interpretive dependencies between phrases in *argument positions*, or *A-positions*, briefly *arguments*. A-positions are positions for phrases with grammatical functions, such as subject, object, etc., to which a predicate assigns a semantic role (agent, patient, beneficiary, etc.), or of which a predicate governs the case (nominative, objective, etc.) In (1), for instance, all the nominal expressions are arguments in A-position:

The old baron was crossing the bridge at dusk with a ramshackle carriage. *The driver* was visibly tired. Suddenly, the carriage tipped over and *the man* fell into the swamp. When *he* had pulled *him/himself* out there came no end to *his* tall tales. (1)

Arguments can be dislocated, ending up in a non-A-position (by topicalization, question formation, etc.), as in (2); *t* indicates their canonical position:

a. *Him*, I never believed the baron to have pulled out *t*
b. *Which man* did he think *t* fell from the bridge
c. *Himself*, the driver pulled *t* out immediately (2)

Binding theory treats the italicized phrases as if they are in the position of *t* (see also below).

Arguments are classified as R-expressions, pronominals, or anaphors. If the head of a phrase has lexical features it is an *R-expression*. Thus 'the old baron', 'no one', 'everyone', 'which man', etc., are all R-expressions. R-expressions are interpretively independent. *Pronominals* ('I', 'you', 'he', etc.) are only specified for *person*, *gender*, and *number* (the ϕ-features). They may, but need not, depend on another argument for their interpretation and they can be accompanied by a pointing gesture, that is, used deictically. *Anaphors* are referentially defective nominal elements: they cannot be used deictically. (A word of caution: some of the literature uses *anaphor* for a class including pronominals, and *reflexive* for anaphor in the present sense.) Anaphors are generally interpreted by binding. Under certain conditions anaphors can, nevertheless, remain unbound (see below). Anaphors come in two types: *simplex anaphors* and *complex anaphors*.

Also reciprocals, such as *each other*, behave as anaphors, although their semantics is more complex (see Heim *et al*., 1991). Also, elements such as '(his/her) own', '(the) other', '(the) same' are in some sense anaphoric. Here, we discuss only simplex and complex anaphors.

Simplex anaphors are like pronominals that are underspecified for certain features. Quite generally, specifications for *number* and *gender* are lacking; a *person* specification may be lacking as well (as in Russian *s'eb'a*, (Mandarin) Chinese *ziji,* or Japanese *zibun*). English lacks simplex anaphors, but cross-linguistically they abound. Some well-studied examples are Dutch *zich*, Icelandic *sig*, Chinese *ziji*, and Japanese *zibun*. Their interpretation often corresponds to English 'himself'.

Complex anaphors generally consist of a pronominal or a simplex anaphor and some other element. These other elements may be of varied provenance. Some are historically intensifiers, and currently semantically virtually empty, such as English *self* in 'himself', Dutch *zelf* (*zichzelf*), and Icelandic *sjalfan* (*sjalfan sig*). Many languages use body-part reflexives. These are based on an element that occurs independently as a nominal head designating a part of the body such as 'head', 'bones'; but also, designations such as 'soul, spirit, reflection' are found (see Schladt, 2000). For instance, in Basque 'the father killed himself' is literally expressed as 'the father killed his head'. The form *bere burua* 'his head', which in this sentence means 'himself', is also used in 'he put the cap on his head'. Other languages double a pronominal form, as in Cachur (spoken in Daghestan) and Old Syriac (a Semitic language), or put a special marker on the verb as in Kannada, a Dravidian language (see Lust *et al*., 2000).

Anaphor binding and pronominal binding differ with respect to allowing 'split antecedents', as in 'John talked to the girls about themselves' and 'John talked to the girls about them'. The pronominal 'them' can refer to John (subject) and the girls (indirect object) together (a 'split' antecedent); the anaphor 'themselves' only allows 'the girls' as an antecedent. (Like many other linguistic tests, this one must be used with caution.)

If *a* binds *b*, *a* is the *antecedent* of *b*. Since binding relations cannot be directly read off linguistic expressions they are indicated by a system of *indexing*. Each argument is assigned an integer as its index: in practice, one uses subscripts such as *i*, *j*, *k*, etc. If *a* and *b* have identical subscripts they are *co-indexed*. Thus, in (a_i … b_i), *a* and *b* are co-indexed. Since indices are just linguistic markers, two expressions can still be assigned the same object in some outside world if they are not co-indexed ('morning star' and 'evening star' are not necessarily co-indexed). Binding without co-indexing is not possible, though. In order for *a* and *b* to be co-indexed, (3) must hold:

> *a* and *b* are nondistinct in features for person, number, and gender (3)

Nondistinctness, rather than identity of features, is required for co-indexing, since in many languages one anaphoric element can have masculine or feminine, singular or plural antecedents. Dutch *zich* and Icelandic *sig* are like that; but they are specified as third person, since they cannot have first- or second-person antecedents. In other languages (for instance, Slavic languages such as Russian) a person specification is also lacking, and we find one anaphoric form for all persons.

Binding relations can also be represented in a *logical syntax notation*. In such a notation, pronouns and anaphors are represented as variables; R-expressions, such as 'every old man', are analyzed containing a *determiner* ('every') and a *set expression* which consists of a *variable* (not overtly represented) and a *restriction* ('old man'). A sentence such as 'Every old man sleeps' can then be represented as 'for all individuals *x*, provided you pick your individuals from *x*'s that are old and that are men, it is also the case that *x* sleeps', or, in formula, $\forall x$ *((old (x) & man (x)) → sleeps (x))*. Often an informal notation is used, in which determiner and restriction stay together, as in $Every\ old\ man_x$ *(x sleeps)*, or $John_y$ *(y sleeps)* (= John sleeps). Here, 'Every old man' and 'John' bind their respective variables. Using this notation, A-binding can also be represented by variable binding. 'Translating' 'himself' in 'John saw himself' as the variable *x*, yields $John_x$ *(x saw x)* as a logical syntax representation. Similarly, in 'Every boy expected Mary to see him', 'him' can be translated as a variable bound by 'Every boy', as in the informal structure $Every\ boy_x$ *(x expected Mary to see x)*.

For binding to obtain, the binder must *c-command* the bindee in the syntactic structure. The standard definition is (4):

> *a* c-commands *b* if and only if *a* does not contain *b* and the first branching (or maximal) projection dominating *a* also dominates *b* (4)

Binding by a non c-commanding antecedent is impossible, as illustrated by the ungrammaticality of *$John_i$'s mother loves himself$_i$*. Putting both conditions together yields (5) as the standard condition on

binding ('iff' = 'if and only if'):

a binds *b* iff *a* and *b* are co-indexed and *a* c-commands *b* (5)

Outline of the Canonical Binding Theory

Over the last few decades, the English system has served as a standard model of the binding theory. Its canonical form is presented in Chomsky (1981), and elaborated in Chomsky (1986).

Anaphors and pronominals impose specific conditions on their binders. An anaphor must be locally bound: its antecedent must be sufficiently 'nearby'. A pronominal may be bound, but not locally: its antecedent must be sufficiently 'far away'. An R-expression cannot be bound at all; that is, it must be *free*. The notion of a *governing category* provides a measure for the relevant distance. As a first approximation, pronominals and anaphors are in complementary distribution. This is captured by the binding conditions in (6):

Binding Conditions
(A) An anaphor is bound in its governing category
(B) A pronominal is free in its governing category
(C) An R-expression is free (6)

Governing category is defined in (7):

γ is a governing category for α if and only if γ is the minimal category containing α, a governor of α, and a SUBJECT accessible to α (7)

The SUBJECT of a category is its most prominent nominal element (including the agreement features in finite clauses). This is illustrated in (8). Binding is indicated by italics; $[_{\text{GC-}\alpha}]$ stands for the *governing category* of α.

a. *John* expected $[_{\text{GC-himself/him}}$ the queen to invite him/*himself for a drink]
b. $[_{\text{GC}-\text{himself/him}}$ *John* expected $[_{\text{Clause}}$*himself*/ **him* to be able to invite the queen]] (8)

(8) exemplifies the *Specified Subject Condition* (SSC); the governing category is the domain of the nearest subject to α. For 'him/himself' this is 'the queen' in (8a) and *John* in (8b).

Finite clauses are governing categories for their major arguments, including their subjects. Noun phrases with possessive phrases are governing categories for any other object they contain. There is a class of exceptions to this generalization, such as (9):

a. They expected that pictures of themselves would be on sale.
b. Max expected the queen to invite Lucie and *himself* for a drink. (9)

Sentences of the type *John$_i$ saw a snake behind him$_i$/?? himself$_i$* are also difficult to fit in with the binding theory of (6) (Chomsky, 1981, 1986). (See below for further discussion and references.)

Binding and Co-reference

A pronominal can be bound by an antecedent, but also be *co-referential* with it. Hence, there is a potential ambiguity when the antecedent is referential (if the antecedent is not referential no ambiguity can arise). The ambiguity surfaces in the two interpretations of (10):

a. Only Lucie loves her husband
b. Binding: (Of all the women) Only Lucie has the property *x* loves [husband of (*x*)]
c. Co-reference: (Of all the women) Only Lucie has the property (*x* loves *a*) & *a* = *the individual* (*for instance*, *Jack*) *who happens to be Lucie's husband* (10)

Readings as in (10b) are also called *sloppy readings*, readings as in (10c) *strict readings*. Consider next:

a. **John* saw *him*
b. We all know what's wrong with Oscar. Everyone hates him. $^{\text{ok}}$Even *Oscar* hates *him* (11)

Binding Condition B rules out (11a), but what about (11b)? Suppose 'Oscar' and 'him' are *co-referential*, being assigned identical values directly, what prevents this in (11a)? Rule I (Reinhart, 1983) regulates binding and co-reference:

Rule I: Noun phrase (NP) A cannot co-refer with NP B if replacing A with C, C a variable A-bound by B, yields an indistinguishable interpretation. (12)

In (11b), under co-reference Oscar is ascribed the property of *Oscar*-hatred: (*x hates him* & him = Oscar). Under binding the property *(x hates x)* = *self*-hatred is ascribed. *Oscar*-hatred and *self*-hatred are different properties. The fragment is only felicitous for *Oscar*-hatred. So, Rule I allows the co-reference interpretation. In (11a) the two interpretations are indistinguishable, hence Rule I rules out co-reference, leaving no well-formed interpretation

since binding is ruled out by Condition B (as it is in (11b)).

Applying (12) requires comparing two different derivations. The processing difficulties this entails have been proposed to explain the fact that children master Condition B at a substantially later age than Condition A (the 'delayed Condition B effect').

Binding and Reflexivity

Many languages have been investigated with binding systems outside the scope of the canonical binding theory. Results indicate that binding uses a modular system, in which the canonical binding conditions arise as special cases. Only a selection of results can be discussed here.

Many languages have a three-way distinction between pronominals, simplex anaphors, and complex anaphors, instead of the two-way distinction covered by the canonical binding theory; some (the Scandinavian languages) even have a four-way system, not counting reflexive possessives.

These systems show that binding interacts with reflexive properties of predicates. A predicate is *reflexive* iff two of its arguments (e.g. subject and object) are co-indexed (Reinhart and Reuland, 1993). A predicate can be *marked* as reflexive by its intrinsic lexical properties (exemplified in English by 'behave' or 'wash'). In English such predicates allow the direct object to be absent; Dutch has a simplex anaphor (*zich*) in such cases. If a predicate is not intrinsically reflexive, argument co-indexing is not sufficient for a licit reflexive interpretation. Reflexivity must be licensed by an extrinsic reflexive marker operating on the lexical entry of the predicate. This is the effect of SELF-anaphors, that is, elements with English *self*, or Dutch *zelf*. For instance, nonreflexive *bewonderen* 'admire' requires the complex anaphor *zichzelf* 'himself', as in *George*$_i$ *bewondert zichzelf*$_i$/**zich*$_i$ 'George admires himself'. When the anaphor and its antecedent are not co-arguments, a complex anaphor is not required, since no reflexive predicate is formed, as in *Jan*$_i$ *voelde* [*zich*$_i$ *wegglijden*] 'John felt [himself slide away]', where the anaphor is a small clause subject.

Cross-linguistically, licensing may also involve clitics, pronoun doubling, body parts, verbal affixes, etc., with varying further syntactic and semantic effects.

Whether a SELF-anaphor must be locally bound is in part determined by its content, in part by its relation to a predicate. In Dutch, *zichzelf* must always be locally bound. In English, a SELF-anaphor is exempted from this requirement if it does not exhaustively occupy the argument position of a predicate. Compare the ungrammatical (8a) where it does, to (9b) where it does not. A discussion of bound versus exempt anaphors based on grammatical functions can be found in Pollard and Sag (1992).

In other languages, for instance Malayalam, the element licensing reflexivity need not be locally bound at all (Jayaseelan, 1997).

Local Binding of Pronominals

In many languages (including all Romance and Germanic languages except English), first- and second-person pronominals can be locally bound (as in French *Je me lave* 'I wash myself' or German *Du sahst dich im Spiegel* 'You saw yourself in the mirror'). An important factor allowing local binding of pronominals is underspecification. Benvéniste (1966) has shown that first- and second-person pronouns are not grammatically, but lexically, marked for number ('we' is not a plurality of 'I's). So, these pronominals are grammatically underspecified. This allows them to be locally bound, despite being true pronominals in all other respects.

Frisian (spoken in a northern province of The Netherlands) also fits this generalization. It has a two-way distinction: (1) a complex anaphor *himsels*, when the predicate is nonreflexive, i.e. where Dutch has *zichzelf*; (2) a pronominal (*him*/etc.) in all environments where Dutch has *zich*, violating Condition B for third person as well. However, Frisian *him*/etc. is also underspecified; not for number, but for Case. This is the reason local binding is allowed in all persons.

LONG-DISTANCE ANAPHORA

Many languages allow anaphoric elements with an antecedent beyond their governing category as defined in (7), or without any linguistic antecedent whatsoever. Icelandic has become a classical case (see Thráinsson, 1979), but there is also long-distance anaphora in English (see Reinhart and Reuland, 1993 for an overview and references). It is often claimed that long-distance anaphors are simplex (i.e. they consist of only one morpheme) and require a subject as their antecedent, but this is a rather rough characterization.

Icelandic *sig* requires an antecedent within an indicative clause, but if *sig* is in an infinitival clause its antecedent may be outside it. The same holds for the cognate forms of *sig* in other Scandinavian languages. Also, *sig* in a subjunctive clause may have a long-distance antecedent. Yet, there are differences

between subjunctives and infinitives. If the antecedency relation crosses a subjunctive, binding is not required: the antecedent need not c-command the anaphor, and the existence of a discourse antecedent (not linguistically expressed) may suffice:

> María var alltaf svo andstyggileg. ψegar Olafur$_j$ kaemi segδi hún sér$_{i/*j}$ áreidanlega aδ fara . . . (Thráinsson, 1991)
> Mary was always so nasty. When Olaf would come, she would certainly tell himself [the person whose thoughts are being presented – not Olaf] to leave [NB. (13) could not begin a story] (13)

Many languages admit anaphor binding which violates the SSC (see (8)). For instance, Russian allows binding across infinitival boundaries; Dutch allows binding into perception verb complements. Yet, in all these cases c-command must be respected.

There is evidence that *sig* in the subjunctive domain behaves like a pronominal instead of an anaphor. Such pronominal use of an anaphoric form is often called *logophoric*.

The term *logophor* was introduced by Hagège (1974) to characterize a paradigm of specialized pronominal elements in languages of the Niger-Congo group. Subsequently, this term has been generalized to all elements with the following characteristics (Clements, 1975, pp. 171–172):

1. logophoric pronouns are restricted to *reportive contexts* transmitting the words or thoughts of an individual or individuals other than the speaker/narrator;
2. the antecedent does not occur in the same reportive context as the logophoric pronoun;
3. the antecedent designates the individual or individuals whose words or thoughts are transmitted in the reported context in which the logophoric pronoun occurs.

Conditions (1) and (3) are not structural, but involve the discourse status of the antecedent. In the following Icelandic example these conditions are met and c-command is not necessary (in all other cases c-command and subject orientation are strictly enforced in Icelandic):

> Skoδun Jóns$_i$ er [aδ ζδ hafir svikiδ sig$_i$] . . . (Thráinsson (1991) opinion John's is that you have betrayed self (14)

Here, *Jón* holds the opinion expressed. (In (13) above, *ser* refers to the person whose thoughts are being presented.) If these conditions are not met, logophoric elements are infelicitous. The situation is more complex than the above quote indicates. In some languages logophoricity is restricted to verbs of saying, excluding thoughts; there may be special logophoric forms with respect to the adressee instead of the speaker, etc. (For more discussion of logophoricity the reader is referred to Sells (1987), and the extensive literature on Icelandic – see the Further Reading list for references.) Well-known further cases of elements that vary between a bound and a referential, logophoric, use are Japanese *zibun* and Chinese *ziji* (see Huang and Tang (1991) and Cole *et al*. (2000) for discussion and references).

Also, English allows a logophoric use of 'himself' (which is not mono-morphemic). Its sensitivity to the discourse status of the antecedent is illustrated by the contrast in (15). (15a) is presented from John's perspective, (15b) from Mary's:

> a. John$_i$ was going to get even with Mary. That picture of himself$_i$ in the paper would really annoy her, as would the other stunts he had planned
> b. *Mary was quite taken aback by the publicity John$_i$ was receiving. That picture of himself$_i$ in the paper had really annoyed her, and there was not much she could do about it (Pollard and Sag, 1992) (15)

It is an important result of these investigations that a systematic distinction exists between true long-distance binding and a logophoric use. A language may allow long-distance binding without admitting a logophoric use of anaphors; the converse holds as well.

CROSSOVER PHENOMENA AND PARASITIC GAPS

Crossover

Since binding is defined in terms of c-command and co-indexing, movement is expected to feed binding. (16) shows this with anaphor binding:

> a. — seemed to himself [John to have been incompetent]
> b. John$_i$ seemed to himself$_i$ [t_i to have been incompetent] (16)

The R-expression 'John', which cannot bind the anaphor 'himself' from its base position, can do so after *A-movement*. (16) involves an antecedent moving from one A-position to another.

Wh-movement, *topicalization*, *relativization*, etc., move a phrase to an *non-A- (= A′-) position*. The process of assigning scope to expressions such as 'everyone' has properties of covert A′-movement.

Pronominals can be bound by *wh*-phrases and by 'everyone':

a. Who$_i$ t_i complained that Mary damaged his$_i$ car?
b. Everyone$_i$ complained that Mary damaged his$_i$ car (17)

When A′-movement crosses a pronominal, two cases are to be considered. In (18) the pronominal c-commands the trace of the moved element:

a. He saw who?
b. *Who$_i$ did he$_i$ see t_i? (18)

(18) instantiates *strong crossover*. The *wh*-trace is an R-expression. 'He' binds the trace; this is a Condition C violation, which is strongly ungrammatical. (See Chomsky, 1982, p. 35 for an alternative account.)

In (19b) the pronoun does not c-command the base position of the *wh*-phrase that crossed over it:

a. His$_i$ mother loves who$_i$
b. $^{??}$who$_i$ does his$_i$ mother love t_i (19)

In (20) the object quantifier 'everyone' is assigned scope over the subject, resulting in a similar configuration:

a. His mother loves everyone
b. $^{??}$Every x_i [his$_i$ mother loves x_i] (20)

Both (19b) and (20b) are not felicitous, but also not as ungrammatical as (18b). Hence this phenomenon is called *weak crossover*. Reinhart (1983) argues that weak crossover violates the requirement that at surface structure the antecedent c-command the bound element from an A-position. It is easily seen that this requirement is violated in both (19) and (20). An alternative is based on the *bijection principle* (Koopman and Sportiche, 1982). This principle requires that a quantifier bind precisely one variable and that a variable be bound by precisely one quantifier. In (19b) and (20b) the quantifier ('who' or 'every') has to bind both the pronominal and its trace, which violates the biuniqueness requirement of the bijection principle.

Parasitic Gaps

A configuration that is reminiscent of weak crossover is found in so-called *parasitic gap* constructions (Chomsky, 1982 and references cited there). The construction is illustrated in (21). There are gaps in the object positions of both 'file' and 'reading' in (21a), and, similarly, in the object position of 'cook' and 'eat' in (21b), yet only one phrase has been extracted:

a. ?Which article$_i$ did John file t_i without reading e_i
b. ?This is the kind of food$_i$ you must cook t_i before you eat e_i (21)

Furthermore, only the direct object gaps of 'file' and 'cook' are in a position from which an element could have been moved. No elements can be moved out of a *without*-clause or a *before*-clause (these are so-called *islands for extraction*). This is brought out by the contrast resulting from filling one or the other position by a pronominal:

a. *Which article did John file it without reading *e*
b. Which article did John file *t* without reading it (22)

Filling the object position of 'file' with a pronominal, as in (22a), makes the other gap the only possible source for the *wh*-phrase, which results in full ungrammaticality. Hence, only one of the gaps can be a trace; the other one has a different status.

The licensing of the gaps in (23a, b), which correspond to the rightmost gaps in (21a, b), is parasitic on the existence of an extraction site resulting from A′-movement. If no such extraction takes place the structure is degenerate:

a. *John filed those articles$_i$ without reading e_i
b. *You must cook this food$_i$ before you eat e_i (23)

The main factors in the distribution of parasitic gaps are given in (24):

In the construction (A), where order is irrelevant and α, *t*, *e*, are co-indexed, in order for the parasitic gap *e* to be licensed (B) must hold :

(A) ... α ... *t* ... *e* ...
(B) i. α c-commands *t* and *e*
ii. *t* does not c-command *e* and conversely
iii. *t* is a variable (24)

From (24Bii) it follows, for instance, that a trace in subject position will not be able to license a

parasitic gap, as illustrated in (25):

*Which articles$_i$ t_i were filed without reading e_i (25)

The reason for the non c-command requirement in (24Bii) is that the 'parasitic gap' must be interpreted as a variable; i.e. it must be A′-bound. If it is bound by an operator such as the *wh*-phrase, the latter can assign it the content necessary for its interpretation. It must be licensed by an operator, since English does not generally allow pure null-pronominals. If the extraction site c-commands the parasitic gap the latter is bound by the trace, not by the operator. Hence, it will not be licensed. In (23) no phrase is able to bind the gap. In (25), on the other hand, the gap is bound by the trace. In neither case can the gap be interpreted. If the gap is assigned content by an operator, and interpreted as a variable, this violates the bijection principle, hence the relative marginality of (21).

CONNECTIVITY AND RECONSTRUCTION PHENOMENA

Can phrases satisfy or violate certain conditions via their traces, or not? The issue is called *connectivity*, and arises in binding, but also in the licensing of so-called *polarity* items. (26) illustrates polarity:

a. Nobody could see anything
b. *Anything$_i$, nobody could see t_i (26)

'Anything' must be in the domain of a negative (or, more generally, downward-entailing) quantifier such as 'nobody'. However, when 'anything' is fronted, this requirement cannot be satisfied via its trace.

For binding, however, (2) showed that pronominals, anaphors, and R-expressions behave as if they are in the position of their traces, when they are moved to an A′-position. That is, they *reconstruct*. Reconstruction is limited to overt A′-movement. A-movement does not show connectivity effects for binding, as illustrated in (27). Despite the fact that 'the claim …' originates from the trace position there is no Condition C violation in (27a), although there is in (27b):

a. The claim that *John* was asleep seems to *him* [t to be correct] (ok. *him* = *John*)
b. It seems to *him* that the claim that *John* was asleep is correct (*him* ≠ *John*) (27)

Where the moved phrase is complex and contains elements that are themselves in A-position more than just reconstruction may seem to be involved. (28a–c) are often taken to show that movement enlarges the domain of anaphor binding:

a. John said [that Bill liked that picture of himself best]
b. John wondered [[which picture of himself] Bill liked t best]
c. [which picture of himself] did John say [t' that Bill liked t best] (28)

In (28a) 'Bill' is the antecedent of 'himself', in accordance with Condition A. In (28b) and (28c) 'John' is also possible as antecedent of 'himself'. Moving 'which picture of himself' causes 'John' to be added as a possible antecedent. This follows if the governing category of 'himself' can be calculated from the source position of the moved phrase (t), its derived position, and also the intermediate t' position. (It is assumed that in (28c) 'which picture of himself' moves to its derived position via the C-projection of the embedded clause.)

Yet, sentences modeled on (28a) do not consistently disallow the matrix subject as an antecedent. Moreover, the latitude found here does not extend to pronominals and R-expressions, which can only be interpreted in their base position. Alternatively, then, reconstruction applies in all cases equally. The additional interpretations for 'himself' would still follow since, being the object of a picture noun, it is in an exempt position and can be interpreted logophorically.

Categorial Grammar and Formal Semantics

Intermediate article

Michael Moortgat, Utrecht Institute of Linguistics, Utrecht University, Utrecht, Netherlands

CONTENTS

Categorial grammar is a lexicalized grammar formalism based on logical type theory. A categorial lexicon assigns one or more types to the atomic elements of a language; the assembly of form and meaning is accounted for in terms of the rules of inference for these types, seen as formulae of a grammar logic. Cross-linguistic variation results from extending the invariant core of the grammar logic with facilities for structural reasoning.

INTRODUCTION

Categorial grammar, a linguistic framework with firm roots in type theory and constructive logic, is well represented in the logical and mathematical literature. This article puts the emphasis more on the categorial modeling of the cognitive abilities underlying the acquisition, use, and understanding of natural language. The sections below address two central questions. First of all, what are the invariants of grammatical composition, and how do they capture the uniformities of the form–meaning correspondence across languages? Secondly, how can we reconcile the idea of grammatical invariants with structural variation in the realization of the form–meaning correspondence?

The slogan 'parsing as deduction' concisely expresses the categorial perspective on these questions. A grammar, essentially, is given by an assignment of types to the elementary units in the lexicon. The type-forming operations have the status of logical connectives: determining whether an expression is well formed amounts to presenting a derivation, or proof, in the logic for these connectives. Natural-language expressions are signs, with a form and a meaning dimension. The categorial type language, consequently, is model-theoretically interpreted with respect to these two dimensions, and a derivation encodes an effective procedure for building up the structural organization of an expression, and for associating this structure with a recipe for meaning assembly.

The article is organized as follows. First, we focus on the form dimension of expressions. We identify the logical constants of the computational system, and study how the base logic for these constants can be extended with facilities for structural reasoning. Then, we see how the logical rules of inference for the type-forming operations can be read as instructions for meaning assembly, and how the structural rules determine which components of an expression can enter into the assembly process.

FORM

The Base Logic

Natural-language expressions are structured objects with a linear order and a hierarchical grouping. In categorial grammar, the traditional parts of speech assume the form of type formulae. The structure of these types mirrors the composition of the expressions they categorize. The set *Type* of type formulae is obtained as the closure of a small set *Atom* of *basic* types under a number of type-forming operations. Individual categorial grammars will differ with respect to the type-forming operations they employ. For our present purposes, the following clauses will be representative:

1. *Atom* is a subset of *Type*.
2. If A is a formula in *Type*, then $\Diamond A$ and $\Box A$ are too.
3. If A and B are formulae in *Type*, then $A \bullet B$, A/B, and $A\backslash B$ are too.

Basic types play a role similar to that of major constituents in phrase-structure grammar: they categorize expressions one can think of as

'complete'. Examples could be the types *np* for proper names, *s* for sentences, and *n* for common noun phrases. Languages can differ as to which basic type distinctions they make. The unary and binary operations provide a vocabulary to categorize expressions in terms of their constituent parts. Informally, a formula $A \bullet B$ categorizes an expression that can be decomposed into a constituent of type A followed by a constituent of type B. An expression with a fraction type A/B (or $B\backslash A$) is incomplete: it combines with an expression of type B on its right (or left, respectively) into an expression of type A. The unary type-forming operations are more recent additions to the categorial vocabulary. They can be thought of as features: an expression of type $\Box A$ issues a request for a feature to be checked; such an expression can be used as a regular A as soon as the $\Box$ feature is eliminated. The operation $\Diamond$ provides the means to perform the required feature-checking.

Frame semantics

To make this informal description precise, Došen (1992) and Kurtonina (1995) make use of *frame-based* models familiar from possible-world semantics for modal logics. For the categorial type language, a *frame* is a tuple $(W, R_\Diamond, R_\bullet)$. W is a nonempty set, the set of expressions. $R_\Diamond$ and $R_\bullet$ are binary and ternary relations over W, interpreting the unary and binary type-forming operations, respectively. One can think of $R_\bullet$ as the 'merge' relation: $R_\bullet xyz$ holds in case x is the composition of the parts y and z. Similarly, $R_\Diamond xy$ holds if the feature-checking relation connects y to x. One obtains a *model* by adding a *valuation* V assigning subsets of W to the atomic formulae. For complex types, the valuation respects the conditions below:

$x \in V(\Diamond A)$ iff there exists a y such that $R_\Diamond xy$ and $y \in V(A)$.
$x \in V(\Box A)$ iff for all y, $R_\Diamond yx$ implies $y \in V(A)$.
$x \in V(A \bullet B)$ iff there are y and z such that $y \in V(A)$, $z \in V(B)$ and $R_\bullet xyz$.
$x \in V(C/B)$ iff for all y and z, if $y \in V(B)$ and $R_\bullet zxy$, then $z \in V(C)$.
$x \in V(A\backslash C)$ iff for all y and z, if $y \in V(A)$ and $R_\bullet zyx$, then $z \in V(C)$.

Type computations, soundness, and completeness

On the proof-theoretic level, we are interested in a deductive system to perform type computations $A \to B$ ('type B is derivable from type A'). We want this system to be faithful to the interpretation of the type-forming operations, in the sense that $A \to B$ is provable iff $V(A) \subseteq V(B)$, for every frame F and valuation V. Such a system is 'sound' and 'complete'.

An axiomatization satisfying the soundness and completeness requirements starts with an identity axiom $A \to A$, and an inference rule allowing one to conclude $A \to C$ from premises $A \to B$ and $B \to C$. Semantically, these express the reflexivity and transitivity of the derivability relation. In addition, one has the inference rules below, establishing the relationship between the interpretation of $\Diamond$ and $\Box$, and between $\bullet$ and left and right division $\backslash$ and $/$. These patterns turn $(\Diamond, \Box)$, $(\bullet, /)$, and $(\bullet, \backslash)$ into what are known as 'residuated pairs' in algebra, or 'adjoint functors' in category theory:

(R0) $\Diamond A \to B$ if and only if $A \to \Box B$
(R1) $A \bullet B \to C$ if and only if $A \to C/B$
(R2) $A \bullet B \to C$ if and only if $B \to A\backslash C$

Elementary theorems

Let us look at some elementary theorems of the grammatical base logic. From the identity axioms of line 1 below, one obtains the Application schemata of line 2 in one step, using the residuation inferences in the 'if' direction; from Application, one derives the Lifting schemata of line 3, this time reasoning in the 'only if' direction:

1.	$A\backslash B \to A\backslash B$ (Ax)	$B/A \to B/A$ (Ax)
2.	$A \bullet (A\backslash B) \to B$ (R2 $\Leftarrow$)	$(B/A) \bullet A \to B$ (R1 $\Leftarrow$)
3.	$A \to B/(A\backslash B)$ (R1 $\Rightarrow$)	$A \to (B/A)\backslash B$ (R2 $\Rightarrow$)

The Application schemata are no doubt the most familiar laws of categorial combinatorics. In fact, the original categorial grammars of Ajdukiewicz and Bar-Hillel were restricted to Application. Using the Application schemata, one can 'lexicalize' the rules of a context-free phrase-structure grammar. Take the productions '$S \to NP\ VP$' and '$VP \to TV\ NP$' for the derivation of a Subject–Transitive-Verb–Object (SVO) pattern. In categorial terms, one types the Transitive Verb as $(np\backslash s)/np$, thus projecting the SVO pattern in two Application steps: rightward application consumes the Object, leftward application the Subject. The auxiliary label *VP* disappears; the complex type $np\backslash s$ expresses its combinatory role.

Instances of Lifting would be type transitions from *np* (the type assigned to simple proper names) to $s/(np\backslash s)$ or $((np\backslash s)/np)\backslash(np\backslash s)$. These lifted types are appropriate for noun phrases with a distribution restricted to the subject position, in the case of $s/(np\backslash s)$, or the direct-object position, in the case of $((np\backslash s)/np)\backslash(np\backslash s)$. What the derivability arrow says here is that any expression that is assigned the type *np* will be able to occur in the subject or object position, but that there can be

expressions with a restricted subject or object distribution, expressed through the higher-order types. One can think of case-marked pronouns, as Lambek (1958) pointed out. With $s/(np\backslash s)$ as the lexical type assignment for 'he'/'she', but $((np\backslash s)/np)/(np\backslash s)$ for 'him'/'her', we correctly rule out 'him irritates she' while allowing 'he irritates her'.

Elementary theorems for the unary type-forming operations are established below:

1. $\Box A \to \Box A$ (Ax) and $\Diamond A \to \Diamond A$ (Ax)
2. $\Diamond\Box A \to A$ (R0 $\Leftarrow$) and $A \to \Box\Diamond A$ (R0 $\Rightarrow$)

An illustration of the added expressivity of the unary operators can be found in Bernardi (2002), where they are used to control the distribution of polarity-sensitive items. Consider the contrast between 'nobody left yet', with the negative-polarity item 'yet', and '*somebody left yet'. In a type language with just the binary type-forming operations, both 'somebody' and 'nobody' would receive the subject type $s/(np\backslash s)$, and 'yet' the modifier type $(np\backslash s)\backslash(np\backslash s)$. Such type assignment is too crude to block the ungrammatical '*somebody left yet'. In the extended type language, the negative-polarity trigger 'nobody' can be assigned the type $s/\Box\Diamond(np\backslash s)$, whereas 'somebody' keeps the undecorated type $s/(np\backslash s)$. By typing the negative-polarity item 'yet' as $(np\backslash s)\backslash\Box\Diamond(np\backslash s)$ one expresses the fact that it requires a trigger such as 'nobody' to check the $\Box\Diamond$ decoration in its numerator subtype. For the derivation of the simple sentence 'nobody left' (with no polarity item to be checked), we rely on the fact that in the base logic, we have $s/\Box\Diamond(np\backslash s) \to s/(np\backslash s)$; i.e., the $\Box\Diamond$ decoration on argument subtypes can be simplified away, allowing the combination (in terms of the Application schema) of 'nobody' with a simple verb phrase 'left' of type $np\backslash s$.

Monotonicity properties

Apart from these theorems, the base logic has several derived rules of inference. With respect to the derivability relation, the operations $\Diamond$ and $\Box$ are order-preserving (isotone). The $\bullet$ operation is order-preserving in its two arguments; the division operations/and $\backslash$ are order-preserving in their numerator, and order-reversing (antitone) in their denominator argument.

$A \to B$ implies:

$\Diamond A \to \Diamond B$ and $\Box A \to \Box B$
$A/C \to B/C$ and $C\backslash A \to C\backslash B$
$C/B \to C/A$ and $B\backslash C \to A\backslash C$
$A \bullet C \to B \bullet C$ and $C \bullet A \to C \bullet B$

From a combinatorial point of view, these rules produce an infinite number of type transformations from some small inventory of 'primitive' ones. Consider the Lifting schema. From it, one obtains the transformations known as Value Raising (for example, lifting a determiner type np/n to $(s/(np\backslash s))/n$) and Argument Lowering (for example, lowering a third-order verb phrase type $(s/(np\backslash s))\backslash s$ to first-order $np\backslash s$).

Alternative presentations, and natural deduction

The categorial base logic allows many alternative axiomatizations, each serving its own function. The essential point is that the different presentations must find their justification in the model-theoretic interpretation of the connectives; i.e., one has to prove that they are equivalent syntaxes for performing valid type computations. In the Gentzen sequent calculus, one replaces the arrows $A \to B$ by statements $\Gamma \Rightarrow B$ ('structure Γ is of type B'). The antecedent Γ is built out of formulae by means of the structure-building operations $\langle\cdot\rangle$ and $(\cdot\circ\cdot)$, counterparts of the logical connectives $\Diamond$ and $\bullet$. The purpose of this presentation is to show that the transitivity rule (the Cut rule) can be eliminated. Every logical rule of inference in the Gentzen calculus introduces a connective either in the antecedent or in the succedent, so that backward-chaining, cut-free proof search immediately yields a decision procedure for categorial derivability, as shown in Lambek (1958) for the binary and in Moortgat (1996) for the unary connectives.

The derivational format of 'combinatory categorial grammar' (CCG) (e.g., Steedman, 2000b) is a Hilbert-style presentation. Functional Application here is taken as the basic, primitive schema for type combination. To the Application schema are added extra schemata, such as Lifting, also known as combinator T. The CCG format of derivations is related to the Gentzen style as the combinator presentation of intuitionistic logic is to its Gentzen presentation. The recursive generalization of the primitive type transformations under monotonicity is important for such 'combinatory' presentations of categorial derivability: without this generalization, one loses completeness.

In a third format, 'natural deduction' (ND), every type-forming connective has an introduction and an elimination rule. As a result, ND doesn't have the pleasant proof search properties of the Gentzen calculus, but it provides a perspicuous presentation of a derivation once it has been found. For this reason, ND is often used in linguistic discussion of categorial analyses. Also, ND is the most

$$\frac{\Gamma \vdash \Box A}{\langle \Gamma \rangle \vdash A}\ (\Box \mathrm{E}) \qquad \frac{\langle \Gamma \rangle \vdash A}{\Gamma \vdash \Box A}\ (\Box \mathrm{I})$$

$$\frac{\Gamma \vdash A}{\langle \Gamma \rangle \vdash \Diamond A}\ (\Diamond \mathrm{I}) \qquad \frac{\Delta \vdash \Diamond A \quad \Gamma[\langle A \rangle] \vdash B}{\Gamma[\Delta] \vdash B}\ (\Diamond \mathrm{E})$$

$$[/\mathrm{I}]\frac{\Gamma \circ B \vdash A}{\Gamma \vdash A/B} \qquad \frac{\Gamma \vdash A/B \quad \Delta \vdash B}{\Gamma \circ \Delta \vdash A}[/\mathrm{E}]$$

$$[\backslash \mathrm{I}]\frac{B \circ \Gamma \vdash A}{\Gamma \vdash B \backslash A} \qquad \frac{\Gamma \vdash B \quad \Delta \vdash B \backslash A}{\Gamma \circ \Delta \vdash A}[\backslash \mathrm{E}]$$

$$[\bullet \mathrm{I}]\frac{\Gamma \vdash A \quad \Delta \vdash B}{\Gamma \circ \Delta \vdash A \bullet B} \qquad \frac{\Delta \vdash A \bullet B \quad \Gamma[A \circ B] \vdash C}{\Gamma[\Delta] \vdash C}[\bullet \mathrm{E}]$$

Figure 1. Natural deduction. $\Gamma \vdash A$ stands for the deduction of a conclusion A from a configuration of assumptions Γ. Axioms are of the form $A \vdash A$. Antecedent structures are built from formulae with the structure-building operations $\langle \cdot \rangle$ and $(\cdot \circ \cdot)$. These are the structural counterparts of $\Diamond$ and $\bullet$, respectively, as the $\Diamond$ and $\bullet$ Introduction rules show.

transparant format to associate meaning assembly with a derivation, as we will see. Figure 1 shows the ND rules for the base logic, using the Gentzen sequent style, which is explicit about the structural configuration of the antecedent assumptions.

Multimodal generalization

One can straightforwardly generalize the base logic to a system where one has not just one single merge and feature-checking relation, but families of them. In terms of modal logic, this means moving from a unimodal to a multimodal system, with frames $(W, \{R^2_i\}_{i \in I}, \{R^3_j\}_{j \in J})$ where the different relations are kept apart by indexing them with a composition mode label. Similarly, in the formula language, we index the connectives for these composition modes. The concept of multiple composition modes is not unfamiliar. For the binary operations, one can think of a distinction between the structure of words (morphology) and the structure of phrases (syntax): one can give a categorial analysis of morphology and syntax in terms of $/$, $\bullet$, and $\backslash$, but still one will want to keep these grammatical levels distinct, say as $\bullet_w$ versus $\bullet_\phi$. For the unary connectives $\Diamond$ and $\Box$, multimodality makes it possible to distinguish a number of named features in the grammar, so that they can play different roles in controlling composition.

The multimodal perspective turns out to be particularly useful once we move beyond the base logic and consider its structural extensions, where one can then have interaction between different binary composition modes (between morphology and syntax, in the case of complement inheritance, for example), and between specific unary control features and binary composition operations. Such interaction principles are discussed below.

The Structural Module

The laws of the base logic do not depend on specific structural properties of the merge and feature-checking relations: the completeness condition does not impose any restrictions on the interpretation of $R_\bullet$ and $R_\Diamond$. In this sense, the base logic can be said to capture the invariants of grammatical composition. Although the base logic already has a rich deductive structure, the system also has its limitations. If an expression can occur in different structural configurations, one would like to relate these configurations. In the base logic, this cannot be done: type assignment is structurally rigid, in the sense that different structural environments will lead to different type assignments. To overcome the problem of structural rigidity, one extends the base logic with facilities for structural reasoning. Technically, such facilities have the status of non-logical axioms, or postulates. They can be introduced in a global or in a controlled fashion. We look at these in turn.

Global structural rules

The postulates below create a hierarchy of categorial systems: with the addition of structural options, the flexibility of type combination increases, but structural discrimination deteriorates.

($\mathrm{A_l}$) $(A \bullet B) \bullet C \rightarrow A \bullet (B \bullet C)$
($\mathrm{A_r}$) $A \bullet (B \bullet C) \rightarrow (A \bullet B) \bullet C$
(C) $A \bullet B \rightarrow B \bullet A$

The rebracketing postulates $\mathrm{A_l}$ and $\mathrm{A_r}$, added to the fragment of the base logic formed by $\bullet$, $/$, and $\backslash$, produce the system known as L, the associative calculus of Lambek (1958). The fragment of the base logic formed by $\bullet$, $/$, and $\backslash$ is known as NL: in Lambek (1961) this system was obtained by dropping the associativity postulates from L. Characteristic theorems of L are the type transitions below: the Geach laws $\mathrm{G_r}$ and $\mathrm{G_l}$, and the functional composition schemata (known as combinator **B** in CCG) of which $\mathrm{B_r}$ and $\mathrm{B_l}$ are the simplest forms.

($\mathrm{G_r}$) $A/B \rightarrow (A/C)/(B/C)$
($\mathrm{G_l}$) $B\backslash A \rightarrow (C\backslash B)\backslash(C\backslash A)$
($\mathrm{B_r}$) $(A/B) \bullet (B/C) \rightarrow A/C$
($\mathrm{B_l}$) $(C\backslash B) \bullet (B\backslash A) \rightarrow C\backslash A$

Adding the commutativity postulate to L produces LP (Lambek calculus with permutation), a

system coinciding with the multiplicative fragment of linear logic, which has a commutative product operation matched by a single linear implication. The distinction between left-incompleteness and right-incompleteness collapses in the presence of the commutativity postulate C.

Extending the base logic with facilities for structural reasoning has consequences for the interpretation of the type-forming operations (Došen, 1992; Kurtonina, 1995). An interpretation with respect to arbitrary frames is obviously not available anymore. Instead, each postulate introduces a corresponding frame constraint restricting the interpretation of the merge relation $R_\bullet$, and completeness is stated with respect to frames respecting the relevant constraints. A Commutativity postulate, for example, would impose the semantic constraint that for all $x, y, z \in W$, $R_\bullet xyz$ implies $R_\bullet xzy$. Similarly for the other postulates discussed. In the presence of such semantic constraints, it will often be the case that one can specialize the abstract relational interpretation to more concrete models. A good example is the system L with its associative composition relation $R_\bullet$. In this case, one can read $R_\bullet xyz$ as concatenation; i.e., $x = y \cdot z$. Pentus (1994) proves that L is indeed complete with respect to this concatenation interpretation.

Controlled structural reasoning

There are many natural-language phenomena that seem to require some of the flexibility offered by the postulates A_l, A_r, and C. Cases of nonconstituent coordination can be naturally handled with the possibilities for type combination that follow from the rebracketing postulates. Displacement phenomena are ubiquitous in natural language, and seem to require some form of commutativity. At the same time, it is clear that in a global form, these structural options overgenerate. Commutativity would entail that well-formedness is preserved under arbitrary changes in word order; free rebracketing makes constituent structure irrelevant for determining grammaticality.

To obtain controlled structural extensions of the base logic, various strategies have been pursued. In the rule-based approach of combinatory categorial grammar, one augments the Application–Lifting basis with structural combinators which, in an unconstrained form, would be overgenerating. One then imposes type restrictions on these extra combinators. In addition, the set of rule schemata (combinators) is kept finite, so that one can avoid the consequences of the recursive generalization of rules under monotonicity. The alternative is to exploit the intrinsic logical instruments for structural resource management offered by richer type systems with unary control features and multimodal interaction principles. To compare these two strategies, consider the following cases of extraction: 'what Alice found' and 'what Alice found there' (see Figure 2).

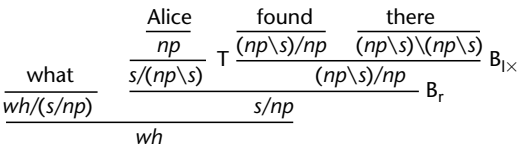

Figure 2. *wh*-extraction: combinator-style derivation. The clause body 'Alice found there' is assigned type s/np by means of the backwards crossed composition combinator $B_{l\times}$. The rule can apply because the cancelled $(np\backslash s)$ satisfies the type restriction on $B_{l\times}$.

In CCG, the peripheral case of extraction ('what Alice found') is derived from an assignment $wh/(s/np)$ to the *wh*-pronoun by lifting the type for 'Alice' to $s/(np\backslash s)$ which is then composed with the transitive verb type $(np\backslash s)/np$ for 'found' by means of B_r. To obtain the nonperipheral case of extraction ('what Alice found there'), one needs the combinator $B_{l\times}$, a form of composition which depends on the commutativity postulate. To avoid collapse into LP, one imposes a side condition on the rule, restricting the middle term B to certain verbal categories, in this case $(np\backslash s)$:

($B_{l\times}$) $(B/C) \bullet (B\backslash A) \rightarrow A/C$ where B is a predicate category

The $\Diamond$ and $\Box$ connectives make it possible to avoid extralogical type restrictions. The postulates P1 and P2 below implement a controlled form of rebracketing and reordering for formulae carrying the $\Diamond$ control feature (Moortgat, 1999). With a lexical type assignment $wh/(s/\Diamond\Box np)$ to the *wh*-pronoun, one obtains peripheral and medial extraction from right branches. Under this analysis, one does not attribute any associativity or commutativity to the $\bullet$ operation itself; displacement effects arise through the interaction of the merge operation with a gap hypothesis carrying the licensing $\Diamond$ feature. A derivation is given in Figure 3.

(P1) $(A \bullet B) \bullet \Diamond C \rightarrow (A \bullet \Diamond C) \bullet B$
(P2) $(A \bullet B) \bullet \Diamond C \rightarrow A \bullet (B \bullet \Diamond C)$

Generative Capacity and Computational Complexity

The modular view on grammatical invariants and structural variation invites a comparison between the categorial landscape and the Chomsky hierarchy. For a recent survey, see Buszkowski (1997).

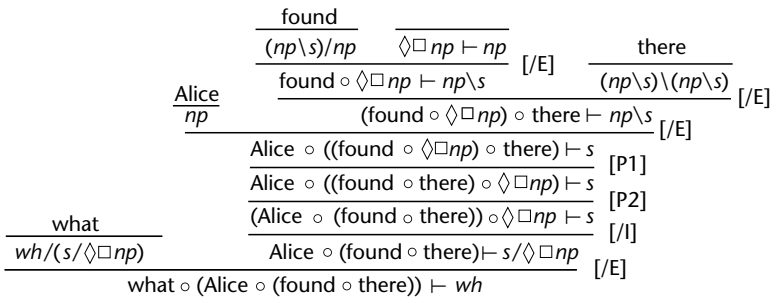

Figure 3. *wh*-extraction: ◊ control. The type assignment to the relativizer 'what' expresses the fact that the relative clause body is a sentence built with the help of a 'gap' hypothesis of type ◊□ *np*. The feature-marked hypothesis has to be withdrawn at the right periphery, but it is not selected in that position. It is related to the nonperipheral direct-object position within the relative clause body by virtue of the postulates P1 and P2. Once it has found the direct-object position, the licensing feature ◊ has done its work and can be cleaned up by the law ◊□ *np* ⊢ *np*. The 'gap' hypothesis is then used as a regular direct object with respect to the selecting verb 'found'.

The discovery in the 1980s of dependency patterns that cannot be adequately captured by context-free grammars has led to an interest in 'mildly context-sensitive' formalisms; i.e., systems with an expressivity beyond the context-free, but sufficiently restricted to have polynomial parsing algorithms. The Ajdukiewicz–Bar-Hillel grammars have long been known to be weakly equivalent to context-free grammars, hence to be too poor to serve as models of universal grammar. The same is true for the base logic described above. The correctness of Chomsky's conjecture that context-free equivalence extends to the Lambek calculus L was finally established in Pentus (1993). This result does not have a direct corollary for polynomial parsability, because the construction of a context-free grammar from an L grammar is of exponential complexity.

For the structural extensions of the base logic discussed above, the challenge is to identify appropriate constraints: it is clear that arbitrary combinator extensions, or structural rule packages, lead to excessive expressivity. But Vijay-Shanker and Weir (1994) show that an appropriately restricted version of CCG is weakly equivalent to the linear indexed grammars, hence polynomially parsable. In a similar spirit, Moot (2002) shows how, with appropriate restrictions on lexical assignments and structural postulates, one can carve out a class of multimodal categorial grammars equivalent to lexicalized tree adjoining grammars and inheriting the polynomial parsability of these systems. The general theory of ◊ and □ as control operators has been investigated in Kurtonina and Moortgat (1997). These authors establish a number of embedding theorems showing that the full logical space between the base logic and LP can be navigated in terms of the control connectives, both in the 'licensing' direction illustrated above (allowing structural inferences that would be unavailable without the control features) and in the 'constraining' sense (blocking structural options that would be licit in the absence of the control features).

More important than weak generative capacity are issues of strong capacity, which in the categorial tradition would mean the proof structures (or their lambda terms, discussed below) that produce a certain string. In this area, Tiede (2001) has obtained interesting results, showing that while the Lambek systems L and NL are weakly context-free, their expressivity in terms of strong capacity goes beyond that of context-free grammars.

Language Learning

Kanazawa (1998) has studied formal learning theory for categorial grammar within Gold's paradigm of identification in the limit on the basis of positive data. The focus is on classical categorial grammars, using only the Application rules, and on combinatory extensions with extra rule schemata. On the input side, Kanazawa considers learning both from strings and from function-argument structures. On the output side, the class of 'rigid' grammars (where the grammar assigns a unique type to each word) is compared to the class of *k*-valued grammars (where at most *k* types are assigned to a lexical item). It is a matter of dispute whether Gold's very abstract formulation of the learning problem is directly relevant for first-language acquisition. An alternative, purely inductive, approach – learning a subclass of the shallow context-free languages – is presented in Adriaans (2001).

The discussion above suggests some directions for further research in this area. First of all, one would like to obtain learnability results for classes of Lambek-style categorial grammars, where the learner has access to both the Elimination rules and the Introduction rules for the type-forming operators. Secondly, one would like to go beyond systems with a 'hard-wired' structural component, in order to investigate the learnability effects of different choices of structural packages, in combination with an invariant base logic. The work of Foret (2001) is promising in this respect: she mixes unification and substitution with Lambek-style deduction, so suggesting modulation of learnability questions in terms of different structural postulates.

Finally, the role of semantic information in learning needs further investigation. The challenge here is to find a level of informativity that would be realistic in the setting of first-language acquisition.

MEANING ASSEMBLY

Categorial grammar adheres to the truth-conditional theory of semantics: the interpretation process establishes a systematic relationship between linguistic expressions and states of affairs in the world in such a way that specifying the meaning of a sentence comes down to giving its truth conditions. Model theory provides the tools to carry out this program. For semantic interpretation this involves the construction of a set-theoretic model of 'the world' in terms of objects and configurations of objects; these set-theoretic constructs then serve as the semantic values of natural-language expressions.

The integrated treatment of syntax and semantics, which is now seen as the most attractive aspect of categorial grammar, is of relatively recent origin. The original Lambek systems (Lambek, 1958, 1961) were presented as syntactic type calculi. At about the same time, Curry (1961) was advocating the use of purely semantic types in natural-language analysis. Curry in fact criticized Lambek for the admixture of syntactic considerations in his category concept, coining the famous distinction between 'tectogrammatic' and 'phenogrammatic' organization. The tectogrammatic level, in Curry's view, provides the appropriate information for meaning composition; the phenogrammatic pertains to the way this abstract grammatical structure is represented in terms of surface expressions. About the actual mapping between the two levels, Curry provides no specific information.

The design of the syntax–semantics interface becomes of central importance in Richard Montague's work. The cornerstone of his 'universal grammar' program is a precise implementation of Frege's *compositionality principle*. Informally, this fundamental principle of natural-language semantics requires that the meaning of a complex expression be given as a function of the meanings of its constituent parts, and the way they are put together. In Montague's algebraic system, compositionality takes the form of a homomorphism, that is, a structure-preserving mapping, between a syntactic and a semantic algebra. Ironically, when van Benthem (1987) reintroduced semantic interpretation in the discussion of Lambek's syntactic calculi, it was by establishing the connection between categorial derivations and Curry's own 'formulae-as-types' program which we describe below. (The discussion below is restricted to functional types; the full Curry–Howard interpretation involves extension to the other type-forming operations.)

Model-theoretic Semantics, Type Theory, and the Lambda Calculus

For semantic interpretation, we associate every type A with a semantic domain D_A. Expressions of type A find their denotations in D_A. Semantic domains can be set up in two ways: directly on the basis of the syntactic types discussed in the previous section, or indirectly, via a mapping from syntactic to semantic types. The indirect option is attractive for a number of reasons. On the level of atomic types, one may want to make different basic distinctions depending on whether one uses syntactic or semantic criteria. For complex types, a map from syntactic to semantic types makes it possible to forget information that is relevant only for the way expressions are to be configured in the form dimension. Finally, the semantic type system naturally fits the language of the typed lambda calculus, which we can then use, together with its standard interpretation, to specify the instructions for meaning assembly.

Semantic and syntactic types

For a simple extensional interpretation, the set of atomic semantic types *SemAtom* could consist of types e and t, with D_e the domain of discourse (a nonempty set of entities, objects), and $D_t = \{0, 1\}$, the set of truth values. The full set of semantic types *SemType* is then obtained by closing *SemAtom* under the rule that if A and B are in *SemType* then $A \rightarrow B$ is also. $D_{A \rightarrow B}$, the semantic domain for a functional type $A \rightarrow B$, is the set of functions from

D_A to D_B. The mapping from syntactic to semantic types $(\cdot)^*$ could now stipulate for basic syntactic types that $np^* = e$, $s^* = t$, and $n^* = (e \to t)$. Sentences, in this way, denote truth values; (proper) noun phrases individuals; common nouns functions from individuals to truth values. For complex syntactic types, we set $(A/B)^* = (B \backslash A)^* = B^* \to A^*$. On the level of semantic types, the directionality of the 'slash' connective is no longer taken into account. The distinction between numerator and denominator – domain and range of the interpreting functions – is kept. Notice that both verb phrases with syntactic type $np \backslash s$ and common nouns are mapped to the semantic type $e \to t$.

The language of the simply-typed lambda calculus

Below, a procedure is presented to associate a derivation $A_1,\ldots,A_n \vdash B$, with a term t of type B representing a recipe for meaning assembly, with parameters $x_1,\ldots,x_n$ for the lexical assumptions $A_1,\ldots,A_n$. To prepare the ground, we build up the set of meaningful expressions (terms) of semantic type A, starting from a denumerably infinite set of variables for each type. For each expression t of type A, we specify its interpretation $[\![t]\!]^g$ relative to an assignment function g which assigns to each variable of type A a member of D_A.

1. *Variables*. Let x be a variable of type A. Then x is a term of type A. Interpretation: $[\![x]\!]^g = g(x)$.
2. *Application*. Let t and u be terms of type $A \to B$ and A respectively. Then $(t\ u)$ is a term of type B. Interpretation: $[\![(t\ u)]\!]^g = [\![t]\!]^g\,([\![u]\!]^g)$; i.e., the result of applying the function $[\![t]\!]^g$ to $[\![u]\!]^g$.
3. *Abstraction*. Let x be a variable of type A and t a term of type B. Then $\lambda x.t$ is a term of type $A \to B$. Interpretation: $[\![\lambda x.t]\!]^g$ is that function h from D_A into D_B such that for all objects $k \in D_A$, $h(k) = [\![t]\!]^{g'}$, where g' is the assignment that is exactly like g except for the possible difference that it assigns the object k to the variable x.

Given this interpretation, certain equalities hold between terms. One can see them as syntactic simplifications, replacing a more complex term (the *redex*) by a simpler one with the same interpretation (the *contractum*):

$(\lambda x.t)\ u \rightsquigarrow_\beta t[u/x]$ provided u is free for x in t.
$\lambda x.(t\ x) \rightsquigarrow_\eta t$ provided x is not free in t.

Formulae as Types, Proofs as Programs

Curry's basic insight was that one can see the functional types of type theory as logical implications, giving rise to a one-to-one correspondence between typed lambda terms and natural deduction proofs in positive intuitionistic logic. A natural deduction presentation for $\to$ starts from identity axioms $A \vdash A$ and has the introduction and elimination rules below, where Γ and Δ represent finite lists of formulae, and where $\Gamma - A$ results from dropping some or all occurrences of A from Γ.

$$\frac{\Gamma \vdash A \to B \quad \Delta \vdash B}{\Gamma, \Delta \vdash B} \to \text{Elim}$$

$$\frac{\Gamma \vdash B}{\Gamma - A \vdash A \to B} \to \text{Intro}$$

Let us write $\Gamma(t)$ for the string of types of free occurrences of variables in a term t. Each term t of type A now encodes a natural deduction proof of the sequent $\Gamma(t) \vdash A$. The Variable clause in the definition of well-formed terms corresponds to the axiom sequent, the Application clause to $\to$ Elimination, and the Abstraction clause to $\to$ Introduction, where the dropped A assumption corresponds to the variable bound by the lambda abstractor. In the opposite direction, every natural-deduction proof is encoded by a lambda term. The normalization of natural-deduction proofs corresponds to the β–η reductions of terms.

Translating Curry's 'formulae-as-types' idea to the categorial type logics we are discussing, we have to take the differences between intuitionistic logic and the grammatical resource logic into account. Below we repeat the natural-deduction presentation of the base logic, now taking term-decorated formulae as basic declarative units. Judgments take the form of sequents $\Gamma \vdash t : A$. The antecedent Γ is a structure with leaves $x_1 : A_1,\ldots,x_n : A_n$. The x_i are unique variables of type A_i^*, where $(\cdot)^*$ is the mapping from syntactic to semantic types. The succedent is a term t of type A^* with exactly the free variables $x_1,\ldots,x_n$, representing a program which given inputs $k_1,\ldots,k_n$ produces $[\![t]\!]^g$ under the assignment that maps the variables x_i to the objects k_i. The x_i, in other words, are the parameters of the meaning-assembly procedure. A derivation starts from axioms $x : A \vdash x : A$. The Elimination and Introduction rules have versions for the right and the left implications. On the meaning-assembly level, this syntactic difference is ironed out, as we already know that $(A/B)^* = (B \backslash A)^*$. As a consequence, we don't have the isomorphic (one-to-one) correspondence between terms and proofs of Curry's original program. But we do read off meaning assembly from the categorial derivation. (See Figure 4.)

A second difference between the programs and computations that can be obtained in intuitionistic implicational logic and the recipes for meaning assembly associated with categorial derivations has to do with the resource management of

$$[/\mathrm{I}]\ \frac{\Gamma \circ x : B \vdash t : A}{\Gamma \vdash \lambda x.t : A/B} \qquad \frac{\Gamma \vdash t : A/B \quad \Delta \vdash u : B}{\Gamma \circ \Delta \vdash (t\ u) : A}\ [/\mathrm{E}]$$

$$[\backslash\mathrm{I}]\ \frac{x : B \circ \Gamma \vdash t : A}{\Gamma \vdash \lambda x.t : B\backslash A} \qquad \frac{\Gamma \vdash u : B \quad \Delta \vdash t : B\backslash A}{\Gamma \circ \Delta \vdash (t\ u) : A}\ [\backslash\mathrm{E}]$$

Figure 4. Natural-deduction rules: term labeling.

assumptions in a derivation. The formulation of the $\rightarrow$ Introduction rule makes it clear that in intuitionistic logic the number of occurrences of assumptions (the 'multiplicity' of the logical resources) is not critical. One can make this style of resource management explicit in the form of structural rules of Contraction and Weakening, allowing for the duplication and waste of resources:

$$\frac{\Gamma, A, A \vdash B}{\Gamma, A \vdash B}\ [C]$$

$$\frac{\Gamma \vdash B}{\Gamma, A \vdash B}\ [W]$$

In contrast, the categorial type logics are resource-sensitive systems where each assumption has to be used exactly once. At the level of LP, we have the following correspondence between resource constraints and restrictions on the lambda terms coding derivations:

No empty antecedents: each subterm contains a free variable.
No Weakening: each λ operator binds a variable free in its scope.
No Contraction: each λ operator binds at most one occurrence of a variable in its scope.

Moving from LP to the grammatical base logic imposes even tighter restrictions on binding: in the absence of Associativity and Commutativity, the 'slash' introduction rules responsible for the λ operator can only reach the immediate children of a structural domain.

The syntax–semantics interface

Applied to the composition of natural-language meaning, the 'proofs-as-programs' approach has some interesting consequences for the syntax–semantics interface.

A first point to notice is the strictly modular treatment of derivational versus lexical semantics. The proof term that is read off a derivation is a *uniform instruction* for meaning assembly that fully abstracts from the contribution of the particular lexical items on which it is built. As a result, no assumptions about lexical semantics can be built into the meaning assembly process as represented by a derivation. The interplay between lexical and derivational semantics is illustrated in Figures 5 and 6. Whereas the proof term in Figure 5 is a faithful encoding of the derivation (modulo directionality and structural operations), the term one obtains in Figure 6 after substitution of lexical meaning programs and β-simplification has lost transparency with respect to the derivation.

The second feature is the limited semantic expressivity of a structure-sensitive type logic: many forms of meaning assembly that can be straightforwardly expressed in the language of the lambda calculus cannot be obtained as Curry–Howard images of the Introduction–Elimination inferences of the categorial base logic.

To resolve the tension between structure sensitivity and semantic expressivity, categorial grammars can exploit a combination of two strategies. Structural reasoning (in terms of combinators or structural postulates) makes it possible to explicitly determine which positions are accessible for semantic manipulation (binding). The example of controlled *wh*-extraction in Figure 3 is an illustration. Secondly, lexical-meaning programs do not have to obey the resource constraints of the derivational semantics. Specifically, we do not impose the single-bind condition on lexical meanings (although the ban on vacuous abstraction does make sense, also in the lexicon.) An example of multiple binding is the lexical lambda term for the relative pronoun 'that' in Figure 6, a program which computes property intersection. Another example would be a reflexive pronoun like 'himself'. With a type $((np\backslash s)/np)\backslash(np\backslash s)$, it consumes its transitive-verb argument in a resource-sensitive way. The identification of subject and object arguments of the verb is realized through its lexical lambda term $\lambda x \lambda y.((x\ y)\ y)$.

The interplay between these two strategies in current research is nicely illustrated by the construal of quantifier scope ambiguities and antecedent–anaphor dependencies. Generalized quantifier expressions, like 'everyone', 'someone', and 'nobody', require an interpretation as sets of properties; i.e., they find a denotation in $D_{(e \rightarrow t) \rightarrow t}$. A syntactic type compatible with such denotations would be $s/(np\backslash s)$. But there are two problems with such a type. First of all, it is restricted to subject position, and one wouldn't like to resort to multiple type assignments for non-subject occurrences. Secondly, it doesn't allow nonlocal scope readings, as in line 3 below, where the embedded quantifier takes scope at the main clause level.

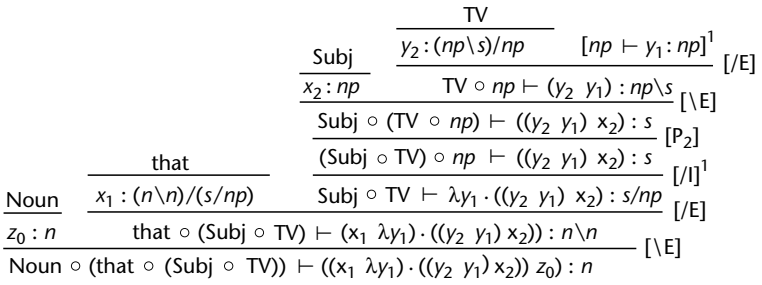

Figure 5. Computation of the proof term for the pattern 'Noun that Subj Transitive-Verb'. Leaves are labeled with variables. The derivation produces a meaning recipe with parameters for the lexical meaning programs. The recipe can be applied to any choice of lexical items fitting the type requirements: 'biscuit that Alice ate', 'book that Carroll wrote', and so on.

1.	biscuit : n – **biscuit**	Lex
2.	that : $(n\backslash n)/(s/np)$ – $\lambda z_{15}.\lambda x_{16}.\lambda y_{16}.((z_{15}\ y_{16}) \wedge (x_{16}\ y_{16}))$	Lex
3.	alice : np – **a**	Lex
4.	ate : $(np\backslash s)/np$ – **eat**	Lex
5.	np : np – y_1	Hyp
6.	ate $\circ$ np : $np\backslash s$ – (**eat** y_1)	/E (4, 5)
7.	alice $\circ$ (ate $\circ$ np) : s – ((**eat** y_1) **a**)	\E (3, 6)
8.	(alice $\circ$ ate) $\circ$ np : s – ((**eat** y_1) **a**)	P2 (7)
9.	alice $\circ$ ate : s/np – $\lambda y_1.$((**eat** y_1) **a**)	/I (5, 8)
10.	that $\circ$ (alice $\circ$ ate) : $n\backslash n$ – $\lambda x_{16}.\lambda y_{16}.$(((**eat** y_{16}) **a**) $\wedge$ (x_{16} y_{16}))	/E (2, 9)
11.	biscuit $\circ$ (that $\circ$ (alice $\circ$ ate)) : n – $\lambda y_{16}.$(((**eat** y_{16}) **a**) $\wedge$ (**biscuit** y_{16}))	\E (1, 10)

Figure 6. Substitution of lexical semantics in the pattern 'Noun that Subj Transitive-Verb'. Bold-face is used for nonlogical constants. In steps 10 and 11, β-conversion is applied on the fly to the application terms obtained from the 'slash' elimination rules. The derivation is presented in the linear or Fitch-style natural-deduction format.

1. Alice thinks someone left.
2. ((**think** ($\exists\ \lambda x.$(**leave** x))) **a**)
3. ($\exists\ \lambda x.$((**think** (**leave** x)) **a**))
4. *Alice* thinks *she* dreams.
5. ((**think** (**dream a**)) **a**)

The construal of antecedent–anaphora relations, like that of quantifier scope, involves nonlocal dependencies beyond the reach of the grammatical base logic, as in line 4 above, where the anaphor in the subordinate clause can pick up its antecedent in the main clause. In addition, meaning composition for anaphora resolution involves a duplication of resources, in the sense that one would like to make the pronoun 'she' in the example above responsible for the copying of the antecedent meaning.

Proposals for dealing with these problems rely either on combinator-style type-shifting rule schemata or on structural extensions of the Lambek calculus. For quantifier scope construal, these options are discussed in depth in Carpenter (1998). For anaphora resolution, Jäger (2001) offers a comparison of the CCG approach of Jacobson (1999) with a type-logical treatment based on identity semantics for anaphora, in combination with a restricted copying rule in syntax, in the form of a controlled structural rule of Contraction. An alternative perspective on scope and anaphora, more in the spirit of Curry's tectogrammatic program, simplifies the categorial type theory to a nondirectional LP system, and enforces structural control by introducing lambda term labeling also for the form dimension of grammatical signs. Oehrle (1994) provides an early formulation of this approach, which has recently found new advocates.

Processing Issues

The interpretation procedure discussed above is essentially dynamic: interpretations are assembled 'online' in the course of the derivation process, rather than being computed *post hoc* from a given static structure. This has led to a distinctly 'categorial' view on processing issues.

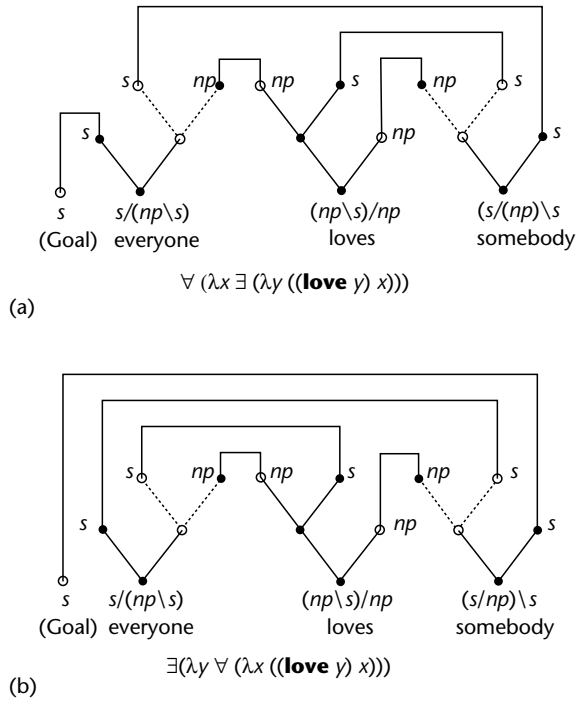

Figure 7. Incremental proof-net construction. The diagrams show a proof net for the sentence 'everyone loves somebody'. Formula decomposition trees have polarized vertices (black for input, white for output). Solid edges represent positive slashes; dotted edges represent negative slashes. A linking of leaves with opposite polarities is well-formed if it produces a graph that is connected, acyclic (for each removal of a dotted edge from a pair), and planar. The net is constructed in a left-to-right incremental fashion. Processing complexity is measured in terms of the number of unresolved dependencies. (a) The subject-wide-scope reading for 'everyone loves somebody' (maximum of 3 unresolved dependencies). This is preferred over (b), the object-wide-scope reading (maximum of 4 unresolved dependencies). Adapted from Johnson (1998) and Morrill (2000).

Incrementality and information structure

The flexible notion of derivational constituency engendered by type-changing principles makes left-to-right parsing directly compatible with incremental interpretation. The resulting categorial modeling of natural-language processing has been worked out in Steedman (2000a). This work shows that derivational constituency is guided by 'prosodic' articulation (intonation contour). To do justice to this dimension of grammatical organization, one needs a richer notion of semantic interpretation, accommodating notions of focus and information structure. Steedman's proposals are formulated in the CCG style; Hendriks (1999) analyzes information packaging and intonation contour in multimodal type-logical terms.

Proof nets

A novel computational view on natural-language processing derives from the 'proof net' approach. Proof nets were originally developed in the context of linear logic, where they elegantly capture the essence of resource-sensitive derivations in graph-theoretical terms. Moot and Puite (2002) refine the proof-net techniques for use with the grammatical type logics discussed in this article, where, apart from resource multiplicity, structural patterns also have to be taken into account.

Johnson (1998) and Morrill (2000) have pointed out that proof nets offer an attractive perspective on performance phenomena. A net can be built in a left-to-right incremental fashion by establishing possible linkings between the input–output connectors of lexical items as they are presented in real time. This suggests a simple complexity measure on a traversal, given by the number of unresolved dependencies between literals. This complexity measure on incremental proof-net construction makes the right predictions about a number of well-known processing issues, such as the difficulty of center embedding, garden-path effects, attachment preferences, and preferred scope construals in ambiguous constructions. An illustration is presented in Figure 7.

CONCLUSION

In this article we have presented the core part of the categorial vocabulary: a set of type forming connectives controlling the structure-building operations of language, and the way in which a derivation is associated with an instruction for meaning assembly.

Cognitive Linguistics

Intermediate article

Gilles Fauconnier, University of California, San Diego, California, USA

CONTENTS

Cognitive linguistics is a theoretical and empirical programme that goes beyond the visible structure of language to investigate the complex background operations of cognition that create grammar, conceptualization, discourse, and thought itself.

INTRODUCTION

Cognitive linguistics is a powerful approach to the study of language, conceptual systems, and human cognition. It addresses the structuring of basic conceptual categories such as space and time, scenes and events, entities and processes, motion and location, force and causation, and also the structuring of ideational and affective categories, such as attention and perspective, volition and intention (Talmy, 2000). In doing so, it develops a rich conception of grammar that reflects fundamental cognitive abilities: the ability to form structured conceptualizations with multiple levels of organization, to conceive of a situation at varying levels of abstraction, to establish correspondences between facets of different structures, and to construe a situation in different ways (Langacker, 1987, 1991).

Much of traditional linguistics (including structural and generative linguistics) focuses on the ways in which words are combined into sentences. For example, in looking at the four English sentences *the plane flies over the city*, *the post office is over the hill*, *the war is over the oil wells*, and *this topic is over my head*, a grammarian might see a single structure, and leave it at that. For cognitive linguistics, these four sentences would present a far greater challenge: to explain how the same structure, and the same word *over*, gives rise to such different kinds of conceptualizations: a plane moving 'above' a city, a post office located 'at the end of' a path on the hill, a war 'caused by' something to do with the oil wells, and a topic 'high' on some scale of difficulty. Hidden behind simple words and everyday language are vast conceptual networks manipulated unconsciously through the activation of powerful neural circuits.

Cognitive linguistics recognizes that the study of language is the study of language use, and that when we engage in any language activity, we draw unconsciously on vast cognitive and cultural resources, call up models and frames, set up multiple connections, coordinate large arrays of information, and engage in creative mappings, transfers, and elaborations. Language does not 'represent' meaning: it prompts for its imaginative construction. Very sparse grammar guides us along rich mental paths, by prompting us to perform complex cognitive operations. A large part of cognitive linguistics centers on the creative 'online' construction of meaning as discourse unfolds in context (Fauconnier and Sweetser, 1996; Sweetser, 2000).

Aspects of language and expression that have often been consigned in formal work to the rhetorical periphery of language, such as metaphor (Lakoff and Johnson, 1980, 1999; Sweetser, 1990) and metonymy (Panther and Radden, 1999; Barcelona, 2000) are central within cognitive linguistics. They are understood to be powerful conceptual mappings essential to human thought, important for the understanding not just of poetry, but also of science, mathematics, religion, philosophy, and everyday speaking and thinking.

Thought and language are embodied. Conceptual structure arises from our sensorimotor experience and the neural structures that give rise to it. Reason is embodied and imaginative. A grammar is ultimately a neural system, and general cognitive capacities drive language (Fauconnier and Turner, 1998, 2002).

The stage was set for cognitive linguistics in the 1970s and early 1980s with Len Talmy's work on figure and ground, Ronald Langacker's cognitive grammar framework, George Lakoff's research on metaphor, gestalts, categories and

prototypes (Lakoff, 1987), Fillmore's frame semantics (Fillmore, 1982) and Fauconnier's mental spaces (Fauconnier, 1994). A wealth of discoveries, empirical studies, and applications have since emerged (Janssen and Redeker, 2000; Tomasello, 1998; Cuyckens and Geeraerts, forthcoming).

GRAMMAR AND COGNITION

The relation of grammar to cognition is studied in fine detail in the foundational work of Talmy (2000) and Langacker (1987, 1991). Talmy shows that there are great restrictions on the conceptual categories that grammatical systems actually specifiy. For example, languages often require that number be marked with forms like singular, plural, or dual, but no language has a system for marking the color of nouns. Topological configurations are marked grammatically, but not Euclidean metrics. (Thus, prepositions like *across* indicate the same configuration regardless of the size of the landmarks (*across the sky*, *across the table*), but absolute size or range of size is not marked or differentiated grammatically.) Talmy singles out multiplexing, and states of boundedness and dividedness, as strongly markable in grammatical systems. He also singles out perspective and sequentializing. Thus, *the door slowly opened and two men walked in* and *two men slowly opened the door and walked in* describe the same event from two different perspectives; *there are some houses in the valley* and *there is a house now and then in the valley* describe the same objective state of affairs, but the second sentence takes us along a sequential path where we 'see' the houses one at a time.

Langacker shows how grammar imposes 'trajector–landmark' organization on scenes and events. In *the table is below the lamp*, the table (the 'trajector') is located with respect to the lamp (the 'landmark'). In *the lamp is above the table* this relationship is reversed: the table serves as landmark. But both sentences reflect the same spatial configuration. 'Profiling' is another important construct of Langacker's cognitive grammar. The word *hypotenuse* evokes a right-angled triangle and 'profiles' a particular part of it: the same line segment without the rest of the triangle is no longer a hypotenuse. In *I melted it*, the word *melted* profiles an entire action chain with causation and change leading to a liquid state. In *it melted easily*, only the change is profiled, although the causation is still evoked. In *it is finally melted*, only the resultant state is profiled, but the unprofiled change is evoked. Langacker analyzes in considerable detail the ways in which component structures are integrated through correspondences and elaboration to form composite structures: for example, how the phonological integration *jar lid* symbolizes the semantic integration of 'jar' and 'lid' (Langacker, 1987, 2000; Van Hoek, 1997).

Other basic aspects of conceptual structuring, as reflected by grammar and found in many languages (Talmy, 2000), include 'fictive motion' (*the blackboard goes all the way to the wall*), 'event integration' (*the ball rolled in*, *the candle blew out*, *I kicked the door shut*), and 'force dynamics' (*the ball kept rolling*, *he refrained from closing the door*). (Force dynamics also applies to social organization and abstract reasoning (Sweetser, 1990).) Fictive motion allows stationary scenes (the position of the blackboard) to be construed in terms of the motion of a fictive trajector (*goes all the way to*). Event integration compresses complex chains of events. Force dynamics is based on our experience of physical forces that cause or prevent motion: *kept rolling* indicates an absence of force to impede the ball's movement; *refrained* indicates a clash of counteracting forces. *Max must be home by ten* indicates a social force (e.g. parental rules, curfew) directed towards an outcome (Max being home by ten). *Max must be home by now* uses the same modal *must* to indicate a logical force directed towards the conclusion that Max is now home.

The way in which language structures space is interesting both linguistically and psychologically. No two languages are quite alike in this respect, although there are some general principles. Deceptively simple-seeming prepositions like *in*, *out* or *over* define elaborate networks of spatial meaning with hundreds of linked schemata, some of which are prototypical and central. Compare the very different senses of *over* in *the plane flew over the field*, *the post office is over the hill*, *the log rolled over*, *the party is over*, *he had to do it over again*, *he overlooked it*, *he looked it over*, *he oversaw it*. A native speaker of English unconsciously masters a vast network of related schemata linked to the single, simple word *over*. Remarkable work on this topic has been done by cognitive linguists (Lindner, 1982; Brugman, 1981; Herskovits, 1986; Vandeloise, 1991; Talmy, 2000). Explicit computational models (Regier, 1996) reflect the cognitive complexity of the human capacity to structure space linguistically.

METAPHOR THEORY

A second strand of work in cognitive linguistics since the 1980s has been the development of metaphor theory. Launched by George Lakoff and Mark Johnson, this line of research begins with the insight

that metaphor is basic and constitutive for all the thinking that we do. Metaphor theory is based on source domains of human experience and on neural connections to our embodied sensations, actions, and emotions. Metaphors create the possibility of 'abstract' reasoning, scientific and mathematical thought, and language and culture generally.

Source domains seem to be used systematically to structure target domains by means of metaphorical mappings. For example, our general way to talk and think about event structure is in terms of motion. In this metaphorical mapping, states are locations, change of state is change of location, causes are forces, purposes are destinations, means are paths to destination, guided action is guided motion, etc. This metaphor is reflected in the language we use to express event structure: *he went crazy, she entered a state of euphoria, the clothes are somewhere between wet and dry, the home run threw the crowd into a frenzy, she walked him through the problem, I've hit a brick wall, we're moving ahead, we're at a standstill* (Lakoff and Johnson, 1999). The structure and inferences of the source domain of motion are projected to the target domain of events and action to create a rich emergent conceptualization.

Time itself is conceptualized in terms of space and motion. In English, times can be represented as objects moving towards and then past a stationary observer, or as objects that are stationary with respect to a moving observer: *the time will come; Christmas is approaching*; *the summer just zoomed by*; *we're getting close to Christmas*; *we've reached the end of May already*.

Conventional metaphors such as these can be extended to enrich conceptual understanding. Time can *fly* and *crawl* and *disappear*. In a line by Shakespeare (*Troilus and Cressida*, IV. v. 202–203; cited in Gibbs (1994)), where Hector greets Nestor, Time becomes a moving person, who holds the hand of the venerable Nestor:

> *Let me embrace thee, good old chronicle,*
> *That hast so long walk'd hand in hand with time.*

MENTAL SPACES AND CONCEPTUAL INTEGRATION

Mental spaces are small conceptual packets, constructed as we think and talk, for purposes of local understanding and action. They are partial assemblies of elements, structured by frames and cognitive models. They are interconnected and can be modified as thought and discourse unfold.

Mental spaces proliferate in the unfolding of discourse, map onto each other, and provide abstract mental structure for shifting viewpoint and focus, allowing us to direct our attention at any time onto partial and simple structures while maintaining an elaborate web of connections in working and long-term memory.

For example, if we say *in reality, Richard Burton loves Elizabeth Taylor, but in the movie, he kills her*, we set up two mental spaces, one for reality and one for the movie. Richard Burton in reality has a counterpart (say Mark Antony) in the movie, and Elizabeth Taylor in reality has a counterpart (say Cleopatra) in the movie. Connections between mental spaces allow access to elements in one mental space via counterparts in other mental spaces (e.g. Mark Antony via Burton). Mental spaces offer a general and elegant means of dealing with opacity, presupposition, counterfactuals, and tense and mood in language.

Take for example the sentence *in 1957, the president was a baby*, appearing in a discourse where a base mental space with G. W. Bush as current US president has been set up. The phrase *in 1957* sets up a new '1957' space. If we take *the president* to describe Bush in the base, its counterpart 'Bush in 1957' will be accessed, and the sentence will mean that Bush was a baby back in 1957. If, on the other hand, we take *the president* to describe someone in the new mental space of '1957', then that person will be both a baby and a president in 1957, and the sentence will mean that a baby was president in 1957. Multiple access possibilities of this kind allow the same sentence to prompt for different connection paths in different situations. A wide range of puzzling reference phenomena can be explained in terms of this general underspecification of connecting paths.

Behind the idiosyncrasies of language, cognitive linguistics has uncovered much evidence for the operation of more general cognitive processes. 'Conceptual integration' is an example of a general cognitive operation on mental spaces that is reflected universally in the way we think.

Conceptual integration consists in setting up networks of mental spaces that map onto each other and blend into new mental spaces in various ways. Some of the integrations are novel, others are more entrenched, and we rarely pay conscious attention to the process, because it is so pervasive. In a conceptual integration network, partial structure from input mental spaces is projected to a new blended mental space which develops dynamic (imaginative) structure of its own.

For example, the counterfactual *in France, Watergate would not have done Nixon any harm* is intended to prompt inferences on the difference between the

American and French political systems. It requires the listener to construct input spaces for American politics and for French politics and to project selectively into a blended space in which Nixon and Watergate are embedded into French politics. The imaginative emergent structure of that mental space (why Nixon is not harmed, etc.) provides insight into the political realities of the two countries.

Most aspects of human life evoke conceptual integration networks. This remarkable cognitive capacity has been studied in a variety of domains, including mathematics, music, action and design, distributed cognition, magic and religion, anthropology and political science (Zbikowski, 2002; Hutchins, in preparation; Sorensen, 2000; Lakoff and Núñez, 2000; Liddell, 1998; Turner, 2001). It has been suggested that the capacity of conceptual integration evolved biologically to reach a threshhold, 'double-scope creativity', that constitutes a necessary condition for the cognitively modern human singularities of art, creative tool-making, religious thought, and grammar (Fauconnier and Turner, 2002).

SUMMARY

Cognitive linguistics goes beyond the visible structure of language and investigates the complex background operations of cognition that create grammar, conceptualization, discourse, and thought itself. The theoretical insights of cognitive linguistics are based on extensive empirical observation in multiple contexts, and on experimental work in psychology and neuroscience (Gibbs, 1994; McNeill, 2000; Coulson, 2001; Mandler, 1992; Gentner, 2001). Results of cognitive linguistics, especially from metaphor theory and conceptual integration theory, have been applied to wide ranges of nonlinguistic phenomena.

Constraint-based Processing

Intermediate article

Bob Carpenter, SpeechWorks International, New York, NY, USA

CONTENTS

In a constraint-based grammar formalism, a class of constraints is used to reduce a class of potential representations to the representations that are well formed, or grammatical.

INTRODUCTION

Linguistic theories have primarily been concerned with the structures of languages and utterances within those languages. Extensionally, all of the mainstream linguistic theories concentrate on picking out the set of grammatical, or well-formed, structures (sounds, words or phrases, for instance) in a language. Intensionally, linguists debate the right way to pick out such structures, often arguing from a cognitive perspective based on evidence of human language development, comprehension or production, or typological variation. Computer scientists are typically concerned with the efficiency of processing in terms of time and space, often sidestepping cognitive issues in the interest of building effective software.

CONSTRAINT-BASED GRAMMAR FORMALISMS

Two basic approaches to characterizing well-formed structures can be usefully compared and contrasted. The first, more traditional, approach is based on the notion of inductive definitions. To use a logical example that motivated linguists, consider an inductive definition of the well-formed formulae (WFF) of propositional logic. First, there is the base case of propositional symbols, which are assumed to be WFFs. Then, if P and Q are WFFs then so is the conjunction (P and Q) and the negation (not P). Iterating these constructions generates the full set of WFFs. Any formula that can be built up from propositional symbols by applying conjunction or negation is taken to be well formed.

The second approach to picking out the well-formed structures is based on constraints. Rather than starting from a small set of structures known to be well formed, a large set of possibilities is considered and the ill-formed ones are removed. For instance, the prime numbers are naturally characterized in this way. Start with all of the natural numbers from 2 onwards, and eliminate the compound numbers, that is numbers that are the product of two smaller numbers greater than one. The remaining numbers are the prime numbers.

Bar-Hillel (1950), working from the tradition of logical languages in mathematics and philosophy, presented one of the first mathematically rigorous definitions of a system for generating the expressions of a natural language. He worked bottom-up from a lexicon associating words and categories, such as *dog* and 'singular common noun', and introduced rules to build larger phrases. For instance, by concatenating a determiner such as *the* with a common noun such as *dog*, the noun phrase *the dog* is generated. This was essentially an early instance of a phrase structure grammar. (*See* **Phrase Structure Grammar, Head-driven**)

Although there is no universally agreed definition, a generative theory is typically taken as one in which a mechanism is proposed for generating (usually by some formal mathematical means) the set of grammatical sentences of a language. Chomsky (1957) proposed perhaps the best-known example of an early generative theory of language. Chomsky introduced the notion of transformation, which he used to relate constructions in a language, such as interrogative and declarative forms of sentences, through derivation. He employed phrase-structure techniques similar to those of Bar-Hillel to generate 'base forms', and then applied various structure-permuting transformations to generate grammatical 'surface forms'. For instance, Chomsky produced the interrogative *will John run* from the delcarative *John will run* by means of a transformation that moves the matrix finite auxiliary to the front of the sentence.

Over the next 20 years, generative systems acquired all the accoutrements of a maturing science. Constraints were introduced to limit the

applicability of some operations. For instance, noun compounding combines two nouns into a new noun, such as *coal oven*, but a constraint would be imposed that the first noun not be plural. By the late 1970s, in the 'government-binding theory' (Chomsky, 1980), the role of constraints on transformations had grown to the point where the transformations themselves were of the general form 'move anything anywhere', requiring constraints to control specifically what moved where. This resulting framework is thus explicitly constraint-based. (*See* **Government–Binding Theory**)

MATHEMATICAL FOUNDATIONS

The mathematics of constraint processing in general involves the distinction between inductive and co-inductive definitions (Barwise and Etchemendy, 1987). An inductive definition provides a base set, and then operations that expand the set. The set defined is then taken to be the smallest set containing the base cases and closed under the operations. A co-inductive definition, on the other hand, begins with a set of structures and provides constraints on the forms of elements. The set defined is the largest subset of the original set satisfying all of the constraints.

The standard general formulation of constraint problems is in terms of logical satisfiability. Consider the simple language of propositional formulae given above, under the standard interpretation. It is natural to ask, for a given formula, whether there is an assignment of truth values to its propositional symbols under which it is true. The formula is thus a kind of constraint on assignments of truth values. Unfortunately, even this simple constraint problem for this simple logical language is very complex computationally. The problem of determining propositional satisfiability (known as 'SAT') is NP-complete (Cormen *et al.*, 1990): every known algorithm to solve such problems can encounter cases whose processing time grows faster than any polynomial. (*See* **Computability and Computational Complexity**)

Robinson (1965) introduced the general technique of 'resolution' for proving theorems in first-order logic. Using the notion of resolution and the simple facts of linguistic agreement, Colmerauer (1993) introduced the notion of logic programming, motivated primarily by the search and constraint problems introduced by linguistic grammars. Colmerauer used logical rules such as the following to code the fact that the noun phrase and verb phrase must agree in number and that the sentence carries the verb form of its matrix verb:

```
s(Words1 + Words2, VerbForm)
  if np(Words1, Number) and
     vp(Words2, VerbForm,
        Number)                    (1)
```

The symbol `s` is taken to be a two-place predicate, whose first argument is a sequence of words and whose second argument is a verb form such as `finite` or `infinitive`. The symbols for noun phrases and verb phrases, `np` and `vp`, are to be read similarly, with an additional argument for number. Such rules are implicitly universally quantified, and thus the above rule can be read as saying that if `Words1` is a sequence of words that forms a noun phrase of number `Number` and `Words2` is a sequence of words that forms a verb phrase of the same number and a verb form `VerbForm`, then the concatenation of `Words1` and `Words2`, indicated as `Words1 + Words2`, forms a sentence with the given verb form `VerbForm`. (*See* **Resolution Theorem Proving**)

The notion of constrained phrase-structure rules was introduced, along with a very general notion of feature, into mainstream linguistics by Harman (1963). Since then, every branch of the field, from phonetics to pragmatics, has adopted some kind of 'feature-based' analysis. In these theories, rather than relying on a positional encoding, as in first-order terms, the values are named.

In theories such as lexical–functional grammar and head-driven phrase structure grammar, feature structures are used to represent partial information. This more general data structure is particularly adept at representing the kind of sparse information found in linguistic constraints, which often indicate the behavior of a handful of linguistic features among hundreds. Feature structures of the form employed in head-driven phrase structure grammar also allow a natural form of knowledge representation through inheritance. Processing with such structures has essentially followed that of first-order terms, with systems being based on constraint resolution and, in particular, unification. (Unification is an operation that takes two terms or feature structures and produces a new term that contains all of the information in both, or returns failure if they are inconsistent.) There are also strong similarities to production systems operating over frames. (*See* **Production Systems and Rule-based Inference**; **Knowledge Representation**; **Lexical-Functional Grammar**)

CONSTRAINT-BASED PARSING

Natural language parsing, as a stage in more general natural language processing, involves generating some or all of the structures compatible with a given sequence of words. Given a context-free grammar and a sequence of words, a representation of all parses can be generated in polynomial time (slightly subcubic). The 'universal recognition problem' involves taking a grammar and a sequence of words and determining whether there is some parse for a sequence of words. Barton *et al*. (1987) showed that the introduction of agreement constraints like those of equation 1 yields a universal recognition problem that is NP-complete; the problem for any fixed grammar, though, remains polynomial. Similarly, word-order constraints added to a general context-free grammar result in NP-complete parsing problems. (*See* **Natural Language Processing**; **Parsing: Overview**)

Most constraint-based parsing systems are hybrids that involve a standard search-based parsing algorithm with side constraints. At any stage where constituents are combined or rules are expanded, a check is made to ensure that the set of constraints remains consistent. If not, the search path is abandoned. At each stage, the information known about variables and their values is represented by means of an assignment to variables. For instance, in parsing *the papers falls* from left to right and bottom up, the determiner *the* is encountered first. This is unspecified for number. When it is combined with the plural noun *papers*, the value of the noun phrase's agreement feature becomes 'plural'. Finally, the attempt to combine the plural noun phrase with the singular verb phrase fails due to a violation of an agreement constraint. Exponential growth in simple parsing arises because the number of possible assignments to variables can grow exponentially. (*See* **Agreement**)

In the field of artificial intelligence, the desire for richer, more structured systems of knowledge representation and reasoning has led to a generalized notion of features and values known as a *frame*. Frames generalize simple feature systems with a finite set of features and a finite set of values by allowing some features to take frames themselves as values. On top of this frame-based representational system, many forms of constraints can be introduced. These lead to a variety of reasoning systems for resolving the constraints. Of particular interest for natural language is the pure constraint-based representation of natural language grammars, which was first introduced in the system KL-ONE (Brachman and Schmolze, 1985).

Of particular interest is the notion of constraint resolution, which is often known as 'classification'. Early work in classification was applied to parsing, most notably in the system KL-ONE. In this purely constraint-based representation of parsing, features are used to represent phrase-structure trees in the same way in which trees are usually coded in computational data structures. For instance, the simple sentence *the kids laughed*, represented as [S [NP [Det the] [N kids]] [VP laughed]], would be represented in a frame as:

```
CAT: S
DTR1: CAT: NP
  DTR1: CAT: Det
    WORD: the
  DTR2: CAT: N
    WORD: kids
DTR2: CAT: VP
  WORD: laughed                    (2)
```

Note that features like CAT (for syntactic category) take simple atomic values, whereas features like DTR1 and DTR2 (for daughter constituents) take values that are themselves frames. A set of grammatical 'rules' can then be naturally modeled as a disjunctive constraint: every local frame must satisfy one of the phrase-structure rules, including lexical rules. In a logical language, this could be expressed as follows:

```
(CAT:S & DTR1:CAT:NP & DTR2:
  CAT:VP) |
(CAT:NP & DTR1:CAT:Det & DTR2:
  CAT:N) |
(CAT:Det & WORD:(the|a|every|
  some|...)) |
(CAT:N & WORD:(kid|boy|dog|...))   (3)
```

Representation of agreement is straightforward:

```
CAT: MAJOR: NP
     AGR: singular
DTR1: CAT: MAJOR: Det
           AGR: singular
      WORD: every
DTR2: CAT: MAJOR: N
           AGR: singular
      WORD: dog                    (4)
```

The constraint on agreement can be represented using equations between paths of features:

```
CAT:NP & DTR1:CAT:Det & DTR2:
  CAT:N & (CAT:AGR = DTR1:CAT:
  AGR) & (CAT:AGR = DTR2:CAT:AGR)
                                    (5)
```

Pollard and Sag's (1994) head-driven phrase structure grammar (HPSG) has taken this representational strategy to the limit, representing all grammatical structure by means of constraints. But rather than being a naive encoding of phrase structure grammars, HPSG followed the linguistic trend of factoring the rule-specific equations such as equation 5 into general theories of agreement, semantics, unbounded dependencies, etc. A typical constraint in HPSG would enforce agreement between a mother and a head daughter, and would apply to every phrase structure configuration. Another constraint might say that the unresolved dependencies in a phrase must be the union of all unresolved dependencies in the daughters. Thus rather than a disjunction of rules like

$$\text{Rule}_1|\text{Rule}_2|\ldots|\text{Rule}_n \qquad (6)$$

HPSG would have

$$\text{Principle}_1 \;\&\; \text{Principle}_2 \;\&\ldots\&\; \text{Principle}_n \qquad (7)$$

Of course, the principles themselves might involve disjunctions of cases. (*See* **Constraint Satisfaction**)

In general, constraint systems such as the one employed in HPSG are Turing-equivalent computational devices, and as such do not even have decidable parsing problems, much less tractable ones. However, the properties of actual models expressed in feature formalisms are much more tractable – the theory actually picked out by HPSG, for instance, is decidable, as are the other major feature-based linguistic theories. Even so, most parsers for HPSG and related constraint-based grammar formalisms are built on top of efficient parsers for phrase structure, with constraints being maintained on the side to filter search.

More recently, the trend in constraint-based theories of language has been to relax the all-or-nothing nature of constraints. In theoretical linguistics, optimality theory, for instance, relies on defeasible constraints that are ordered by strength (Archangeli and Langendoen, 1997). Within computational linguistics, statistical models have largely supplanted logical ones, with the advantage that constraints are not 'hard', but rather 'soft'. That is, like optimality theory, statistical algorithms search for the 'best' structure. In statistical models, that is assumed to be the one with the highest likelihood. In optimality theory, it is the one violating the fewest high-ranking constraints.

Constraints on Movement

Advanced article

Gert Webelhuth, University of North Carolina, Chapel Hill, North Carolina, USA

CONTENTS

Within a sentence, constituents may appear in the local context of the items they stand in a grammatical relation with or they may move to other positions. Such movement phenomena are subject to a number of grammatical constraints.

INTRODUCTION

Theories of syntactic movement try to capture the systematic relationship between groups of sentences such as

[$_S$ *Sandy* wants to show *those pictures* to Jill] (1)

[$_S$ Those pictures Sandy wants to show to Jill] (2)

[$_S$ *Those pictures* I am told [$_S$ Sandy wants to show to Jill]] (3)

In all three sentences the noun phrase *those pictures* is understood as the thing that Sandy wants to show to Jill, but only in sentence 1 does the noun phrase appear in the position immediately following the verb *show*, which is the canonical position for a noun phrase being interpreted as the thing whose state changes as a result of the event denoted by a verb like *show*. In sentences 2 and 3, the noun phrase appears intuitively too far to the left, at the left edge of a clause, a position frequently occupied by a characteristic set of elements in many languages of the world, namely question phrases (sentence 4), relative pronouns (sentence 5), and expressions receiving particular emphasis (sentence 6):

Which pictures does Sandy want to show to Jill? (4)

The pictures *which* Sandy wants to show to Jill are lying on the floor. (5)

The pictures on the left I like but the ones on the right I find ugly. (6)

In transformational grammar, it is assumed that sentences containing dislocated phrases are generated in two steps by a formal grammar. The first step occurs within the phrase structure component and puts each semantic dependent of a verb (or other part of speech) into a local relationship with that verb. This is often referred to as a 'base-generated' structure. For example, the base-generated structure of sentence 2 would be sentence 7, which is structurally identical to sentence 1:

[$_S$ Sandy wants to show *those pictures* to Jill] (7)

The second step, a 'movement' transformation, moves the NP *those pictures* to the beginning of the clause and thereby creates the visible surface order of sentence 2.

Sentence 1 would also be derived from the basic structure in sentence 7, the difference between sentences 1 and 2 being that the NP *those pictures* stays in its base-generated position in sentence 1 but moves to the left sentence periphery in the process of deriving sentence 2.

Not every potential movement of an expression like the movement of *those pictures* in sentence 2 leads to a grammatical sentence. This is illustrated by examples 8 and 9, and 10 and 11:

Sandy met the photographer who showed *those pictures to Jill*. (8)

**Those pictures* Sandy met the photographer who showed to Jill. (9)

Sandy questioned the assumption that the photographer showed *those pictures* to Jill. (10)

Those pictures Sandy questioned the assumption that the photographer showed to Jill. (11)

There must thus exist constraints on movement that allow sentence 2 to be derived from sentence 7 by movement of *those pictures* but which prevent the NP from moving to the left in sentences 8 and 10. This article will discuss the nature of these constraints.

THEMATIC RELATIONS AND ARGUMENT STRUCTURE

In order to address the question of what constraints on movement exist, one needs a way to tell which expressions have moved in a given sentence and where the movement originated. Rather than postulating sentence 7 as the common base structure of sentences 1 and 2 and deriving sentence 2 from sentence 7 by moving *those pictures* to the left, one might alternatively take the left-peripheral occurrence of the NP in sentence 2 as its base position and derive its position to the right of the verb in sentence 1 by a rightward movement operation. One consideration that favors the original derivation over this hypothetical alternative is that sentence 7 base-generates the moved NP next to the verb that it is semantically related to, in the following sense.

Verbs typically refer to events that contain a certain number of participants that stand in a relation specified by the verb. In the case at hand, the verb *show* refers to an event of showing that has three participants: somebody shows something to somebody. Other verbs may refer to events that contain fewer participants: thus, the verb *sneeze* refers to an event with just a single participant, and the verb *peel* refers to a two-place event where somebody peels something. However, across events, participants may share similar properties. For instance, the participant who peels potatoes is more actively involved in the peeling event (in the sense that he or she brings the event into existence) and as a result of this action changes the state of the potatoes. Likewise, whoever shows pictures to somebody else is typically more actively involved in the action and changes the state of the other participants of the event. There has been considerable effort in linguistics to develop a classification of participant roles.

Table 1 contains a number of participant roles that are widely used in the description of word meanings. (The 'theme' role assumed a prominent position when the concept of participant roles came into wide use, and therefore participant roles are often referred to as 'thematic' or 'theta' roles.)

Verbs (and other parts of speech) can be classified according to how many participants their events involve and which participant roles must be present. This information is often referred to as the 'argument structure' of a verb. Table 2 lists some verbs and the argument structures in which they are typically used.

Most verbs have more than one argument structure, i.e. they are compatible with more than one combination of arguments. For instance, *open* can be used with a single patient argument as in *the door opened* or with both an agent and a patient as in *Sue opened the door*.

LINKING BETWEEN LEXICAL AND SYNTACTIC STRUCTURE

The argument structure of a verb strongly influences the syntactic configuration in which its arguments are realized, as can be seen by examining the example sentences in Table 2. In each case, the subject precedes the verb. The intransitive verbs in (a), (b) and (c), i.e. those with a single participant role in their argument structure, make their single argument into a subject. In verbs with multiple participant roles the choice of subject is determined by the following two principles. (Argument-linking principles only apply to active verbs. The linking of arguments in passive verbs is determined by the

Table 1. Some common participant roles

Name	*Abbreviation*	*Approximate definition*
Agent (Actor)	Ag	A participant most actively involved in the event or a participant who causes a change of state in other participants.
Patient (Theme)	Pt	A participant who undergoes a change of state in the event.
Experiencer	Exp	A participant who undergoes a mental or perceptual change of state.
Source	So	A participant who is the source of a transfer or movement.
Goal	Go	A participant who is the goal of a transfer or movement.

Table 2. Typical argument structures of verbs

Verb	*Argument structure*	*Example sentence*
(a) *bark*	(Ag)	The dog *barked*.
(b) *die*	(Pt)	The dog *died*.
(c) *hallucinate*	(Exp)	The witness *hallucinated*.
(d) *kick*	(Ag, Pt)	The horse *kicked* the dog.
(e) *see*	(Exp, So)	The horse *saw* the dog.
(f) *show*	(Ag, Pt, Exp)	The owner *showed* the dog *to* her neighbor.
(g) *give*	(Ag, Pt, Go)	The owner *gave* the key *to* her neighbor.

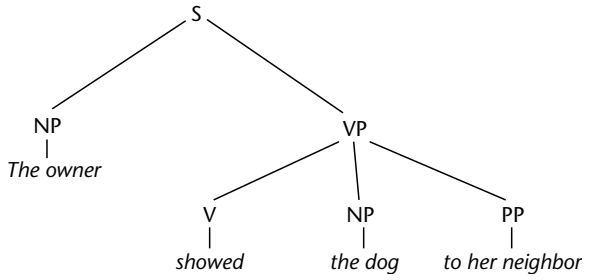

Figure 1. A syntactic structure determined by the argument structure (Ag, Pt, Exp).

linking in the active verbs from which the passive verbs are derived. See Dowty (1991), Levin (1993), and Davis (2001) for further discussions of argument linking.)

1. The participant that is most agent-like is realized as the subject in transitive verbs.
2. The participant that is most patient-like is realized as the direct object of transitive verbs.

In 'X-bar theory', subjects are analyzed as specifiers and direct objects as the NP immediately following the verb within the verb phrase. The argument structure (Ag, Pt, Exp) for the verb *show* thus determines the syntactic structure shown in Figure 1 for sentence (f) in Table 2.

The canonical position of the agent is before the verb, whereas the patient canonically follows the verb. This makes the order in sentence 1 a more natural candidate for the base order than the order in sentence 2. Indeed, sentence 1 is felt as more neutral by native speakers of English. The word order in sentence 2 obtains only under certain constructional conditions, as illustrated in sentences 4, 5 and 6.

ARGUMENTS FOR POSITING MOVEMENT

The motivation for analyzing some sentences in terms of base-generating an expression in one place and subsequently moving it to another place is that it elegantly captures certain grammatical generalizations which would otherwise be hard to account for. One class of such generalizations relates to the issue of argument structure which we have already discussed. For example, sentences based on the verb *show* are ungrammatical if the theme participant remains unexpressed:

*The owner showed to her neighbor. (12)

The ungrammaticality of example 12 can be captured elegantly by requiring that in the base structure of a sentence, the argument structure of every word must be fully realized by respecting linking constraints like the two principles given above. The verb *show* has a patient argument, which according to the second of those principles should be expressed as the first postverbal NP; this condition is not met in example 12, which is therefore ungrammatical. By deriving sentence 14 from 13 and sentence 16 from 15, we have an immediate explanation of why they are grammatical, in contrast to example 12:

Which dog did the owner show to her neighbor? (13)

The owner showed which dog to her neighbor. (14)

Which dog did Sandy say the owner showed to her neighbor? (15)

Sandy said that the owner showed *which dog* to her neighbor. (16)

In sentences 14 and 16, the structures from which sentences 13 and 15 are derived, the patient argument of *show* appears immediately behind the verb in base structure. In example 12, however, no patient NP appears in the sentence at all, either in postverbal position or in a possible moved position, and hence this syntactic structure does not fully realize the argument structure of the verb *show*.

Another powerful argument for movement operations comes from the locality of certain grammatical relations, such as agreement. For instance, present-tense verbs in English systematically agree with their subjects in person and number:

The *owner shows*/**show* the dog to her neighbor. (17)

But they do not systematically agree with any expression outside their clause, because subject–verb agreement is a local relationship:

*The *onlookers* think that the owner *show* the dog to the neighbors. (18)

Yet, in sentences like 19 where the subject of the subordinate clause headed by *show* appears at the beginning of the main clause, the verb *shows* still agrees with the dislocated constituent in person and number, just as it does in sentence 20 where *the owner* stays within the subordinate clause:

Which owner do the onlookers think [$_S$ *shows*/**show* the dog to the neighbors]? (19)

The onlookers think [$_S$ *the owner shows*/ **show* the dog to the neighbors]. (20)

If subject agreement relations are determined before *wh*-extraction, then the verb *show* should agree with its subject in both sentences 19 and 20, no matter whether that subject is subsequently moved to a position in the main clause from which agreement with the embedded verb is otherwise impossible.

The co-occurrence restrictions on anaphoric pronouns provide similar motivation for movement. These expressions must find an antecedent within the immediate clause containing them:

The journalists said [$_S$ *the youngest participants* only paid attention to *themselves*]. (21)

In this sentence, *themselves* can only be understood as referring to the subject of the subordinate clause *the youngest participants*. If the reading were intended whereby the youngest participants only paid attention to the journalists, a personal pronoun would have to be substituted for *themselves*:

The journalists said [$_S$ the youngest participants only paid attention to *them*]. (22)

Compare sentence 23 to sentences 21 and 22:

Who did the journalists say [$_S$ only paid attention to *themselves*]? (23)

In this sentence, the NP *who*, moved from the subordinate clause to the initial position of the main clause, must still be interpreted as the antecedent of the anaphoric pronoun *themselves*, even though it no longer occurs within the immediate clause containing the anaphor. In fact, *who* must be chosen as the antecedent even though it is linearly further away from *themselves* than the subject of the main clause *the journalists*. All of these facts fall into place when we examine the base structure that underlies sentence 23:

The journalists said [$_S$ *who* only paid attention to *themselves*].

Of the two potentially available antecedents of *themselves* in sentence 23, only *who* is contained within the immediate clause containing the anaphor in base structure. If the co-occurrence restriction on anaphoric pronouns applies before the kinds of movement operations discussed here, then the empirical facts about sentence 23 immediately follow, because *who* has been moved out of the subordinate clause whereas *the journalists* was never contained in the same clause as *themselves* and therefore is not capable of anteceding it. The co-occurrence options of moved expressions in their base position should carry over to the new positions they occupy following movement operations.

ROSS'S CONSTRAINTS

Ross (1967), reacting to earlier proposals by Chomsky (1964), presented the first systematic investigation of movement constraints on a large scale. One movement rule that is systematically constrained in many languages is *wh*-movement, the rule that moves a *wh*-expression to the left periphery of a sentence in the formation of an interrogative clause. As Ross showed, this rule may operate in an unbounded fashion in English, i.e. the *wh*-expression can move an arbitrary number of clauses to the left:

What did Bill buy _? (25)

What did you force Bill to buy _? (26)

What did Harry say you had forced Bill to buy _? (27)

What was it obvious that Harry said you had forced Bill to buy_? (28)

And so on. Yet, we find that the following examples are all ungrammatical:

*What did Bill buy potatoes and _? (29)

*What did that Bill wore _ surprise everyone? (30)

*What did Cindy believe the claim that Otto was wearing _? (31)

*Whose did you find _ book? (32)

*What$_1$ did Jill wonder where$_2$ Sandy put $_{-1}$ $_{-2}$? (33)

The underscores in these examples mark the base positions of the moved *wh*-expressions and point to the intended interpretations. For instance, the intended interpretation of example 30 is similar to that of the echo-question in example 34:

That Bill wore WHAT surprised everyone? (34)

Clearly, the paradigm in examples 25 to 33 cannot be captured by putting an upper limit on the number of words or sentences that a *wh*-expression can move across on its way to the left periphery of the sentence. The movement path of the *wh*-word in the grammatical sentence 28 is much longer than the one we find in the ungrammatical sentence 32.

Ross proposed that what matters is the structural organization of the string that *wh*-movement crosses. For instance, to distinguish between examples 25 and 29, Ross formulates the 'coordinate structure constraint' namely, that in a coordinate structure, no conjunct may be moved, nor may any element contained in a conjunct be moved out of that conjunct.

In example 29, *what* is contained in the coordinate noun phrase *potatoes and what*:

Bill bought [$_{NP\text{-}1}$ [$_{NP\text{-}2}$ potatoes] and [$_{NP\text{-}3}$ what]] (35)

The coordinate structure constraint prevents the *wh*-movement transformation from pulling NP-3 out of the coordinate structure NP-1, and so example 29 is ungrammatical.

Example 30 may be contrasted with sentences like:

What did Cindy say that Bill wore _? (36)

These examples are structurally different in that *what* is extracted from a subject clause in example 30 but from an object clause in example 36. Ross formulates the 'sentential subject constraint' to prohibit any movement operation from extracting an element from a sentential subject. Example 31 involves a violation of yet another constraint, the 'complex NP constraint' which blocks extraction from complement clauses to nouns. Compare example 31 with the similar sentence:

What did Cindy believe that Otto was wearing _? (37)

What makes sentence 37 grammatical in contrast to 31 is that the clause *that Otto was wearing what* from which the interrogative element is extracted is a complement to a verb in the grammatical context in sentence 37 but a complement to the noun *claim* in 31, violating the complex NP constraint.

Ross formulates a substantial number of constraints on transformations, as well as empirical insights which have been elaborated on in later work. Ross's doctoral thesis is generally considered one of the most insightful and influential works in the history of generative grammar.

THE CONDITIONS FRAMEWORK

Chomsky (1973) sought to systematize a number of constraints on transformations, including constraints on movement and constraints on semantic interpretation. This effort to postulate general structural constraints that can replace groups of language-particular or construction-specific constraints marked the beginning of a research program that was highly influential and led to the theories of 'government' and 'binding' and the 'minimalist program' which dominated syntactic theorizing in the 1980s and 1990s. The three most far-reaching constraints that Chomsky proposes are the 'tensed sentence condition', the 'specified subject condition', and the 'subjacency condition'.

The tensed sentence condition captures the differences between examples 38, 39 and 40, under the assumption that these are derived from 41, 42 and 43 respectively by movement of the quantifier *each* to the right:

The candidates hated *each* other. (38)

The candidates expected [$_S$ *each* other to win] (39)

*The candidates expected [$_S$ that *each* other would win] (40)

The candidates *each* hated the other(s). (41)

The candidates *each* expected [$_S$ the other(s) to win] (42)

The candidates *each* expected [$_S$ that the other(s) would win] (43)

In example 40, unlike 38 and 39, the quantifier must move into a tensed sentence. In 39, the complement

of *expected* is analyzed as a sentence in order to give this verb a uniform subcategorization frame. Yet, in 39 the quantifier moves into a nonfinite sentence and in 38 it moves into the noun phrase *the other*.

The tensed sentence condition prohibits a rule from applying to two constituents if one of the constituents is contained within a tensed sentence and the other one occurs outside that sentence.

The tensed sentence condition needs to be supplemented by the specified subject condition, since subjects of complement clauses behave differently from non-subjects, as a comparison between examples 38, 39 and 40 and the examples below illustrates:

The candidates expected [$_S$ PRO to defeat *each* other] (44)

*The candidates expected [$_S$ the soldier to shoot *each* other] (45)

The candidates$_1$ *each* expected [$_S$ PRO$_1$ to defeat the other] (46)

The candidates *each* expected[$_S$ the soldier to shoot the other] (47)

Both 44 and 45 are nonfinite, so the tensed sentence condition is unable to account for the grammaticality contrast. What differentiates them is that, in its rightward movement, *each* must cross the lexicalized subject *the soldier* in 45, whereas in 44 it must only cross the abstract anaphoric subject PRO. The specified subject condition prohibits a transformation from relating two constituents if they are separated by a specified subject, where lexical subjects always count as specified.

Finally, the subjacency condition generalizes a number of earlier conditions on movement out of sentences and noun phrases. This will be discussed below.

BARRIERS

Chomsky (1986) attempts to unify all movement constraints in terms of a phrase-structurally defined notion of 'barrier', which is also meant to play a role in the theory of government. Chomsky starts from the assumption that complements generally play a more active role in extraction constructions than either subjects or adjuncts. Consider the following examples:

Who did [$_{IP}$ Mary find [$_{NP}$ a picture of _]]? (48)

*Who did [$_{IP}$ [$_{NP}$ a picture of _] scare the children]? (49)

*Who did [$_{IP}$ Mary laugh [$_{PP}$ when she found a picture of _]]? (50)

??Which car did Mary sleep [$_{PP}$ while Jill fixed _]? (51)

*Which mechanic did Mary sleep [$_{PP}$ while _ fixed the car]? (52)

*How quickly did Mary sleep [$_{PP}$ while Jill fixed the car _]? (53)

(Note the intended interpretation in example 53: *how quickly* modifes *fixed*.)

Examples 48, 49 and 50 show that it is easier to extract a constituent from a complement than from a subject or an adjunct. In 49 *who* has been extracted from the subject of the sentence, and in 50 from an adjunct, and both sentences are worse than 48. Examples 51, 52 and 53 show that under certain conditions it is also easier to extract complements than to extract subjects or adjuncts. Each of these examples involves extraction from an adjunct, but the violation incurred by the subject in 52 and by the adjunct in 53 is felt to be stronger than the violation incurred by the complement in 51.

Complements are thus both easier to extract and easier to extract from, whereas subjects and adjuncts are harder to extract and harder to extract from. Chomsky develops a complex web of constraints and definitions in an attempt to capture these generalizations. Crucial to his approach are certain assumptions about the X-bar theory of phrase structure, including the tree structure shown in Figure 2.

One problem with these assumptions is that Chomsky requires this full abstract structure to be

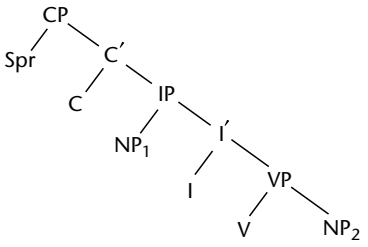

Figure 2. Chomsky's proposed uniform structure for sentences. 'C' stands for complementizers like *that* and *whether*; 'Spr' is a 'landing site' for *wh*-operators of any part of speech; 'I' stands for inflectional elements and auxiliaries; 'NP$_1$' is the clausal subject position; and 'NP$_2$' is the clausal direct object position.

present even in sentences where the structure is not supported by observable morphological or lexical material. Thus, even simple sentences like *Mary worked* are given abstract C and I nodes, even though there is no empirical evidence for the existence of a complementizer or a self-standing inflectional element separate from the verb in these kinds of sentences.

In order to account for the contrasts in examples 48 to 53, which show that it is possible to extract from a complement but impossible to extract from subjects or adjuncts, Chomsky formulates several assumptions. Firstly, he defines 'blocking categories' as maximal projections that are not theta-governed by a lexical head. Here, lexical heads include the major parts of speech (verb, adjective, noun, etc.) but specifically exclude the minor parts of speech (complementizer and inflection).

IP is governed by C, while VPs and subjects are governed by the I. Adjuncts may in principle be governed by lexical heads, but they are, by definition, not theta-marked. Thus, IP, VP, subjects and adjuncts are blocking categories. Complements are the only class of expressions that are always theta-marked (this is a requirement of Chomsky's (1986) 'projection principle') and they are governed by a lexical head. Thus, complements are not blocking categories.

According to this definition, then, VPs should be barriers to movement, but this is empirically incorrect. Chomsky therefore proposes a mechanism that allows the 'barrierhood' of VP to become voided. He defines barriers to movement as follows: IP is a barrier for everything within its subject or a sentence-level adjunct; subjects and adjuncts are barriers for everything contained in them; and CP is a barrier for everything contained within IP.

The ungrammaticality of examples 49 and 50 now follows, given the subjacency condition, which stipulates that no movement step is allowed to cross more than one barrier. In 49, the subject NP is a barrier and so is the IP. The extraction of *who* from [$_{IP}$ [$_{NP}$ *a picture of* _] …] thus crosses two barriers, implying that the sentence is ungrammatical. Example 50 is similar, except that in this case the second barrier is the adjunct PP. In contrast, example 48 is grammatical, since the complement NP is not a barrier, given that it is theta-marked by a lexical head.

Chomsky also addresses the data in examples 51, 52 and 53. While adjuncts are generally hard to extract from, the judgment of any given extraction depends on the kind of element that is extracted. In English, extraction of complements from movement islands often yields a slightly more favorable judgment than extraction of subjects or adjuncts from the same kind of island. Chomsky uses the 'empty category principle' (Chomsky, 1981) in an attempt to solve this problem. According to this principle, traces must be properly governed, i.e. they must be either theta-governed by an X^0 head or antecedent-governed. To be antecedent-governed, no barrier is allowed to intervene between the trace and its antecedent (i.e. the moved expression or another one of its traces).

From this definition of proper government it follows that the trace of a complement is always properly governed and hence need not be antecedent-governed. Subject and adjunct traces, in contrast, are not governed by X^0 heads that theta-mark them and thus need to be antecedent-governed in order to be properly governed. Extraction of a complement from an adjunct thus yields a violation only of the subjacency condition, as shown earlier, whereas extraction of a subject or an adjunct under the same conditions yields a violation of the empty category principle in addition to the subjacency violation incurred by complements. Examples 52 and 53 should thus be stronger violations than example 51.

The barriers framework has a number of conceptual and empirical weaknesses. Ultimately, Chomsky abandoned it to pursue even more abstract phrase-structural theories. Other researchers turned their back on the principles-and-parameters framework, believing that the syntactocentric, derivation-driven design of the theory as a whole, rather than individual definitions or principles, were to blame for its chronic empirical problems. The proliferation of abstract phrase-structure categories has already been mentioned. Furthermore, there are large amounts of data that are incompatible with the main ideas of the Barriers framework. There are languages in which the subject–object and object–adjunct asymmetries that Chomsky's theory is specifically designed to derive do not obtain. For instance, in Swedish subjects can be extracted much more easily than Chomsky's theory predicts. Moreover, with respect to adjuncts, von Stechow and Sternefeld (1988, p. 371) present constructions in German that show the precise opposite of what Chomsky's theory predicts: adjuncts can be extracted from certain phrases that do not allow complements to escape. In fact, even English is much less uniform than Chomsky's theory would lead one to expect. Santorini (2001) has collected a list of attested examples that violate a number of prominent constraints on movement that have been postulated, including the following

example which contains an extraction from an adjunct:

a scenario that government agencies are spending billions of dollars preparing for (54)

Other data confirm that principles-and-parameters theories are an oversimplification of the data. Culicover (1999) presents the following contrast, illustrating that whereas prepositions generally allow their complement to move away in English, the preposition *since* is an idiosyncratic lexical exception to this generalization which cannot be captured by setting a category-wide parameter:

*Which party hasn't John called since _? (55)

As successive reforms of Chomsky's parametric framework have been unable to address these sorts of detailed empirical problems, constraint-based lexicalist theories of grammar have gained increasing acceptance in linguistics, psycholinguistics, language acquisition, and computational linguistics. We will now discuss such theories.

NON-TRANSFORMATIONAL APPROACHES

Non-transformational approaches to grammar are generally motivated by a belief that, as Chomsky has sought more elegant answers to a restricted set of problems, his theories have become less empirically realistic and the theoretical constructs he invokes have become less open to theory-neutral verification by other researchers. In the 1980s and 1990s, a number of Chomskyan linguists moved on to other theories, in particular constraint-based lexicalist theories.

One problem that systematically arises with Chomsky's theory is that the broad generalizations he attempts to derive are counterexemplified by small classes of items or individual words. In order to circumvent this problem, researchers have developed tools that are capable of deriving grammatical generalizations of variable scope, including the fully productive generalizations that Chomsky's theory can handle, but also semi-productive patterns and completely idiosyncratic phenomena.

Currently the most credible alternatives to Chomsky's syntactocentric principles-and-parameters approach invoke a sophisticated set of lexical and constructional tools in the analysis of grammatical phenomena, including movement phenomena. Most prominent among these theories are 'Head Driven Phrase Structure Grammar' (Pollard and Sag, 1994), 'Lexical Functional Grammar' (Bresnan, 2000), and 'Construction Grammar'. The remainder of this article will focus on the approach to movement proposed in the first of these theories.

Head Driven Phrase Structure Grammar developed from 'Generalized Phrase Structure Grammar' (Gazdar *et al*., 1985). The desire for a linguistic theory that is simultaneously formally precise, empirically accurate and broad, and computationally implementable in an efficient manner, led Gazdar to avoid all transformations in his theory, including those that move constituents from a base-generated position to another position in a tree-altering fashion. Instead, he proposed that 'movement' is a metaphor for a featural dependency in a tree, encoding the information that a constituent that in principle can be expressed in one part of a tree can also be expressed elsewhere in that tree.

Sag and Fodor (1994) and Bouma *et al*. (2001) have combined Gazdar's theory of extraction with a theory of argument realization that gives words fine control over the syntactic realization options of their arguments. Together with constructional constraints on the flow of argument information in a syntactic tree, these assumptions yield an empirically powerful theory of extraction phenomena which its adherents believe to be capable of deriving the same broad generalizations that Chomsky's syntactocentric theory is able to capture, without sacrificing coverage of semi-productive and idiosyncratic phenomena.

Bouma *et al*. make use of the idea that a word can be represented by a data structure having an argument structure and a valence. The argument structure of a word is involved in interpretative properties, including the binding theory, while the valence determines the surface-syntactic context that the word must appear in (for principled reasons, the theory does not countenance any unobservable syntactic levels, such as Chomsky's D-structure or LF, nor any unobservable signs such as traces and phonologically empty heads). Part of the individual grammar of a language is a set of principles that determine how each of a word's arguments may be realized on the surface. Thus, if the language permits arguments to be realized morphologically, then they will not be projected into the syntax, which makes the dependence on phonologically empty subjects superfluous and keeps syntactic structures concrete and open to theory-independent verification. Extraction phenomena are handled in terms of permissible mappings between argument structure and valence. Just as words have the ability to determine

whether or not their arguments can be spelled out morphologically, they have the ability to constrain the syntactic realization options of their arguments: arguments that appear in a word's valence are spelled out in the word's local syntactic domain, whereas the descriptions of arguments that appear in the word's GAPS specification are percolated upward in the syntactic tree until this information appears in a syntactic configuration where a filler sign is found which is featurally compatible with the argument description. For the verb *show* in examples 1 and 2, an argument structure like the following would be postulated:

$$\text{ARG-ST} \ < \text{NP}_{\text{agent}}, \ \text{NP}_{\text{patient}}, \ \text{PP}_{\text{goal}} > \qquad (56)$$

Since *show* permits each of its arguments to be realized either locally or nonlocally, its valence and gaps specification may be any of the following, among others:

$$\begin{array}{l}\text{SUBJ} \ < \text{NP}_{\text{agent}} > \\ \text{COMPS} \ < \text{NP}_{\text{patient}}, \text{PP}_{\text{goal}} > \\ \text{GAPS} \ \{\}\end{array} \qquad (57)$$

$$\begin{array}{l}\text{SUBJ} \ < \text{NP}_{\text{agent}} > \\ \text{COMPS} \ < \text{PP}_{\text{goal}} > \\ \text{GAPS} \ \{\text{NP}_{\text{patient}}\}\end{array} \qquad (58)$$

$$\begin{array}{l}\text{SUBJ} \ < \text{NP}_{\text{agent}} > \\ \text{COMPS} \ < \text{NP}_{\text{patient}} > \\ \text{GAPS} \ \{\text{PP}_{\text{goal}}\}\end{array} \qquad (59)$$

Whereas subjects and complements must be realized within the valence domain of the verb, the information in GAPS is percolated up the tree in a fashion that allows fillers to be found for these gaps outside the verb's local valence domain. This is how long-distance dependencies arise. Specification 57 is used to generate surface forms like sentence 1, where each of the three arguments of *show* is generated within its local valence domain. Specification 58 would underlie a sentence like sentence 2, where the subject and the PP object remain within the valence domain, but the direct object NP is realized as a filler at the beginning of the clause. Specification 59 would underlie such sentences as *To Jill I want to show these pictures* or *to whom do you want to show these pictures*, where the PP argument is realized at a distance.

This theory gives words full control over whether an argument may or must be realized within the local valence domain of the word. It is thus predicted that, as in other grammatical domains (e.g. inflection), some languages will be very homogenous in their constraints, whereas others will be less so. It is even predicted that different head types within a language may behave differently. There is impressive evidence to support this prediction. For instance, whereas verbs in English permit their specifier (their subject) to be extracted, nouns never do, as example 32 demonstrates. This generalization can be captured by imposing featural well-formedness conditions on the permissible relationship between members of the parts of speech noun and verb and their respective specifier arguments. The kind of lexical idiosyncrasy that is represented by example 55 in the extraction domain (i.e. that *since* does not allow its NP argument to be realized in GAPS) is parallel to idiosyncratic lexical requirements in other domains (e.g. that a verb exceptionally requires a different case on its direct object than most other transitive verbs in the language).

Other differences between languages and constructions can be captured elegantly by constraining the values of the GAPS attribute in different parts of the syntactic tree or in different constructions. For instance, in languages where extraction from subjects is impossible, it suffices for the grammar to contain a constraint that the GAPS value of any subject be the empty set. An analogous constraint will prevent extraction from adjuncts or *wh*-islands where these constraints are empirically called for. Finer distinctions can be drawn by imposing constraints on the content of GAPS in specific constructions and languages. Thus, it would be easy to derive the generalization that arguments are easier to extract from some constructions whereas adjuncts are easier to extract from others. Universal tendencies that are not the result of parsing or memory preferences can be encoded in terms of the grammatical archetypes proposed in Ackerman and Webelhuth (1998), which are conceived of as the set of grammatical concepts that guide the language learner's acquisition process.

Construction Grammar

Introductory article

Adele E Goldberg, University of Illinois, Urbana, Illinois, USA

CONTENTS

Construction Grammar is a linguistic theory concerned with the nature of speakers' knowledge of language. Like traditional grammars, Construction Grammar takes the basic units of language to be form–meaning pairings, or constructions.

CONSTRUCTIONS

A *construction* is defined as a pairing of form with meaning/use, such that some aspect of the form or some aspect of the meaning/use is not strictly predictable from the component parts or from other constructions already established as existing in the language. On this view, phrasal patterns, including the constructions of traditional grammarians, such as relative clauses, questions, locative inversion, and so on, are given theoretical status. Words (or really, *morphemes*) are also constructions, according to this definition, since their form is not predictable from their meaning or use. Given this, it follows that the mental dictionary or *lexicon* is not neatly delimited from the rest of grammar, although phrasal constructions differ from lexical items in their internal complexity.

Both phrasal patterns and lexical items are stored in an extended 'constructicon'. Elements within the constructicon vary in degrees of idiomaticity. At one end of the idiomaticity continuum, we find very general, abstract constructions such as the subject–predicate construction; at the other end, we find simple lexical items and constructions with all of their lexical fillers specified but with noncompositional meanings (e.g. 'kick the bucket'). In between, we find the full range of possibilities: for example, idioms which have freely fillable positions (e.g. 'keep/lose X's cool'), compositional collocations with fixed word order (e.g. 'up and down'), phrasal patterns that are only partially productive (e.g. the English ditransitive), and phrasal patterns which are partially morphologically specified (e.g. 'The *X*er, the *Y*er', as in 'The less it rains, the better the potatoes').

Construction Grammar shares with several other current theories, including Head-Driven Phrase Structure Grammar, Cognitive Grammar, and Montague Grammar, the basic and fundamental idea that the construction (or *sign*) is central to an account of language. This view of grammar can be contrasted with the claim made by Principles and Parameters theories that constructions are entirely epiphenomenal, a mere by-product of the interaction of the principles of Universal Grammar, once the values of the parameters are fixed. Although most aspects of language are highly motivated, in the sense that they are related to other aspects of the grammar and are non-arbitrary, Construction Grammar holds the view that much of language is idiosyncratic to varying degrees and must therefore be learned.

Declarative, Monostratal Representation

A given sentence is licensed by the grammar if and only if there exists in the language a set of constructions which can be combined (or superimposed) to produce an accurate representation of the surface structure and semantics of that sentence. An ambiguous sentence is a sentence for which there exists more than one set of constructions that can be assembled to produce a possible representation. Constructions are represented declaratively, and any constructions which do not conflict may be combined to give rise to grammatical expressions. Thus Construction Grammar is monostratal: no derivations are posited.

Typically, particular sentences (or *constructs*) instantiate several constructions simultaneously. For example, sentence (1) below instantiates the subject–predicate construction, the ditransitive construction, the determiner construction ('the letter'), the past tense morphological construction ('fax-*ed*'), and five simple morphological constructions, corresponding to each word in the sentence:

Elena faxed Ken the letter. (1)

Integrated Information

Conventionalized aspects of both meaning and use are directly related to particular syntactic patterns within individual constructions. Thus, Construction Grammar does not assume that syntax is generally isolated or isolatable from semantics or conditions of use. Construction Grammar also eschews a strict division between the pragmatic and the semantic. 'Frame-semantic' (encyclopedic) meaning is considered fundamental to an adequate understanding of linguistic entities, and as such is integrated with more traditional definitional characterizations. Generalizations about particular arguments being topical, focused, inferable, and so on, are also stated as part of the constructional representation. Facts about the use of entire constructions, including register, dialect variation, etc., are stated as part of the construction as well. Thus a construction may be posited because of something not strictly predictable about its frame-semantics, its packaging of information structure, or its context of use.

Relations among Constructions within a Language

Constructions do not form an unstructured set, but rather a highly integrated system, based on general principles of categorization. Constructions are typically closely related to other constructions, and are, in that sense, not arbitrary. Generalizations across constructions are captured within the theory via an inheritance hierarchy, which allows shared structure to be represented.

For example, an abstract *Left Isolate* construction is inherited by several different constructions, exemplified by the following:

a. the woman who she met yesterday (restrictive relative clause)
b. Abby, who she met yesterday (nonrestrictive relative clause)
c. Bagels, I like. (topicalization)
d. What do you think she did? (main clause nonsubject *wh* − question) (2)

Each of these patterns – restrictive and nonrestrictive relative clauses, topicalization, and *wh*-questions – requires a distinct construction of its own, owing to its particular formal and pragmatic properties. But each inherits from the more general Left Isolate construction, which specifies the properties that are shared. In particular, this construction has two 'sisters', with the specification that the left sister satisfies the valence requirement of some predicator at an undefined depth in the right sister; the right sister is a maximal verb phrase, with or without a subject. Thus the Left Isolate construction serves to capture the generalizations across these various patterns.

Formalization

Many practitioners of this theory have adopted the use of a unification-based formalism in order to rigorously detail the specifications of particular constructions. Thus each construction is represented by an Attribute–Value Matrix (AVM). Each attribute can have at most one value. Attributes may be *n*-ary, or may be feature structures themselves.

Any pair of AVMs can be combined to license a particular expression, as long as there is no value conflict on any attribute. When two AVMs unify, they map onto a new AVM, which has the union of attributes and values of the two original AVMs.

RESEARCH FOCUS

Data

Research in Construction Grammar has emphasized the importance of attested data, gathered from discourse or corpora. At the same time, Construction Grammarians routinely supplement corpus data with data gained from introspection, one obvious reason being that corpora do not contain sentences marked as unacceptable. Another source of data comes from psycholinguistic experimentation.

Full Coverage: Lexical Semantics and Marked Constructions

There has been a focus on the semantics and distribution of particular lexical items within the framework, owing to the belief that the rich semantic/pragmatic constraints on individual words or idiomatic phrases reveals much about our knowledge of language. There has been a great deal of attention paid to marked constructions within the theory. For example, consider the Covariational Conditional construction, exemplified by 'the more you think about it, the less you understand'. Independent knowledge of 'the' and grammatical comparison will not directly predict that this relevant

class of expressions will exist or have exactly the form and meaning they have; therefore a distinct construction is posited. Other examples of marked constructions include the 'What's *X* doing *Y*?' construction, exemplified by sentences such as 'What's that fly doing in my soup?', and the Nominal Extraposition construction, e.g. 'It's amazing the difference!'.

As these examples indicate, Construction Grammar aims to account for the full range of facts of any language, without assuming that a particular subset of the data is part of a privileged 'core'. Researchers argue that marked constructions shed light on more general issues, and serve to illuminate what is required for a complete account of the grammar of a language. Construction Grammarians takes the point of view that the ordinary patterns of grammar do not differ qualitatively from these sorts of quantitatively more complex constructions.

Argument Structure Constructions

In many current linguistic theories, the form and general interpretation of basic sentence patterns of a language are taken to be determined by semantic and/or syntactic information specified by the main verb in the sentence. The sentence patterns given in (3) and (4) indeed appear to be determined by the specifications of 'give' and 'put' respectively:

Chris gave Pat a ball. (3)

Pat put the ball on the table. (4)

'Give' is a three-argument verb and is expected to appear with three complements corresponding to agent, recipient, and theme. 'Put', another three-argument verb, requires an agent, a theme, and a location, and appears with the corresponding three complements in (4). However, while (3) and (4) represent perhaps the prototypical case, the interpretation and form of sentence patterns of a language are not reliably determined by independent specifications of the main verb. For example, it is implausible to claim that 'sneeze' has a three-argument sense, and yet it can appear as in (5):

She sneezed her tooth across the yard. (5)

The following attested examples similarly involve sentential patterns that do not seem to be determined by independent specifications of the main verbs:

'She smiled herself an upgrade.' (Douglas Adams, *Hitchhiker's Guide to the Galaxy*; Harmony Books) (6)

'We laughed our conversation to an end.' (J. Hart, *Sin*; 1992, Ivy Books) (7)

Moreover, verbs typically appear with a wide array of complement configurations. Consider the verb 'sew' and the various constructions in which it can appear (labeled in parentheses):

a. Pat sewed all afternoon. (intransitive)
b. Chris sewed a shirt. (transitive)
c. Pat sewed Chris a shirt. (ditransitive)
d. Pat sewed the sleeve shut. (resultative)
e. Pat sewed a button onto the jacket. (caused − motion)
f. Chris sewed her way to fame and fortune. (way − construction) (8)

In Construction Grammar, instead of predicting the surface form and interpretation solely on the basis of the verb's independent specifications, the lexical verb is understood to combine with an argument structure construction (e.g. the ditransitive, resultative, the caused-motion construction, etc.). Verbs constrain the type of argument structure constructions with which they can combine by their frame-specific semantics and particular obligatory roles, but they typically can combine with constructions in several ways.

It is the argument structure constructions that provide the direct link between surface form and general aspects of the interpretation such as something causing something else to move, someone causing someone to receive something, something moving somewhere, someone causing something to change state, and so on. The argument structure constructions, which provide the basic sentence patterns of a language, directly reflect these types of basic frames of experience. That is, the skeletal patterns, independently of the main verb, designate such patterns of experience. Thus constructions are invoked both for marked or especially complex pairings of form and meaning and for many of the basic, unmarked patterns of language.

FUTURE PROSPECTS

Cross-linguistic Work

Constructions that are sometimes labeled as the 'same' in two languages typically differ subtly in their form, their meaning, and/or their use. Thus

Construction Grammarians have generally been cautious about trying to explain generalizations that may not be exceptionless. There is, however, a growing body of work on constructions in various languages, and a growing focus on accounting for cross-linguistic tendencies, similarities, and implicational hierarchies.

Psycholinguistics: Processing and Acquisition

A central claim made by Construction Grammar is that words and phrases are the same basic type of entity: learned pairings of form and meaning/use. A good deal of interest in the theory has been generated within psycholinguistics, by researchers in both processing and acquisition, because they see in Construction Grammar the possibility of a psychologically plausible and testable linguistic theory.

Conversation, Structure of

Introductory article

Herbert H Clark, Stanford University, Stanford, California, USA

CONTENTS

Conversations emerge as people use dialogue to coordinate on joint activities they engage in. People proceed turn by turn as they reach local agreements on the course of each section and subsection, including the opening and closing of the conversation itself.

INTRODUCTION

Conversations are the product of people engaged in joint activities. A joint activity is one in which two or more people have to coordinate with each other to succeed. When two people waltz, play a duet, or wrestle, they coordinate their individual actions largely by gesture, touch, and other techniques. When two people gossip, plan a vacation, or negotiate a contract, they coordinate largely through dialogue. The structure of these conversations emerges as the participants jointly manage their way through the gossip, the planning, or the negotiation.

Conversations, therefore, reflect the joint activities they coordinate. Every joint activity has participants who are distinct from bystanders, onlookers, or overhearers. In most joint activities, each participant has a role, such as clerk or customer, teacher or student, friend calling or friend called, and the roles help determine what the participants do and say. Most joint activities have mutually recognized goals such as exchanging gossip, planning a vacation, or negotiating a contract, and these have subgoals. Some goals are set from the start, but others get established in the course of the conversation. The participants also have private agendas – such as being polite, or finishing quickly – and these, too, constrain what they do and say. Often, people alternate between two or more joint activities – such as gossiping and eating dinner – and the structure of their conversation reflects the alternations.

ACTIONS OF DIALOGUE

It takes coordination to carry out a joint activity. Joint activities have boundaries – distinct beginnings and ends, and transitions from one part to the next – but these boundaries don't exist until the participants agree to them. To enter a planning session, for example, two people must agree on (1) what the joint activity is to be, (2) who is to take part, and (3) in what roles. They must also maintain or change these agreements at each transition point. People accomplish all this with dialogue, locally, turn by turn.

One basic method for reaching these agreements is the *adjacency pair*, as in this spontaneous example from Svartvik and Quirk (see Further Reading):

Ann	where is your office,
Burton	in the Strand,
Ann	oh well, yes,

Adjacency pairs consist of two parts, by different speakers, where part 2 is conditionally relevant given part 1. Part 1 is a *proposal*, and part 2 is expected to be the *uptake* of that proposal. Here, in turn 1, Ann proposes that Burton tell her where his office is, and in turn 2, he takes up the proposal by saying that it is in the Strand. Ann and Burton use the two turns to agree on the content, participants, and roles of Ann's projected joint action. They would have failed to reach that agreement if, for example, Burton had replied 'What do you mean?' (failing to coordinate content) or 'You mean me?' (failing to coordinate participants). Turns 2 and 3 constitute a second adjacency pair, an assertion plus its uptake.

People in conversation use adjacency pairs for many types of joint actions. They use them for exchanges of information (as in Ann and Burton's question plus answer), greetings ('Hi,' 'Hi'), farewells ('Bye,' 'Bye'), offers ('Have a beer,' 'Thanks'),

orders ('Sit down,' 'Yes, sir'), and apologies ('Sorry,' 'Oh, that's okay'), among others. They use them for even the simplest exchanges of information ('In the Strand,' 'Oh well, yes').

Adjacency pairs can also be used to *project* larger sections, as in this spontaneous example:

B I like tuh ask you something.
A Shoot.
B Y'know *I*'ad my license suspended fur six munts.
A Uh huh.
B Y'know for a reason which, I rathuh not, mention tuh you, in othuh words, – a *ser*ious reason, en I like tuh know if I w'd talk tuh my senator, or – somebuddy, could *they* help me get it back.

B's first turn is a *pre-question*. With it he proposes to ask A a question, and A agrees. B now has the freedom to take up preliminaries to his question, and it takes the two of them several turns to do that. Only then does he ask his question proper, 'Could they help me get it back?' Pre-questions project not only the eventual question but preliminaries to that question.

Pre-questions and their responses belong to a large family of so-called *pre-sequences*. Here are a few more examples:

Pre-request	Customer	Do you have hot chocolate?
	Waitress	Yes, we do.
Pre-invitation	Man	What are you doin?
	Woman	Nothin. What's up?
Pre-narrative	June	Did I tell you I was going to Scotland?
	Kenneth	No.
Pre-conversation	Caller	(rings telephone)
	Recipient	Miss Pink's office.

Each pre-sequence prepares the way for another joint action. The pre-request sets up a request ('I'll have one'); the pre-invitation sets up an invitation ('Would you like…'); the pre-narrative sets up a narrative; and the pre-conversation sets up an entire telephone conversation.

SECTIONS OF CONVERSATIONS

Conversations tend to emerge as a sequence of topics, or sections. Each section reflects a different phase in the overall joint activity – the next bit of gossip, the next segment of the vacation being planned, the next issue of the contract being negotiated. The participants must agree on the opening and closing of each section, and that is where pre-sequences are useful.

Sections that consist of narratives (jokes, anecdotes, recountings of events), for example, are often introduced by a pre-narrative and its response. The following is an instance from Svartvik and Quirk (see Further Reading):

Nancy: I acquired an absolutely magnificent sewing-machine, by foul means, did I tell you about that?
Kate: no,
Nancy: well when I was. doing freelance advertising – (proceeds to give a five minute narrative)

Nancy proposes to tell Kate a story ('Did I tell you about that'), and Kate accepts ('No'). That allows Kate to embark on her narrative – an extended section of the conversation. It takes both parties to agree, because the recipient can always decline, as in this example, also from Svartvik and Quirk:

Connie: did I tell you, when we were in this African village, and (- they were all out in the fields, - the)
Irene: (yes you did, yes, - yes)
Connie: babies left alone, -
Irene: yes.

Irene interrupts Connie (the speech in brackets is overlapping) to say that she *has* heard the story, and the two of them then go down a different path. So conversations are opportunistic: the paths people take depend on the opportunities that become available with each agreement. Nancy and Connie use their pre-narratives to find the best way to proceed and, receiving different replies, go in different directions.

People help signal which opportunities they are taking by using *discourse markers*. For example, Nancy used 'well' to signal that she was introducing a change in perspective as she began her story. Other discourse markers indicate such boundaries as the start of a new topic (e.g., 'so', 'then', 'speaking of that'), the start of a digression ('incidentally', 'by the way'), or the return from a digression ('anyway', 'so'). All help in coordinating what happens next.

Opening a conversation takes special coordination as two or more people move from not being in a conversation to being in one. The following is the opening of a conversation between acquaintances, again from Svartvik and Quirk:

Karen: (rings Charlie's telephone)
Charlie: Wintermere speaking? -
Karen: hello?
Charlie: h*el*lo
Karen: Charlie

Charlie: Yes
Karen: actually it's
Charlie: hello Karen
Karen: it's me
Charlie: M
Karen: I (- laughs) I couldn't get back last night, (continues)

First, Karen and Charlie coordinate contact through a proposal to have a conversation (the telephone ring) and its uptake ('Wintermere speaking?'). Next, they mutually establish their identities. Karen tells Charlie that she recognizes him in turn 5, but Karen has to say 'hello?' 'Charlie', and 'actually it's' before he identifies her in turn 8. Only then does Karen introduce the first topic. It took 10 turns for them to coordinate on the participants, roles, and content of the conversation.

Conversations are no easier to close, as illustrated in this ending to a telephone conversation:

June and I'll. I'll ring again, as soon as I can on the tenth, uhh to definite confirm it,
Kay right,
Kay okay,
June right,
June thanks a lot,
Kay r. right,
June bye bye,
Kay bye

Although June and Kay finish a topic in turns 1 and 2, they cannot hang up without agreeing to hang up. So in turn 3, Kay proposes to close the conversation ('Okay'), and although June could introduce a new topic, she agrees to Kay's proposal ('Right'). That opens up the closing in which the two exchange thanks ('Thanks a lot' 'Right') and then good-byes. The two must *agree* to close the conversation before they actually close it.

GROUNDING WHAT IS SAID

People carry out joint activities against their *common ground* – their mutual knowledge, mutual beliefs, and mutual assumptions. They infer their common ground from past conversation, joint perceptual experiences, and joint membership in cultural communities. When Ann asks Burton 'Where is your office?' she *presupposes* certain common ground – for example, that Burton works on computers and has an office in London, but that she doesn't know where. And with the question itself, she *adds to* their common ground that she wants to know. Conversations proceed by orderly increments to common ground – especially to the common ground relevant to the current joint activities.

So if conversations are to succeed, the participants must *ground* what they say. To ground what is said is to establish the mutual belief that the addressees have understood the speakers well enough for current purposes. One technique for grounding is the adjacency pair itself. When Burton said 'In the Strand', he displayed to Ann how he had interpreted her question. If Ann hadn't been satisfied with that interpretation, she could have corrected it, for example by replying 'No, I meant …'. By following up Burton's reply with 'Oh well, yes,' she displayed her acceptance of his interpretation. Another technique is the *back-channel response*, *acknowledgment*, or *continuer*. In two-party conversations, addressees are expected to add 'uh huh' or 'mhm' or 'yeah' at or near the ends of certain phrases. With these, they signal that they understand well enough for the speaker to continue.

Grounding is sometimes achieved through *side sequences*, as in this spontaneous example, once more from Svartvik and Quirk:

Roger well there's no general agreement on it I should think,
Sam on what?
Roger on uhm - - on the uhm – the mixed up bits in the play, the
Sam yes

When Sam didn't understand Roger's 'it', he initiated an embedded adjacency pair in turns 2 and 3, a side sequence, to clear up the problem. Only when he had cleared it up did he acknowledge or agree with 'Yes'. Side sequences are initiated to clear up not only mishearings and misunderstandings but other preconditions to taking up the first part ('Why do you want to know?'). Grounding is sometimes accomplished by overlapping speech. When Irene interrupted Connie's offer 'Did I tell you …' to say, 'Yes you did, yes, – yes', she was signaling to Connie that she already understood and Connie didn't need to go on.

CONCLUSION

The structure of conversations emerges step by step as people coordinate on each new move in their joint activities. People need to coordinate on the content, participants, and roles of each joint action, and they do that in a sequence of local, opportunistic agreements. It is these techniques that give conversations their structure.

Discourse Processing

Intermediate article

Barbara Di Eugenio, University of Illinois, Chicago, Illinois, USA

CONTENTS

The theory of discourse processing concerns the computational processes underlying the interpretation and production of text encompassing more than one sentence – i.e., discourse. Discourse is generally taken to be written, and often, but not always, monologic.

INTRODUCTION

Two phenomena are considered intrinsic to discourse processing: the interpretation and production of phrases and utterances whose meaning depends on the discourse context; and the fact that a sequence of two or more utterances almost always conveys a meaning that is more than the sum of the meanings of the individual utterances. Consider the following example:

> As soon as they got to the beach, Karin jumped into the water. She was so hot from the long drive. (1)

Example 1 illustrates the issues most closely associated with the above phenomena: respectively, reference resolution and production, and text coherence.

Reference resolution concerns the interpretation of those noun phrases speakers use to refer to what are called discourse entities; i.e. entities in the model of the discourse – for example, *Karin*, *she*, *the long drive*. Reference resolution is closely related to the notion of processing of anaphora. This article will discuss the converse problem of referential expression generation, namely, how to choose a specific referential expression among all those that can potentially be used to refer to a discourse entity. (*See* **Anaphora, Processing of**)

It is difficult to define text coherence exactly. We could define it as the quality of a text that is 'tied' together in just the right way. It is text that can be readily comprehended by the hearer, apparently without effort; at the same time, it is text where relations between different sentences are not so explicit as to make it uninteresting. Example 1 is coherent; however, consider the following:

> As soon as they got to the beach, Karin jumped into the water. She hates ice cream. (2)

Example 2 sounds incoherent: it is likely that the hearer will wonder about the connection between hating ice cream and jumping into the water. The hearer may proceed to invent scenarios in which the text makes sense: for example, Karin had ice cream on the way to the beach, it gave her a stomach ache, and her way to deal with stomach aches is to swim. Scenario building of this sort is an exercise precisely in accounting for text coherence; i.e., in explaining text in terms of sentence connections to one another. However, this does not mean that every possible link between the sentences should be explicit. Expanding Example 1 results in a more tedious text, not a clearer one:

> As soon as they got to the beach, Karin jumped into the water. She was so hot from the long drive, so she wanted to cool down. Because the temperature of the sea is generally much lower than that of the air, going for a swim accomplished her goal. (3)

Thus, text coherence appears to obey Grice's maxims of quantity. (*See* **Implicature**)

Text coherence encompasses more than appropriate connections between individual sentences. Discourse appears to have a hierarchical structure: sentences are part of segments, which in turn are part of superordinate segments. Informally, a segment can be defined as a group of locally coherent utterances (see below for a more formal definition).

Consider the following discourse:

(a) Georgia called Jeffrey on the phone.
(b) She wanted to wish him happy birthday.
(c) She also asked him if she could borrow his tent.
(d) She had bought a tent herself a few months back.
(e) However, it got torn on her summer hikes.
(f) After the phone call, she went out for a jog. (4)

Discourse 4 is about Georgia's activities. Intuitively, we recognize that sentences (a) through (e) form a subsegment S_{a-e} of the whole discourse, as they pertain to Georgia's phone call to Jeffrey. In turn, sentences (c), (d), and (e) form the subsegment S_{c-e} of S_{a-e} that concerns the request for the tent; and sentences (d) and (e) form subsegment S_{d-e} of $S_{a-e,}$ because together they provide a justification for the request in sentence (c).

We will now look at how different researchers account for text coherence in both its manifestations, connections between sentences and discourse segmentation, and how coherent discourses can be interpreted and generated.

THEORIES OF DISCOURSE STRUCTURE

Two theories of discourse structure came to the fore in the mid-1980s, and these are still the most prominent: Grosz and Sidner's (1986) and Mann and Thompson's (1988).

Grosz and Sidner's theory (GST) sees discourse structure as the surface manifestation of the relationships among elements of the intentional structure underlying the discourse. The intentional structure is comprised of the intentions that a speaker brings to the discourse. There will be a primary intention, the discourse purpose (DP), which is, the intention that underlies engaging in that particular discourse. Further, a discourse segment purpose (DSP) is associated to each discourse segment, which is fully individuated by the corresponding DSP. Each DSP specifies how the specific segment contributes to achieving the overall DP. A plausible DP underlying the whole of discourse 4 is *Tell hearer about Georgia's activities*. The DSP associated to the subsegment S_{d-e} could be something like *Explain to hearer why Georgia needs to borrow Jeffrey's tent*. GST does not specify which intentions can count as DPs or DSPs, except by noting that they are meant to be recognized (cf. Grice's notion of utterance-level intentions). DSPs can be related to one another only via two relationships: dominance and satisfaction-precedence. DSP_1 dominates DSP_2 if DSP_2 is intended to provide part of the satisfaction of DSP_1. DSP_1 satisfaction-precedes DSP_2 if DSP_1 must be satisfied before DSP_2. Grosz and Sidner argue that the intentional structure of the discourse is also intertwined with the attentional state, the set of entities that are salient at any point in the discourse. Attentional state is modeled by a set of focus spaces, which are associated to discourse segments, and contain the entities salient within the corresponding discourse segments. The processing of focus spaces is modeled via a stack. Shifts of attentional state that are local to a discourse segment are outside the scope of GST, but are accounted for by centering theory (Grosz *et al*., 1995; Walker *et al*., 1998).

Mann and Thompson (1988) propose 'rhetorical structure theory' (RST) as a descriptive framework that identifies hierarchical structure in text. RST is based on relations between two non-overlapping text spans, the 'nucleus' and the 'satellite'. The nucleus is the central member of the pair; the satellite is peripheral. Relations include an effect and constraints on nucleus and satellites. The relations defined by Mann and Thompson include 'elaboration', 'enablement', 'evidence', and 'contrast'; comparable inventories of discourse relations have been proposed by a number of other researchers (e.g. Hobbs, 1979; Lascarides and Asher, 1993). For example, the evidence relation has as effect that the belief of the hearer in the nucleus is increased, and a constraint that the hearer will find the satellite believable. In Mann and Thompson's view, an analyst will first identify the minimal units of the analysis, which they assume to be clauses. Then, the analyst will start applying relation schemas to adjacent text spans, which are minimal units or, recursively, constituents of relations. In the end there will be one relation schema encompassing text spans that cover the whole text.

From these brief descriptions, we can see that GST mainly accounts for the segmentation aspect of discourse coherence, but does not address how individual sentences are linked to one another by domain or rhetorical relations. As Grosz and Sidner believe that the intentions underlying discourse are too diverse, they argue that it would impossible to enumerate the intentions that can serve as DSPs; hence, they conclude that enumerating a fixed set of relations, as in RST, is wrong. On the other hand, RST accounts both for individual relations between individual sentences and for hierarchical segmentation of the discourse. The latter is a side effect of

how the RST analysis is conducted. Note that an analysis of a discourse according to GST generally results in fewer and shallower segments than an RST analysis.

Grosz and Sidner present their theory as a computational account of discourse processing, but they do not provide much insight into the underlying computational processes, except by proposing that the attentional state is modeled as a stack. Mann and Thompson do not make any computational claims; however, their theory has been widely used in computational linguistics. The question thus arises, which processing paradigm is most appropriate for each theory. GST lends itself to a top-down model of discourse processing: the hearer recognizes the DP, and then recursively the subordinate DSPs. RST, on the other hand, lends itself more directly to a bottom-up interpretation of discourse.

A synthesis of GST and RST has been proposed (Moser and Moore, 1996). The synthesis is based on the observation that the dominance relation between intentions in GST closely corresponds to the 'nucleus versus satellite' distinction between text spans in RST.

INTERPRETATION OF DISCOURSE

Discourse interpretation consists of the computational inferences that compute the extended meaning of discourse. We can divide the approaches into two main groups: logical approaches that compute domain and rhetorical relations between sentences in written texts (Lascarides and Asher, 1993), and plan inference approaches that compute the speech acts performed by participants in a dialogue (Perrault and Allen, 1980; Litman and Allen, 1990; Carberry and Lambert, 1999). Plan inference approaches have been applied mainly to dialogue; nevertheless, they are considered part of discourse processing. Because of its inherent difficulty, not many researchers have tried to compute discourse segmentation as proposed in GST, but see Lochbaum (1998) for such an attempt.

Traditionally, approaches to inferring relations between sentences make use of some type of logical inferencing, such as a variant on non-monotonic logic or abduction. We will briefly look at approaches based on abduction (Hobbs *et al*., 1993). Abduction is an unsound inference rule that reasons from an effect to a potential cause: for example, 'the alarm went off, so there is a burglar in the house'. Clearly, there may be other reasons why the alarm went off (e.g. the landlady forgot to switch it off). Abduction is a useful reasoning mechanism because it tries to find the best explanation for a fact. As far as discourse coherence is concerned, an abductive approach tries to find the most plausible coherence relation linking two utterances, on the basis of rhetorical, domain, and world knowledge. An abductive approach will build a full explanation that supports a specific coherence relation. For example, to establish a cause relation between the two sentences in example 2, an abductive approach would build an explanation, expressed in first-order predicate logic, akin to the one in example 3. The problem abduction has to face is how to choose the most plausible explanation among many possible ones. One can adopt heuristics, such as choosing the explanation that uses the fewest assumptions, or compute the probability of each explanation and choose the most likely one. Both approaches have serious flaws: the former, that even plausible heuristics can fail fairly often; the latter, that it is unclear over which space of events to compute those probabilities.

The computational approaches just discussed are not explicitly based on cognitive findings on text comprehension. Nevertheless, questions addressed by cognitive scientists and psycholinguists have affected computational models. Relevant issues include: inference control (i.e. which of the many possible inferences are made at comprehension, and which later, during recall); and how the connectedness of sentences affects reading times and the accuracy of recall. For example, it has been found that sentences that have a close causal connection are read faster and result in better content recall (Myers *et al*., 1987).

Plan Inference

The plan inference approach to discourse has been applied mainly to dialogues, although applications to monologic discourse that describes one or more agents' actions have also been attempted. It originated at the end of the 1970s (Perrault and Allen, 1980), with the goal of providing an interpretation for indirect requests such as *I need to be in Boston on the 20th in the afternoon* (directed to a travel agent), or *The next train to Brighton* (directed to a clerk at the ticket booth). It rests on three components: the notion of speech acts from pragmatics; a theory of belief, desire, and intentions from computational linguistics, which in turn owes much to the philosophy of action; and planning models from artificial intelligence.

Every utterance counts as an action performed by the speaker (a speech act), such as asking or

promising (Austin, 1962). (We are oversimplifying here. In reality there are three acts associated with each utterance: locutionary, illocutionary, and perlocutionary. The term 'speech act' has come to refer mostly to the illocutionary act.) Utterances can perform speech acts directly, as in example (a) below, or indirectly, as in example (b):

(a) Please find me a flight that arrives in Boston on the 20th in the afternoon.
(b) I need to be in Boston on the 20th in the afternoon. (5)

To explain how a statement such as example 5(b) can count as a request, proponents of the 'inferential' approach (Searle, 1975) contend that indirect speech acts concern felicity conditions on the corresponding direct act. For example, a request such as example 5(a) is felicitous under the assumption that the speaker wants to fly to Boston on that specific date and time. Example 5(b) then works because it explicitly states the speaker's mental attitude, once the hearer has recognized that the literal meaning of it is inappropriate and must be 'repaired' by some inference. (*See* **Pragmatics, Formal**)

Planning is a computational technique from artificial intelligence that, given a goal s_g to achieve, builds a plan, a partially ordered sequence of actions whose execution will bring the agent from the initial state s_0 to s_g. Often the plan is built as a tree, whose leaves are the actions to be executed; the internal nodes represent actions at a higher level, which decompose into lower-level actions. For example, if an agent has the goal *Attend conference in Washington* and lives in Chicago, the agent may build a plan that includes taking a flight from Chicago to Washington; in turn, to achieve taking the flight, the agent will need to buy a ticket, drive to the airport, and board the plane. Planners build plans on the basis of action operators, which must include: preconditions, the conditions that need to hold for the action to be executable; effects, what becomes true after performing the action; and body, a decomposition into a partially ordered set of subactions whose execution will result in the execution of the action.

In the plan inference approach, speech acts are modeled as action operators from planning. However, the logical language in which the operators are expressed is augmented with mental attitudes such as knowledge, beliefs, and desire. For instance, a formalization of `Request` (S, H, α) will include as a precondition that the speaker S wants the hearer H to perform action α (one of the felicity conditions on requests), and as an effect that H wants to perform α. Such a formalization can be used to build the interpretation of an indirect speech act via plan inference rules that work backwards from the utterance to its interpretation. One such rule is: if γ is a precondition of action α and H believes S to want γ, then it is plausible that H believes S to want α. Note that the representation can also be used by a regular planner to produce a speech act, starting from a communicative goal to be achieved.

The plan inference approach has been extensively used in dialogue modeling. The original model has been extended in various ways, such as by introducing different levels of inferred plans (e.g., the discourse plan and the domain plan) that the speaker is pursuing (Litman and Allen, 1990; Carberry and Lambert, 1999).

Approaches to discourse based on abduction, non-monotonic logic or plan inferencing, while elegant, suffer from brittleness. One missing domain axiom may cause the model to fail as it is not able to find a complete explanation. Thus, many implemented systems, instead of just using a logical approach, use information that can easily be derived from the surface form of the utterance, such as intonation, connectives, idiomatic expressions, and lexical associations between words (Reithinger and Maier, 1995; Qu *et al*., 1997; Samuel *et al*., 1998). These cues to the phenomenon of interest are derived from linguistic and corpus analysis (see below).

GENERATION OF DISCOURSE

From a computational point of view, discourse generation concerns the production of coherent, extended text. Whereas discourse processing is seen as the last stage in language interpretation, after parsing and semantic analysis, it is the first stage for language production. Computationally, language generation starts from a nonlinguistic representation of information that we can consider parceled into messages to be conveyed. The first task to be performed is discourse planning; i.e. imposing ordering and structure over the set of messages to be conveyed. This is followed by sentence planning and linearization, including sentence aggregation (grouping the elements of the discourse plan together into sentences) and the choice of referential terms to individuate the entities of interest. The final step is linguistic realization proper, namely, applying the rules of grammar in order to produce a text that is syntactically and morphologically correct.

Here, we concentrate on discourse planning, and on referring expression generation.

Planning and Linearization

There are two main approaches used to generate a coherent discourse: planning, and schemata.

The discourse planner is given a communicative goal to achieve such as `Intend` S (`Intend` H α). Communicative goals represent the speaker's intentions to affect the beliefs or goals of the hearer. The planner will build a plan consisting of rhetorical actions to achieve the given communicative goal. For example, to achieve `Intend` S (`Intend` H α), S may look for a β such that S expects H to want β, and then utter β as motivation for α (motivation is an RST relation):

> Come to the party on Saturday. I will make your favorite deviled eggs. (6)

The connection between discourse planning and the theories of discourse structure discussed earlier has mainly been achieved through RST. RST relations are recast in the terms of planning operators (Moore and Paris, 1993). The planner posts a high-level communicative goal such as `Intend` S (`Intend` H α) in terms of the effect ε the text should have on the reader. The planner will then search for an RST operator whose effect unifies with ε, and post the subgoals that correspond to constraints on the nucleus and satellite of that rhetorical relation. These subgoals are recursively expanded until the planner reaches the leaves of the rhetorical structure tree, which are expressible as simple clauses.

Schemata are an alternative approach to using a planner. Schemata represent common patterns that texts in a specific domain or genre follow (McKeown, 1985). A schema specifies how a particular discourse plan should be built using other schemata or messages, and the discourse relations that hold between different components of the discourse plan. Although schemata are not generally developed following a planning model, they can be considered as compilations of discourse plans produced by a planning system. As a mechanism for generation, schemata are less flexible, but easier to develop, than a fully-fledged discourse planner. For example, because schemata lack information on the intentions of the speaker, they cannot be used if the system needs to replan, for example if the explanation of a certain p is not understood by the hearer and the discourse planner needs to build a different explanation for p (Moore and Paris, 1993).

Note that a discourse plan, whether built by a planner or as a schema instantiation, does not encode decisions regarding how the leaves should be parceled into individual sentences, or how these sentences should be connected. For instance, the two sentences in example 6 could be linked in a variety of different ways, both paratactically and hypotactically. For example:

> Come to the party on Saturday if you don't want to miss your favorite deviled eggs. (7)

There are also more subtle decisions that need to be made. In example 6 the adjective *favorite* in the second clause may well be derived from a full proposition in the discourse plan, such as *You like the deviled eggs I make a lot*. This is why many researchers consider lexicalization as part of sentence planning. Lexicalization is concerned with choosing words to express concepts and relations.

The solutions proposed in the literature for sentence planning and linearization are diverse, but some general paradigms are beginning to emerge.

Establishment of Referential Terms

The task of generating referring expressions is to select words or phrases to identify discourse entities. The choice of referring expressions greatly affects the readability of a text. Compare the two texts below, the second of which always uses the nominal expression *Bill Gates*.

> When a Stanford University professor asked for volunteers to have their heads scanned, Bill Gates was the first to volunteer.
> The billionaire CEO of Microsoft Corporation sat patiently while a laser scanner orbited his head several times. A short time later, a 3-D image of Gates's head floated on a screen. (8)

> When a Stanford University professor asked for volunteers to have their heads scanned, Bill Gates was the first to volunteer.
> Bill Gates sat patiently while a laser scanner orbited Bill Gates's head several times. A short time later, a 3-D image of Bill Gates's head floated on a screen. (9)

In text 9, the repeated use of the proper name *Bill Gates* makes the text sound clumsy. The much more fluent text 8 makes use of different forms of proper names (*Bill Gates* or simply *Gates*), pronouns (*his*), and complex definite referring expressions (*the billionaire CEO of Microsoft Corporation*).

The problem of generating referring expressions can be subdivided into two tasks:

- Initial introduction, or how to perform the initial reference to a discourse entity.
- Subsequent references. This includes choosing between a pronoun and a definite description: if the latter is chosen, then the question is which features of the entity in question to include in the description.

The initial introduction and the choice of pronoun or definite description are generally performed by algorithms based on the 'given–new' distinction (Prince, 1981) or on centering (Grosz *et al*., 1995; Walker *et al*., 1998) or on a combination of the two. (*See* **Computability and Computational Complexity**)

Regarding the choice of appropriate definite descriptions, early approaches (Appelt, 1985) took a full planning approach to generating referring expressions. This means that in principle they could generate any description that satisfies a given communicative goal. As this approach was computationally inefficient, later approaches, most notably Dale's (1992), focused on the restricted problem of building a 'distinguishing description'. A distinguishing description is true only of the entity being described and of no others among the currently salient discourse entities. These algorithms generally aim at finding the minimal distinguishing description. However, even computing a minimal distinguishing description is an inherently hard computational task. Dale and Reiter (1995) showed that it is NP-hard by reducing it to a set cover problem. Moreover, humans do not produce minimal distinguishing descriptions, either because humans also face computational limitations, or because they intend to achieve other goals besides identification (Jordan, 2000). In text 8, the complex noun phrase *the billionaire CEO of Microsoft Corporation* may be used to introduce information that the hearer is not expected to know, or, more likely in this case, to remind the hearer of Gates's position. Algorithms used today try to strike a balance between conciseness of the definite description and reproducing human behavior, as observed in corpus analysis.

EMPIRICAL APPROACHES TO DISCOURSE

In the 1990s there was a shift in focus towards a rigorous empirical foundation for discourse processing work. The general methodology that has emerged (Walker and Moore, 1997) comprises the following components:

- Development and evaluation of coding schemes. Coding schemes are used to annotate language corpora for features deemed likely to affect the phenomena under study (e.g. correlates of discourse segments, minimality of referential expressions with respect to providing distinguishing descriptions). A necessary condition for a coding scheme to be useful is that it be reliable, namely, that two or more independent coders can use that coding scheme to annotate the same text in a 'similar enough' way. Much research has thus been devoted to measures of inter-coder agreement (Carletta, 1996; Di Eugenio, 2000).
- Extraction of information from the annotated corpus. Researchers use either statistical measures or data mining tools on the annotated features (Di Eugenio *et al*., 1997; Poesio and Vieira, 1998; Samuel *et al*., 1998; Jordan, 2000). The purpose is to verify hypotheses (e.g. the hypothesis that in real-world situations speakers use minimal distinguishing descriptions), and to find linguistic correlates of higher-level phenomena, such as intonation patterns and adverbs for discourse segmentation.
- Development of computational frameworks based on the information extracted from the corpus. For example, the result of an annotation for referring expressions is used to inform algorithms to generate referring expressions (Poesio and Vieira, 1998; Jordan, 2000).
- Evaluation. The computational models developed either theoretically or on the basis of corpus analysis need to be evaluated. This has motivated much interest in evaluation methodologies for computational models and implemented systems (e.g. Walker *et al*., 1997). However, it is still too early to report specific results that determine which techniques, models, or systems are the most promising. Systematic evaluations have only recently become the norm, and there is no standard test-bed of problems and phenomena that can be used to make comparisons across systems and techniques.

Disfluencies in Spoken Language

Intermediate article

Jean E Fox Tree, University of California, Santa Cruz, California, USA

CONTENTS

Speech disfluencies are phenomena that cause a break in the smooth flow of talk, affecting speaking and understanding. Everyone who talks produces disfluencies. Several decades of research have provided a good understanding of the types of disfluencies people produce, and a beginning understanding of why disfluencies occur and how they impact addressees.

CATEGORIES OF DISFLUENCIES

Disfluencies are any of a group of phenomena that cause a break in the smooth flow of spoken talk. Three main categories of disfluencies are: (1) pauses; (2) *um*s and *uh*s; and (3) repetitions, replacements, and restarts, although there are others. Disfluencies are normal nonfluent speech, as opposed to dysfluencies, or abnormal nonfluent speech, such as stuttering (Wingate, 1984).

A pause is a stretch of speech that is heard as silence. Pauses are usually identified as times when the speaker is not saying anything, but they may also be heard when there is no actual silence in the speech, but rather a slowing down of tempo. Traditionally, only silences over a quarter of a second long were considered meaningful breaks in talk (Goldman-Eisler, 1968), but some have argued that pauses over a tenth of a second long should form the lower cutoff point (Hieke *et al*., 1983). Most pauses in spontaneous talk are under 1 second long (Jefferson, 1989); in fact, pauses over 3 seconds have defined conversational lapses (McLaughlin and Cody, 1982). Pauses have been further categorized by their position in the clause, such as whether they are within or between sentences, or their purpose, such as whether or not they are produced for rhetorical effect. Although only a subset of pauses may be disfluent pauses, it can be hard to determine whether a pause is a disfluency or not.

*Um*s and *uh*s describe a group of sounds that sound, in English, like /um/ and /uh/, with some variation in the shape of the vowel (/em/ and /eh/, for example). They are sometimes referred to as fillers or filled pauses. These labels descend from historical comparisons between *unfilled pauses* (pauses) and *filled pauses* (*um*s and *uh*s; Maclay and Osgood, 1959); *um*s and *uh*s were thought to be ways to fill silence to show that a speaker intends to continue speaking (Cook, 1971). But this theoretical position has not held up over time. To avoid the implication that *um*s and *uh*s are equivalent to or alternative versions of silent pauses, some researchers identify them only as *um*s and *uh*s, or use the label *interjection*. Instead of being equivalent to pauses, *um*s and *uh*s indicate the lengths of upcoming pauses, with *um*s indicating major pauses and *uh*s minor pauses (Clark, 1994; Clark and Wasow, 1998; Smith and Clark, 1993).

Repetitions, replacements, and restarts are stretches of speech where people have: (1) stopped the smooth flow of speech; (2) possibly uttered a pause, *um* or *uh*, or other words such as *I mean* or *you know*; and (3) resumed their talk (Clark, 1996). In repetitions, words are repeated exactly in the resumption, as in 'of her of her daughter'. In replacements, some words are repeated but some are changed, as in 'there were a lot of tricks that the um tricks and toys that the ant could play with'. In restarts, no words are repeated, as in 'what would you-can I help you?'. Although people can detect problems that need correcting after hearing themselves start to say something wrong (Levelt, 1989), people can also choose in advance when they will suspend their speech, detecting problems while speaking and suspending their speech when they have the continuation ready (Blackmer and Mitton, 1991; Fox Tree and Clark, 1997). People also choose how to resume fluent talk, resulting in various resumptions.

The part of speech that is stopped is sometimes called the *reparandum*, and the part of speech that is resumed is sometimes called the *repair* (Levelt,

1983). The term 'repair' has also been used to refer to repetitions, replacements, and restarts as a group along with similar phenomena (Fox Tree and Clark, 1997). But the term 'repair' can imply the revising of something said earlier, which is not always the case for these disfluencies. For example, repetitions can be viewed as early commitments to speaking at particular moments with subsequent restorations of continuity in the resumption (Clark and Wasow, 1998), instead of as second occurrences' revising first occurrences, without changes.

The three types of disfluencies discussed here – pauses, *um*s and *uh*s, and repetitions, replacements, and restarts – are interrelated. Pauses can predict upcoming repetitions, replacements, and restarts. *Um*s and *uh*s indicate the lengths of upcoming pauses. And information between the suspension and resumption of repetitions, replacements, and restarts can contain pauses or *um*s and *uh*s.

DISFLUENCIES IN LANGUAGE PRODUCTION

Since at least the 1960s, disfluencies have been seen as windows into the speech production process. They could be the auditory remains of a problem in turning thoughts into words, or they could be the normal result of speakers' planning their talk. Hypotheses about disfluencies' aetiologies or purposes were arrived at by analyzing when they occurred.

Hypotheses about pauses were that they were epiphenomena of a general need for more processing time to produce talk (Levelt, 1989), or the result of more specific effort at lexical access (Goldman-Eisler, 1968; Maclay and Osgood, 1959; Martin and Strange, 1968), syntactic formulation (Brotherton, 1979; Clark and Wasow, 1998; Duez, 1982; Ferreira, 1991; Maclay and Osgood, 1959), or phonological encoding (Ferreira, 1991). Pauses were also thought to be used more purposefully for rhetorical effect (Duez, 1982; Kowal *et al*., 1985), such as making people appear sincere (Maclay and Osgood, 1959). Pause placement also influenced hypotheses about the order of speech production processes, such as that syntactic formulation precedes lexical access (Maclay and Osgood, 1959).

Similar hypotheses were made about *um*s and *uh*s. Without distinguishing between proposals that they are symptoms or signals, *um*s and *uh*s have been thought to foreshadow: (1) general speech production difficulty (Brotherton, 1979; Reynolds and Paivio, 1968) or specific difficulty, such as upcoming delays (Clark, 1994) or error avoidance (Jefferson, 1974); (2) particular kinds of words, such as difficult to produce or unpredictable words (Brotherton, 1979; Tannenbaum *et al*., 1965) or words with more competitors (Schachter *et al*., 1991); (3) the major chunks of talk in a discourse (Swerts, 1998); (4) difficulty in planning what one wants to say and how to say it syntactically (Maclay and Osgood, 1959; Martin and Strange, 1968; Reynolds and Paivio, 1968); (5) speakers' desires to maintain control of the floor in a conversation (Maclay and Osgood, 1959); and (6) speakers' desires to show awareness of upcoming delays, to avoid being cast in a negative light by a silent pause (Smith and Clark, 1993).

Repetitions, replacements, and restarts in speech production come about because of a variety of problems, including conceptualizing ideas, formulating sentences, selecting words, or articulating utterances (Levelt, 1989). Different types of production trouble may yield different kinds of recovery (Tannenbaum *et al*., 1965). One explanation for the reason repetitions, replacements, and restarts look the way they do is that speakers follow rules for making them well formed (Levelt, 1983, 1989). They are well formed if there is a way of converting the suspended talk and the resumption into a coordination; for example, because 'there were a lot of tricks that the- um tricks and toys that the ant could play with' could be filled out to the well-formed sentence 'there were a lot of tricks that the [ant could do, and] um tricks and toys that the ant could play with', the replacement without the bracketed talk is well-formed.

DISFLUENCIES IN LANGUAGE COMPREHENSION

Fewer researchers have explored the role of disfluencies in speech comprehension.

Disfluencies can be difficult to detect in talk, although listeners can detect them with effort (Martin, 1967; Martin and Strange, 1968). Detection of pauses may depend on where in the clause they fall; one study found that within-clause pauses can be detected if they are over 200 ms, but between-clause pauses need 500 ms to 1000 ms for detection (Boomer and Dittmann, 1962). Detection of *um*s and *uh*s varies depending on whether listeners are paying attention to what speakers are saying or how they are saying it (Christenfeld, 1995). Detection of repetitions and restarts takes place after the smooth flow of speech has stopped (Lickley and Bard, 1998).

None the less, effects of disfluencies on comprehension have been measured. There are generally two different measurement techniques, those that

involve offline tasks (measuring comprehension after speech has been heard) and those that involve online tasks (measuring comprehension while speech is being heard).

In offline tasks, disfluencies have influenced what listeners think about a speaker's personality. For example, pauses can make a conversationalist appear less adept (McLaughlin and Cody, 1982), and also have implications for interpretations of what the speaker does or does not know (Brennan and Williams, 1995). Saying *um* can make people who know the answer to a question appear less sure of their answer, or give the appearance that someone who doesn't know the answer really does know it. *Um*s can also make people appear more relaxed compared to speech with the *um*s replaced by pauses, although pauses make people appear less relaxed than no pauses (Christenfeld, 1995). Offline tasks have also demonstrated that pauses can aid in syntactic disambiguation (Price *et al*., 1991), and, if placed at syntactic boundaries, can improve recall of the gist of sentences (Reich, 1980). *Um*s and *uh*s can provide turn-ending or turn-continuation information, depending on whether they fall at grammatical or ungrammatical points (Cook and Lalljee, 1970).

In online tasks, disfluencies have been shown to produce a variety of effects. *Uh*s speed up the recognition of upcoming words in sentences but *um*s don't, a result that can be attributed to their differing roles in anticipating the lengths of upcoming pauses (Fox Tree, 2001). Attention may be heightened after hearing an *uh* in anticipation of the short upcoming pause and continuation, but it may not be after *um* because of the indeterminacy of the upcoming delay. Repetitions do not negatively affect recognition of subsequent words (Fox Tree, 1995), as would be expected if repetitions are a solution to a fluency problem as opposed to an error (Clark and Wasow, 1998). But certain kinds of restarts, those altering information mid-sentence, do slow recognition (Fox Tree, 1995). Restarts are only costly when listeners need to store information about one part of the discourse record while making the correction. Information between the suspension and resumption can help listeners follow the speaker successfully (Fox Tree and Schrock, 1999).

Distinctive Feature Theory

Introductory article

Elizabeth Hume-O'Haire, Ohio State University, Columbus, Ohio, USA
Stephen Winters, Ohio State University, Columbus, Ohio, USA

CONTENTS

The term 'distinctive features' is used in phonology to refer to the minimal units of sound that serve to distinguish the meaning of one word from another within a language. Distinctive features generally correspond to a specific articulatory or acoustic property of sound.

INTRODUCTION

Distinctive features are the universal set of cognitive properties associated with the speech sounds that are used in language. Distinctive features determine the contrasts which may exist between speech sounds, account for the ways in which these sounds may change, or *alternate*, and define the sets of sounds – known as natural classes – which may behave similarly in language. This limited set of features enables linguists to make powerful predictions about the kinds of sound structures that are expected to exist in the languages of the world. As universal properties of speech sounds, distinctive features also provide key insights into the cognitive organization of sound in language. The fact that distinctive features have such explanatory power makes their discovery one of the most important advances in linguistic science during the twentieth century.

THE FUNCTIONS OF DISTINCTIVE FEATURES

Contrast

The notion of contrast in language has been important for as long as linguists have been aware that the relationship between sound and meaning is arbitrary. For example, there is no logical connection between the sounds used to express the word 'tree' and the actual meaning of the word 'tree'. It does not matter, therefore, what particular sounds a language chooses to express the meaning of a word like 'tree'; what matters is that the sounds combined to form this word are distinct from those that combine to denote a word with a different meaning, such as 'true'. In other words, the sounds of language are meaningful only inasmuch as they *contrast* with one another.

Linguists originally conceived of contrast as a relationship that held between two entire sounds, such as between the [b] and [p] in a pair of words like 'bit' and 'pit'. Further investigation revealed, however, that such contrasts were always based on certain aspects of the articulation (i.e. the pronunciation) or the acoustics (i.e. the physical characteristics of sound waves) of the individual sounds. A [b] and a [p] differ, for instance, only in that the articulation of [b] involves the low-frequency vibration of the vocal cords (denoted by the distinctive feature [voice]) while the articulation of [p] does not. Likewise, the sound [s] contrasts with the sound [θ] (which is represented in English by *th*, as in 'with') in that, acoustically, [s] is louder and has more energy concentrated in higher frequencies, while [θ] is quieter and has acoustic energy spread across a broad range of frequencies. This acoustic distinction is represented with the feature [strident]. Any two sounds can differ meaningfully only in terms of such 'distinctive features' of their articulations or acoustics. Furthermore, linguists have observed that there are only a limited number of such features that can make meaningful distinctions. This insight has the important implication that the number and kind of meaningful sound distinctions in any language is limited by the set of available distinctive features. The fact that language is limited in this way – and is not completely arbitrary – provides significant evidence for the universal cognitive structures the mind imposes on language.

Natural Classes

Distinctive features further organize language by defining groups of sounds which may exhibit similar sound patterns. A *natural class* of sounds in a language consists of those sounds which share certain distinctive features to the exclusion of all other sounds in the language. Such natural classes of sounds often pattern together in similar ways. For example, the labio-velar sound [w], as in 'wit', cannot follow a specific group of sounds in English; [w] may follow [d] or [k] sounds, as in 'dwell' or 'quell', but it may never follow sounds like [b], [f], or [m]. That is, there are no words in English like 'bwell', 'fwell', or 'mwell'. The group of sounds which [w] cannot follow in English is collectively known as the natural class of *labial* consonants. The distinctive feature [labial] characterizes sounds that are articulated with the lips; as such, [labial] generalizes over the more specific phonetic categories of *bilabial* (pronounced with two lips, as in [b] or [p]) and *labio-dental* (pronounced with both the lips and the teeth, as in [f] or [v]). Though such finer distinctions could be made, phonological systems ignore them. The fact that distinctive features may draw broader distinctions than objectively exist in speech production or transmission provides further evidence for their essentially cognitive status. The observation that it is the sound [w] that fails to occur before a [labial] consonant also follows from the view that sounds defined by a common feature are predicted to pattern together, such as in the [labial] cooccurrence restriction; labio-velar [w] also belongs to the natural class of [labial] sounds.

Alternations

Speech sounds may also *alternate* with one another under certain conditions. The voiceless [s] sound, which may designate plural formations in English, alternates with a voiced [z] sound whenever it follows any of the natural class of voiced sounds at the end of a word which it pluralizes. Voiced [z] is always found after the voiced [b] in 'cabs', for instance, while the voiceless [s] always follows the voiceless [p] in 'caps'. The alternation here is not simply between the sounds [s] and [z] but between the distinctive feature of voicing which distinguishes the two. In fact, all sound alternations in language may be defined in terms of distinctive features. Furthermore, since distinctive features define natural classes of sounds, an entire group of sounds (as opposed to just one) is predicted to condition or undergo the same alternation. Thus, the pronunciation of the English plural ending as voiceless [s] occurs after all words ending in a voiceless sound, for example, [p, t, k, f]. Characterizing alternations in terms of distinctive features therefore not only captures the observation that speech sounds do not alternate arbitrarily but also provides linguists with a powerful predictive device.

THE NATURE OF DISTINCTIVE FEATURES

Phonetic Grounding

Although the primary motivation for the existence of a feature comes from considerations of language sound patterning as noted above, features are defined in the phonetic terms of articulations and acoustics. For example, the common articulatory property of sounds defined by the feature [coronal] for both consonants and vowels is a constriction involving the front or mid-portion of the tongue. Speakers use such articulations to produce sounds like [ʃ] (usually represented in English with the spelling *sh*), as in 'shirt', and [i], as in 'magazine'. Acoustically, the vocal tract configuration that this articulation creates results in a sound produced with a greater concentration of energy among the higher frequencies used in speech sounds.

Table 1 provides a list of some commonly used distinctive features along with their articulatory definitions.

Feature Values

A feature's ability to minimally contrast two sounds with each other is generally represented by listing that feature with either of two opposite values, indicated before a given feature by a plus or minus symbol. For example, the property of voicing which distinguishes [b] from [p] in English is defined by the feature values [+voice] and [−voice], respectively. The characterization of a sound as [+voice] indicates that it bears the property of vocal cord vibration, while the value [−voice] defines sounds which lack vocal cord vibration. Thus, it is possible to refer to natural classes defined by each of these two feature values.

There are certain features, however, for which the negative value never defines a natural class of sounds. In such cases, these features contrast by virtue of either their presence or absence in a sound; there is no negative feature value, as there is for voicing, which can be referred to in the formal description of the sound system. Such features are considered to be unary-valued, or privative. Place

Table 1. Some distinctive features and their articulatory definitions

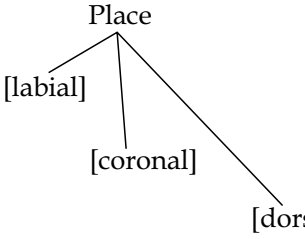
[sonorant]	Sounds which are produced without an obstruction which would impede the flow of air that has passed through the vocal cords in voicing. Sonorant sounds include vowels, nasals (e.g. [n, m]), liquids (e.g. [l, r]), and glides (e.g. [j, w]).
[voice]	Sounds produced with vocal cord vibration, e.g. [b, z, n, r, i, w].
[nasal]	Sounds produced with a lowered velum, which allows air to pass through the nose, as in nasal consonants and nasalized vowels.
[continuant]	Sounds produced in such a way that air flows continuously through the vocal tract as in, among others, vowels and fricatives, e.g. [f, s].
[lateral]	Sounds produced by lowering the mid-section of the tongue at the sides, allowing air to flow out near the molars, e.g. [l].
[strident]	Sounds produced in such a way as to create a turbulent noise, e.g. [f, v, s, z].
[labial]	Sounds produced with a constriction formed by the lower lip, e.g. [p, b, f, v, m, o, u].
[coronal]	Sounds produced with a constriction formed by the front or mid-portion of the tongue, e.g. [t, z, ʃ, i, e].
[dorsal]	Sounds produced with a constriction formed by the back of the tongue, or dorsum, e.g. [k, g, u, o].
[high]	Sounds produced by raising the body of the tongue towards the roof of the mouth, e.g. [i, u].
[low]	Sounds produced by lowering the body of the tongue away from the roof of the mouth, e.g. [a].

of articulation features ([labial], [coronal], [dorsal]) are typically considered to be unary-valued, for example. Since it is impossible to refer to sounds defined by the lack of a given property, this approach makes the strong prediction that sounds defined by the absence of a given feature, for example nonlabial sounds, will not function as a natural class in sound systems.

FEATURE GEOMETRY

In the earliest versions of distinctive feature theory, all of the features that comprised a speech sound were considered to have the same status – no features were more closely related to each other than to any others. In more recent years, however, linguists have begun to recognize that there is internal organization of the features within a speech sound. The fact that certain features commonly pattern together motivates the idea that there are 'natural groupings' of features into higher-level functional units. For example, in many languages the features [labial], [coronal], and [dorsal] function together as a unit. In English, for instance, the nasal sound in a prefix such as 'en' typically takes on the place of articulation value of a following consonant, a process commonly referred to as *place assimilation*. Thus, the nasal is pronounced as coronal [n] before coronal sounds (as in 'encircle', 'endanger'), as labial [m] before labial sounds ('empower', 'embitter'), and as a dorsal nasal [ŋ] ('ng') before dorsal sounds ('encamp', 'encourage'). Notice that all three place features are involved and, furthermore, it is *only* the place of articulation value that is adopted from the following consonant. The three place features are thus patterning together as a functional unit.

An influential model of feature representation known as *feature geometry* incorporates the insight that certain features regularly function together by grouping these sets of features into constituents. Evidence from processes such as nasal place assimilation suggests that the place features [labial, coronal, dorsal] are grouped together into a single Place unit, as shown in (1). Since sounds are defined in terms of more than just place features, the representation in (1) constitutes only one of potentially many feature groupings that, combined together, define the universal geometry of speech sounds.



(1)

A crucial assumption embodied in this type of model is that phonological processes are described most simply by reference to a single element – either a feature (e.g. [labial], [voice]) or the head of a constituent (e.g. Place). As a result, the model

makes strong predictions about the way in which features (and hence, speech sounds) function in language. For example, a phonological process may be described by reference to an entire constituent, such as Place, as would be the case for the process of nasal place assimilation in English described above. Or, a phonological process may be described in terms of any of the features individually. As seen above in the discussion of English plural formation, for example, the phonological process resulting in the alternation between voiceless [s] and voiced [z] can be described simply by reference to the feature [voice]. However, since processes are defined by reference to a single element, the model rules out phonological processes that would be described by a subset of features headed by a constituent. Given the feature grouping in (1), for instance, the sounds characterized by the features [coronal] and [labial] should never pattern together to the exclusion of those with the feature [dorsal]. Thus, no language should have a nasal assimilation rule in which the nasal consonant acquired the place feature of a following [coronal] or [labial] consonant, but not that of a [dorsal] consonant.

FEATURES AND MARKEDNESS

Linguists have long observed that, across languages, certain speech sounds are more common than others. The most common sounds are considered *unmarked* while progressively rarer sounds are considered more and more *marked*. Interestingly, there are certain groups of marked segments which never exist in a language unless another, less marked group of segments does as well. For instance, a language will never have voiced stops unless it also has voiceless stops, or nasal vowels without also having oral vowels. Since the existence of these marked natural classes always implies the existence of the less marked class, the relationship that holds between them is called an *implicational law*. Distinctive feature theory elegantly captures such cross-linguistic relationships between natural classes; for example, the implicational law that holds between voiced and voiceless stops can be characterized as: [+voice, −continuant] → [−voice, −continuant]. Informally stated, this rule claims that any language with voiced stops such as [b, d, g] must also have voiceless stops such as [p, t, k].

Universal patterns of markedness have also been claimed to correspond to the order in which children acquire contrasts (and thereby features) during language acquisition. Children generally acquire less marked sounds before acquiring the contrasts that define distinct, but more marked sounds in the system; extremely marked sounds may sometimes never be acquired at all. An apt example of the latter is the English *r* sound whose markedness stems in part from its articulatory complexity: it is commonly produced with multiple articulations, including lip rounding, retroflexion (curling or bunching of the front of the tongue), and pharyngeal constriction (a narrowing of the passageway between the root of the tongue and the back of the pharynx). A possible featural description of the sound would thus need to include three place features: [labial], [coronal], and [pharyngeal]. Conversely, the less marked [t] sound is specified for only a single place feature, [coronal]. The inherent difficulty of acquiring more marked sounds, such as English *r*, means that these sounds are not as likely to be passed on to succeeding generations as less marked sounds are. It only follows, therefore, that less marked sounds will appear in more languages than marked ones will.

CONCLUSION

Analyzing speech sounds in terms of fundamental properties known as distinctive features accounts for a wide variety of phenomena in language sound systems, including contrast, the grouping of sounds together into natural classes, and the alternations of sounds in various contexts. Along with this evidence, regular patterns in markedness, language acquisition, and historical change strongly attest to the psychological reality of features and the contrasts they define in speech sound systems. Understanding the nature of distinctive features and the various functions they have therefore provides crucial insights into the cognitive organization of sound in language. (*See* **Phonology**)

Ellipsis

Intermediate article

Robert C May, University of California, Irvine, California, USA

CONTENTS

A linguistic ellipsis, most generally expressed, is a truncated or partial linguistic form. It is a linguistic form in which constituents normally occurring in a sentence are superficially absent, licenced by structurally present prior antecedents.

INTRODUCTION

A linguistic ellipsis, most generally expressed, is a truncated or partial linguistic form. This partiality is measured relative to a complete sentence; an elliptical sentence is one in which some of the constituent parts of a 'full' sentence are missing. For example, in answer to the question 'Who went to the store', one may answer 'Max went to the store'. In most contexts, however, speakers would avoid such prolixity and instead would employ an elliptical form: 'Max went', 'Max did', or even just 'Max' would suffice as answers to the question. The reason that they would suffice appears to be quite obvious; it is because they mean just what 'Max went to the store' means, except they express this more economically by leaving off at least part of what can otherwise be gleaned from the initial question. From such simple examples we can already observe a fundamental property of ellipsis that we would expect to be captured under any account of the relation between elliptical and non-elliptical forms: meaning is constant under ellipsis. Specifying this constancy is not as straightforward as it may initially appear, however, and trying to capture what it amounts to has been an on-going issue in linguistic theory. It has been an issue of particular importance because the accounts of elliptical phenomena have been used to bring empirical weight to fundamental claims about linguistic theory, including the extension of the notion of linguistic identity, the relation of syntax and semantics, and the abstractness of grammar.

To frame our discussion, we note the most well-known types of elliptical constructions that have been studied in the literature:

VP-ellipsis: Max went to the store, and Oscar did, too
gapping: Max went to the store, and Oscar to the arcade
sluicing: Max went to the store, but Oscar wondered why
stripping: Max saw Sally at the store, and Oscar, too
pseudo-gapping: Max loves Jane, and Harry does Sally
N'-ellipsis: Max's father went to the store, but Oscar's went to the arcade

Each of the these types of ellipsis have idiosyncratic properties. For example, with gapping there is a well-known correlation of the direction of gapping and word order, and with sluicing the restriction that the complementizer of a sluiced clause must be interrogative; these are among observations originating with Ross (1969, 1970). Our purpose here is not, however, to survey the differences between these various elliptical phenomena but to explore two fundamental properties that they all have in common: (1) ellipsis is of a syntactic constituent; (2) an antecedent occurrence of the elided constituent governs the ellipsis. For example, in VP-ellipsis the elided material is a verb phrase, and the ellipsis is licensed in the presence of a fully lexicalized antecedent: in the case above, 'went to the store'. The primary issue for ellipsis is how to properly characterize (1) and (2); what sorts of linguistic description are called for to capture these fundamentally grammatical aspects of ellipsis in their full generality? A number of subsidiary issues are implied by answers to the primary questions, including the nature of the grammatical mechanisms that account for the absence of the lexical material: is it a deletion of underlyingly present syntactic elements; or are these elements absent even at the underlying level? In what follows we will outline some of the main approaches that have been developed to these issues, focusing primarily on the case of VP-ellipsis, largely because the relevant

theoretical issues have been most clearly and widely discussed in this context.

VP-ELLIPSIS

Syntactic Reduction: The Transformational Theory

The initial approaches to ellipsis within contemporary linguistic theory attempted to account for the semantic constancy alluded to above by reducing it to syntactic constancy. The idea here is quite intuitive: if an elliptical form can be seen as a syntactic repetition of a corresponding non-elliptical form, i.e. as simply two occurrences of the same syntactic form, then it would follow immediately that they have the same meaning. The first systematic investigations along these lines is found in the work of J. R. Ross in the late 1960s (Ross, 1967, 1969). The approach plays itself out very naturally with respect to the deep structure/surface structure distinction: elliptical and non-elliptical forms have the same deep structure but different surface structures, the difference arising from the application of transformations that delete syntactic structure to give the elliptical forms. That (1) and (2) fall together was taken as a natural consequence of assuming that the transformational rules involved delete syntactic constituents and do so under identity with an antecedent constituent. So, for example, because there is an antecedent occurrence of the verb phrase 'went to the store', 'Oscar did, too' can be derived from 'Max went to the store' by VP-deletion.

During this period in the development of generative grammar, it was generally assumed that deletion transformations were constrained by a general theoretical condition that required the 'recoverability' of deletions; cf. Peters and Ritchie (1973) for discussion of the formal importance of this condition for the theory of transformations. Informally put, a deletion transformation satisfies this condition if it is possible to reconstruct the deleted material from within the structural context that the rule applies. Deletions that apply under identity obviously meet this criterion. For example, VP-deletion would appear to meet the condition because within the overall sentence 'Max went to the store, and Oscar did, too' we can reconstruct the deleted VP as a copy of the antecedent VP. However, two problems were noticed that indicated quite clearly that such deletion rules fail to meet the recoverability criterion.

The first problem is that the domains in which transformational rules apply are not the same as the domains in which deleted constituents can match up with their antecedents. While the domain of transformational rules is the sentence, the antecedent/deletion pairing is not restricted to this domain but transcends sentential boundaries. So, in our example of VP-deletion, we could replace the conjunction with a full stop, turning one sentence into two: (1) 'Max went to the store' and (2) 'Oscar did, too'. Moreover, we could imagine discourses in which other sentences would be interpolated between them or, even more telling, discourses in which the two sentences were uttered by different speakers. VP-deletion, it would appear, is not a rule of *sentence* grammar, but of *discourse* grammar.

Notice that broadening the applicability of syntactic deletion operations to discourse does not impact on what would seem a more fundamental aspect of recoverability, the reconstructive aspect of deletion given by the syntactic identity of the deleted constituent and its antecedent. The following observations, initially made by Ross (1967) do, however, and herein lies the second problem. Consider the following sentence:

Max saw his mother, and Oscar did, too (1)

Clearly, there is a reading of (1) that entails that Max and Oscar saw one and the same person; they each saw Max's mother. This interpretation could easily be obtained on the transformational view by taking the deep structure of (1) to be roughly (1′):

Max saw Max's mother, and Oscar saw Max's mother (1′)

(1) can derived from (1′) first by applying VP-deletion, applicable given the identity of the verb phrases, to be followed by pronominalization in the first clause. The construal of (1) characterized in this way is not, however, the only construal available of this sentence. It can also be understood in a manner comparable to (1″):

Max saw Max's mother, and Oscar saw Oscar's mother (1″)

The problem is that although (1″) ought to be a possible underlying source for (1), it is not a structure to which VP-deletion can apply, since the verb phrases are not identical. Insofar as (1) can be derived from an underlying form like (1″), it will be a nonrecoverable deletion.

Semantic Non-Reduction: The Property Theory

The ambiguity shown by (1) between a 'strict identity' reading (1′) and a 'sloppy identity' reading (1″)

thus scotches a transformational account of the sort envisaged as deletion under identity. But what went wrong? The answer that emerged is that the underlying problem lies with the initial presumption, that semantic constancy can be reduced to syntactic constancy. Deletions, in some sense, must still be recoverable, not least because knowing what has been deleted is necessary for understanding an elliptical sentence. But what is to be recovered is not syntactic information *per se*, but information about the logico/semantic roles played by syntactic expressions; it is in the identity conditions applicable to these roles that we are to look for the conditions that govern deletion. The semantic constancy of ellipsis, in this view, is not to be reduced to something else, but is to have a direct semantic analysis.

The nonreductionist approach found its fullest hearing in the work of Ivan Sag (1976) and Edwin Williams (1977) in the mid-1970s. The central observation animating this approach is that a sentence such as 'Max saw his mother' is ambiguous, depending upon whether the verb phrase 'saw his mother' expresses the property of seeing Max's mother or the property of seeing one's own mother. These two properties are not unrelated; the latter is an abstraction of the former, being general where the former is particular. This ambiguity, however, is masked in simple sentences because 'Max saw his mother' has the same truth conditions under either interpretation of the verb phrase. It becomes unmasked in elliptical contexts: depending on which property the ellipsis is taken as being identical with, different interpretations are obtained. Thus, if in 'Max saw his mother, and Oscar did, too', the ellipsis is understood as the property 'saw Max's mother' the strict reading ensues; if the ellipsis is understood as 'saw his own mother', the sloppy reading follows. In either case note that what is elided is identical with the antecedent; they each express the same property. In this view, the constancy of ellipsis is thus a matter of property identity, and this is an inherently semantic notion.

These ideas found a natural representation by assuming that the logical representation of natural language incorporate aspects of a λ-calculus. These sorts of logistic systems (first introduced by Church), incorporate an operation that abstracts properties from propositions. This operation, known as λ-abstraction, derives from the proposition expressed by 'Max read *Moby Dick*' the property: λx (x read Moby Dick). This is to be parsed as a λ-operator binding a variable in the following open sentence; it is interpreted as a characteristic function, taking an individual as argument and returning a truth value. If we supply an argument for this function, represented by placing it before the λ-expression: Max, λx (x read Moby Dick), we can return to our original proposition by the inverse operation, λ-conversion; we effect this by placing the argument in the place of the variable in the open sentence, and erasing the λ-operator.

In their analysis of ellipsis, Sag and Williams make two basic assumptions about the semantics of natural language. First, following a suggestion of Barbara Partee (1975), they assume that verb phrases are interpreted as λ-expressions, so that the logical form of 'Max read Moby Dick' would be represented as immediately above. Second, they assume that anaphoric pronouns can be interpreted as either constants or variables. Taking these together, it follows that 'Max saw his mother' is representationally ambiguous between the following logical forms: 'Max, λx (x saw Max's mother)' and 'Max, λx (x read x's mother)'. In the first form, the pronoun is represented as a constant specifying its anaphoric reference; in the latter, the pronoun occurs as a bound variable. Thus far these representations are only distinguished formally; via λ-conversion both convert to the same proposition. The distinction becomes more than this, however, when a third assumption comes into play: VP-ellipsis requires identity of λ-expressions. This gives two representations for 'Max saw his mother, and Oscar did, too':

Max, λx (x saw Max's mother) & Oscar, λy (y saw Max's mother) (2)

Max, λx (x saw x's mother) & Oscar, λy (y saw y's mother) (3)

The first representation is of the *strict* reading; the second clause means Oscar saw Max's mother. The second representation is of the *sloppy* reading; in it, the second clause means that Oscar saw his own mother; that is, Oscar saw Oscar's mother.

The part of the identity conditions in λ-expressions relevant to strict and sloppy identity is known as the alphabetic variance condition. This condition breaks down into two subcases. The first applies to λ-expressions if there are only bound occurrences of variables; in this case, the λ-expressions must be exactly the same up to alphabetic values of the variables. Thus, in (3) for example, the λ-expression on the left is nondistinct from that on the right because they are alphabetic variants, differing only in that where 'x' occurs on the left, 'y' occurs on the right. That is, it matters not that we have 'x' on the right and 'y' on the left so long as the

pattern of binding remains unaltered. When this is changed, the condition is not satisfied; a consequence of this is that a sloppy reading is unavailable in 'Max saw his mother, and Oscar believes Jane did, too'; i.e. the right-hand clause cannot mean that Oscar believes that Jane saw Oscar's mother. This is because in the following representation, which would represent this reading, there are no λ-expressions that are alphabetic variants: 'Max, λx (x saw x's mother)' and 'Oscar, λz (z believes Jane, λy (y saw z's mother))'. In particular, 'λx (x saw x's mother)' and 'λy (y saw z's mother)' are not alphabetic variants because 'z' is free within the λ-expression while the corresponding occurrence of 'x' is bound. Not all free occurrences of variables within λ-expressions are illicit however; this is the effect of the second case of the condition that permits λ-expressions to be alphabetic variants only if the free variables are all bound by the same operator. This is what we find in the representation of 'Max saw everyone before Oscar did':

$$\forall x \text{ (Max, } \lambda y \text{ (} y \text{ saw } x\text{) before Oscar, } \lambda z \text{ (} z \text{ saw } x\text{))}$$

Although within each λ-expression there is a parallel occurrence of 'x' free, they are both bound by the universal quantifier, and hence are alphabetic variants.

The success of this account in overcoming the problems that plagued the prior transformational approach extends beyond the account of strict and sloppy identity. Because the notion of property identity on which the account depends is semantic, unlike in the syntactic account, which was limited by the structural extent of structural descriptions of transformational rules, there is nothing comparable that inherently restricts the context in which the identical properties may occur. Therefore, in the absence of some external constraint, the antecedent of an ellipsis may occur in positions quite detached in discourse from the ellipsis itself; the sentence in which the antecedent is expressed neither needs to be adjacent to the elliptical sentence, nor need it be uttered by the same speaker. All that is required is that the antecedent of the ellipsis be sufficiently salient in the surrounding context.

Property theory and the syntax of ellipsis

The property theory approach initiated by Sag and Williams has been highly influential in the study of ellipsis, and there have been any number of variations of this view. One important source of these variations arises from a changed perspective regarding what is the main syntactic issue raised by elliptical constructions. In the transformational deletion analysis, the concern was over what we may call the 'generation' problem: what are the syntactic operations that produce elliptical structures? But on the property theory, which assigns the explanatory role to semantics for the matters that were so troublesome *vis-à-vis* recoverability for the prior account, the focus is shifted to the mapping problem: how are syntactic structures translated into semantic structures? In particular, how are verb phrases translated into λ-expressions that satisfy the identity conditions (alphabetic variance)? Understanding the mapping problem in this way places a constraint on its solutions; however syntactic derivation is to be effected (i.e. whatever the solution to the generation problem is), it must be such that it allows for systematic translation. There are two broad approaches to the mapping problem falling within this constraint that differ in their views of the need to attribute syntactic structure to the ellipsis in order to generate the property it expresses.

The first, the rich syntax view, assumes that elliptical structures retain a syntactic relation to forms in which all constituents are structurally present. Thus, whatever procedures translate 'Oscar read *Moby Dick*' also translate 'Oscar did, too', because at the input to the translation, the latter has the same structure as the former. The rich syntax view thus calls for the 'reconstruction' of syntactic information in order to obtain a property that then serves as the basis of comparison for identifying salient antecedent properties in the context of an ellipsis. This is the view Sag and Williams take, although they differ on the derivational direction of this relation. Sag takes the elliptical structure to be derived from the non-elliptical by deletion, while Williams reverses the direction of the derivation, the non-elliptical arising from the elliptical by syntactic copying. The alternative, the poor syntax view, sees no need for such a syntactic relation; in this view, at all stages of derivation the elided phrase is missing, or if not actually missing is structurally noncomplex; i.e. an empty category with no internal constituents (cf. Hardt, 1993). Since there is no verb phrase, there is also no translation to a property, however, and hence, in contrast to the rich theory, there is no basis of comparison for determining the antecedent of an ellipsis. But, according to this view, there is in fact no need to derive this, for there is an independent model to draw upon, the anaphoric resolution of pronouns. In both the ellipsis/antecedent and the pronoun/antecedent relations, a possibly complex antecedent for a syntactically simple element is determined by the conditions on salience in

context. Thus, the relation of ellipsis to antecedent in 'Max read *Moby Dick*, and Oscar did, too' is comparable to the relation of pronoun to antecedent in discourse (e.g. 'Herman Melville wrote *Billy Budd*. He is more famous, however, for *Moby Dick*') or even more directly to VP-anaphors like 'so' and 'it' (e.g. 'Max read *Moby Dick*, and so did Oscar') for which elided verb phrases are, in this view, the covert analogues. In the poor syntax view, then, there is no reconstruction as in the rich view; information relevant to the resolution of the ellipsis is only that which is found in the antecedent.

Problems with the property theory

In subsequent research a number of problems have emerged with the property theory. One case, initially observed by Shalom Lappin (1984) calls into question the validity of the second clause of the identity condition in λ-expressions on the basis of examples such as (4):

I know which book Max read, and which book Oscar didn't (4)

Recall that the restriction that λ-expressions are alphabetic variants only if the free variables are all bound by the same operator is what accounted for 'Max saw everyone before Oscar did' as discussed above. But in allowing for this case, (4) should be disallowed, for here the λ-expression corresponding to the elided phrase – λz (z read x) – contains a free variable bound by a different operator (i.e. the *wh*-phrase in the second clause) than that which binds the free variable in the λ-expression corresponding to the antecedent phrase.

A second sort of case, derived from initial observations of Schiebe (1971) and Dahl (1974), is among a series of cases most extensively discussed in joint research by Robert Fiengo and Robert May (Fiengo and May, 1994), who label them the 'eliminative puzzles of ellipsis'. It does not pertain directly to the identity condition but to a systematic overgeneration problem in the translation of pronouns. This case, which Fiengo and May called the 'many-pronouns puzzle', arises when the number of pronouns is increased beyond the one found in the standard examples used to illustrate strict and sloppy identity:

Max said he saw his mother, and Oscar did, too (5)

Here, the expectation is that there should be a four-way ambiguity. This is because whether a pronoun is translated as a constant or a variable is independent of how any other pronoun is translated, predicting, for n-many pronouns, 2^n readings. Thus in (5) the pronouns could be (i) both variables, (ii) both constants, (iii) the first one a variable, the second a constant, or (iv), vice versa, the first a constant, the second a variable. Given the correspondence of variables with the sloppy reading, and constants with the strict reading, (i) and (ii) will result in 'across-the-board' sloppy and strict readings, respectively, while (iii) and (iv) will give readings mixed between sloppy and strict. The problem is that in (5) we observe only three, not four, readings: precluded is the reading corresponding to (iv). The ellipsis in (5) cannot be glossed as '… and Oscar said Max saw Oscar's mother'. What we actually observe in this case, as well as in those of increasing complexity, are only $n+1$ readings; readings do not grow exponentially.

Syntactic Reduction Redux: The Dependency Theory

What the 'many-pronouns puzzle' indicates is that the assumption of translational independence embedded in the property theory's account of anaphora is incorrect, suggesting instead that what is involved is some dependence relation between the pronouns. The most highly developed theory that seeks to capture these dependencies is the dependency theory developed by Fiengo and May (1994). Central to the dependency theory picture is that dependencies must have a syntactic characterization, and in establishing this result, Fiengo and May turn away from the nonreductive account of ellipsis embedded in the property theory, and return to a reductive syntactic approach. The dependency theory assumes that a sentence such as 'Max saw his mother' is structurally ambiguous, the ambiguity being attributed to a distinction in the representation of anaphoric pronouns that indicates whether the pronoun is formally dependent on its antecedent or not. By Fiengo and May's conventions, grammatically anaphoric pronouns are represented by co-indexing, with those that are formally dependent on their antecedent marked by 'β', those that are not by 'α'. 'Max saw his mother' thus has the following pair of representations: 'Max_1 saw his_1^{α} mother' and 'Max_1 saw his_1^{β} mother'. The dependency that a β-marked pronoun enters into is specified via a structural description of the sequence of categories that lies between the pronoun and its antecedent. So for the latter structure, this would be the dependency: $\langle(Max, his), 1, \langle NP, V, NP\rangle\rangle$, where the first member of the triple is the elements of the dependency, the (unique) antecedent and the dependent pronouns, the second

the index of the elements in the dependency, and the third the string of categories that links the co-indexed elements together.

The dependency theory is applied to ellipsis by holding that the identity conditions that allow for ellipsis are satisfied in the following two sorts of structure, where, given the co-indexings, the first represents the strict reading and the second represents the sloppy reading.

Max_1 saw his_1^{α} mother, and Oscar_2
saw $\textit{his}_1^{\alpha}$ *mother*

Max_1 saw his_1^{β} mother, and Oscar_2
saw $\textit{his}_2^{\beta}$ *mother*

While it is apparent that in the first structure the antecedent and elided verb phrases are simple syntactic copies, it is not in the second, for the pronouns are different in the two verb phrases. This discrepancy is reconciled by allowing for an identity condition such that dependencies are the same so long as there is the same sequence of categories, regardless of the index; dependencies that stand in this relation – same pattern, different index – Fiengo and May call '*i*-copies'. The dependencies in which the pronouns in the latter structure occur meet this criterion: since they are *i*-copies, they are sufficiently alike to allow for ellipsis even though the pronouns are syntactically distinct. On the other hand, where there are no dependencies to be calculated – where the pronouns are marked α, not β – there is no alternative but for the index of the pronoun to be unchanged.

Sloppy identity on the dependency theory view is thus the re-creation of an antecedent structural pattern of anaphora; strict identity, on the other hand, is the re-creation of the anaphora itself. Either may be extended to more complex structures, but when they are certain limitations arise. Thus, recall the 'many-pronouns puzzle' that swirled around examples such as (5) above – 'Max said he saw his mother, and Oscar did, too'. For this case, there are four possible combinations of indices for the antecedent; of these, only three give rise to well-formed elliptical structures:

Max_1 said he_1^{α} saw his_1^{α} mother, and Oscar_2
said $\textit{he}_1^{\alpha}$ *saw* $\textit{his}_1^{\alpha}$ *mother*

Max_1 said he_1^{β} saw his_1^{β} mother, and Oscar_2
said $\textit{he}_2^{\beta}$ *saw* $\textit{his}_2^{\beta}$ *mother*

Max_1 said he_1^{β} saw his_1^{α} mother, and Oscar_2
said $\textit{he}_2^{\beta}$ *saw* $\textit{his}_1^{\alpha}$ *mother*

$^{*}\text{Max}_1$ said he_1^{α} saw his_1^{β} mother, and Oscar_2
said $\textit{he}_1^{\alpha}$ *saw* $\textit{his}_2^{\beta}$ *mother*

The first case is the across-the-board strict reading; since both pronouns are α, they have the same index in the antecedent and the ellipsis. The second case is across-the-board sloppy: the two pronouns are in a dependency, with 'Oscar' as the antecedent in the same way structurally as the pronouns in the prior clause are in a dependency with 'Max'. The third structure represents the mixed reading: the first pronoun is β, and thus may be in a dependency. The second pronoun, however, is α so it must be strict, i.e. co-indexed with 'Max', not 'Oscar'. The final case is the one that is excluded. This is because the dependency that reaches from the pronoun 'his' to 'Oscar' as antecedent is not structurally identical to any dependency in the prior clause. Insofar as there is a dependency in that clause, it must be to the closer possible antecedent, the pronoun 'he', but this is not structurally parallel to the dependency in the clause with the ellipsis that has a greater syntactic extent.

Antecedent-Contained Deletion

Thus far, the structural context of ellipsis we have considered has been that of a discourse; i.e. the ellipsis and its antecedent have each occurred in independent sentences. While the examples we have examined are ones in which these sentences are conjoined, this is not essential, for in all the examples 'and' could be replaced by a full stop. The one exception was 'Max saw everyone before Oscar did', but notice here that the ellipsis is contained in an adjunct, not a subordinate, clause, so that even this case falls under the generalization that the ellipsis and its antecedent are syntactically independent. The generalization, however, appears to clearly fail in the following case:

Dulles suspected everyone that Angleton did (6)

Sentence (6) is well formed, and is naturally understood to mean the same thing as its unelided counterpart, 'Dulles suspected everyone that Angleton suspected'. But in this case the elided VP is not independent of its antecedent – rather it is contained within it – and hence the name for this construction, 'antecedent-contained deletion'. Notice that not only does antecedent-contained deletion appear to run counter to the generalization, but it does so in a particularly curious way. We understand the antecedent of the elided VP to be that VP headed by the verb 'suspected'. But if we plug that VP into the ellipsis, it will again contain the ellipsis: 'Dulles suspected everyone that Angleton suspected everyone that Angleton did'.

Additional iterations of the process will continually give structures that still contain an ellipsis. Given this vicious regression, it is unclear how we are to establish the relation of ellipsis and antecedent.

The critical insight here was provided by Sag (1976). Sag observed that if we attend to the logical form of (6), that at the appropriate level of syntactic description it falls under the antecedence generalization. This is because (6) contains a quantified phrase, and this must be scoped out; if we assume that the logical structure of (6) is roughly as follows: '$\forall x$: Angleton *suspected* x (Dulles suspected x)', we then need only observe that here the ellipsis (filled in and indicated by italics) is no longer contained within the antecedent. (This logical form is comparable to the logical form that would be assigned to the fully lexicalized counterpart of (6).) Thus, the significance of antecedent-contained deletion, given the generalization regarding the relation of ellipsis and antecedent, is that the notion of structure relevant to this generalization must be sufficiently abstract so as to represent the logical form of sentences. In May (1985) it is argued that this structure is a form of syntactic structure, a result of the syntactic rule QR, which gives (7) as a representation of (6):

[everyone that Angleton did [Dulles suspected t]] (7)

In this structure the ellipsis is no longer contained within the antecedent, and so we can now plug in the antecedent VP without any regress:

[everyone that Angleton *suspected* t [Dulles suspected t]] (7′)

May's account of antecedent-contained deletion has been one of the main arguments that has been cited in support of the view that there is a syntactic level – *LF* – that represents the logical structure of natural language; see May (1985, chap. 1), as well as Hornstein (1995), for a contrary view.

VP-ANAPHORA

Previously, we briefly mentioned the phenomena of VP-anaphora, citing examples like 'Max hit Oscar, and Harry did it, too' or 'Max hit Oscar, and Harry did so, too'. These cases are closely akin to VP-ellipsis except that they have an anaphoric element – 'so' or 'it' – rather than an ellipsis. VP-anaphora is distributionally more restricted than VP-ellipsis. For example, with stative verbs, VP-ellipsis is possible, but not the 'it' form of VP-anaphora, and the 'so' form is marginal; compare 'Max knows French, and Oscar does, too' with 'Max knows French, and Oscar does it, too' and 'Max knows French, and Oscar does so, too'. However, what is more relevant to the present discussion is that with VP-anaphora we can find the same ambiguity of strict and sloppy identity that we observed with VP-ellipsis; compare 'Max hit his mother, and Oscar did, too' with (8):

Max hit his mother, and Oscar did it, too (8)

As before, the second clause can be taken to mean that Oscar hit Max's mother (strict) or that Oscar hit Oscar's mother (sloppy).

Examples like (8) pose issues as to how we are to understand ellipsis. If VP-anaphora and VP-ellipsis display uniform behavior, it would seem natural to posit a uniform analysis. One way to do this would be to take ellipses as anaphoric elements, silent counterparts, if you will, of 'it' or 'so'. (For one account along these lines, couched in a variant of the property theory, see Hardt (1993).) In this view, in which VP-ellipsis is reduced to VP-anaphora, that ellipsis involves some sort of syntactic reconstruction is effectively denied. The alternative would be to run the reduction in the opposite direction by maintaining that at an appropriately abstract syntactic level VP-anaphora, like VP-ellipsis, is syntactically complex, and that the overt pronominal elements are but superficial syntactic reflexes. In either account, the goal would be to isolate a level of representation in which VP-anaphora and VP-ellipsis are structurally nondistinct in order to account for their common behavior.

This search for a common analysis, however, needs to be weighed against ways in which VP-anaphora and VP-ellipsis do not cluster but diverge in properties. One sort of divergence has already been mentioned: namely, the distributional differences. Another can be gleaned from examples of antecedent-contained deletion, as in (9):

Dulles talked to everyone that Angleton did (9)

If VP-ellipsis were just a variant of VP-anaphora, then we would expect that the VP-anaphora version of (9) would also be grammatical. But, as was observed by Fiengo and May (1994), it is not:

*Dulles talked to everyone that Angleton did it (9′)

This case indicates (along with the distributional facts cited above) that there are substantial differences between VP-anaphora and VP-ellipsis. It remains an open research question how observations like these can be integrated with those about

strict and sloppy identity; until then it remains equivocal whether VP-ellipsis and VP-anaphora are a unified phenomenon.

SUMMARY

Returning to our initial observation, we have seen that capturing the basic intuition of semantic constancy under ellipsis devolves to the issue of the proper way to state the identity conditions that govern ellipsis. That ellipsis in general requires a notion of identity was the initial insight of the transformational account; its flaw, in a sense, was that the notion of identity it had available was not sufficiently abstract. What followed were attempts to find the right locus of abstractness for ellipsis. The property theory argues that the appropriate identity conditions are semantic and does not fundamentally question the relative lack of abstractness of the underlying syntax. The dependency theory, in contrast, argues for a more abstract notion of syntax by refining the criteria for identity of occurrences of syntactic categories. But regardless of how matters turn out, it is clear that in seeking to fix the identity conditions for ellipsis, issues fundamental to our conceptions of linguistic description have been raised. Phenomena relevant to these issues extend beyond what we have been able to consider here. Among them are further interactions with anaphora, such as the 'vehicle change' effect noticed by Fiengo and May (1994): the observation that 'Mary loves John, and he thinks that Sally does, too' is interpreted as comparable to 'Mary loves John, and he thinks that Sally loves him, too', not 'Mary loves John, and he thinks that Sally loves John, too'. Moreover, we have left aside discussion of the conditions on discourse that allow an ellipsis to be resolved, including conditions on discourse coherence with respect to antecedents that may occur in sentences at some degree of removal in the discourse (cf. Kehler, 2000), and on the abstractness of discourse: e.g. consider when Butch says to Sundance at the edge of the cliff before jumping: 'I will if you will', indicating that the antecedent need not even be uttered (cf. Chao, 1987). We have tried, however, to highlight some of the core issues that have animated the discussion and that have made understanding elliptical phenomena of continued interest within linguistic theory.

Finite State Processing

Intermediate article

Gertjan van Noord, University of Groningen, Groningen, Netherlands

CONTENTS

Finite state processing is the analysis of (natural) language by means of finite state automata. Finite state automata are computational devices with limited capabilities.

FINITE STATE AUTOMATA

A finite state automaton (Kleene, 1956) is a formal computational device which defines a language in the mathematical sense of a set of strings (where a string is a sequence of symbols). Finite state automata have finite memory; therefore they are only capable of defining languages of a particularly simple kind: the 'regular' languages. A finite state automaton is often represented by a transition diagram; some examples are shown in Figure 1.

Finite state automata provide a well-understood mechanism for the definition of simple languages: the theory of finite state automata is at the heart of theoretical computer science and mathematical linguistics.

Finite state automata are efficient: the problem of deciding whether a given string is a member of a language defined by a finite state automaton can be solved within a time linear in the size of the input string. Moreover, any finite state automaton can be converted into an equivalent 'deterministic' automaton. For deterministic automata, the time taken to solve the decision problem is independent of the size of the automaton (nondeterministic automata may require time exponential in the size of the automaton). Two finite state automata are equivalent if they define the same language.

Finite state automata can be combined using a variety of operations. If M_1 and M_2 are finite state automata defining the languages L_1 and L_2 respectively, then there is a very simple algorithm to construct a finite state automaton which defines $L_1 \cup L_2$. In a similar way, finite state automata can be constructed for intersection, complementation and difference. An example of intersection is given in Figure 1.

The 'concatenation' of two languages L_1 and L_2 is defined as $L_1 \cdot L_2 = \{xy | x \in L_1, y \in L_2\}$; the 'Kleene closure' of a language L is defined as $L^* = \{x_1 \ldots x_n | x_1 \in L, \ldots, x_n \in L\}$. There are simple algorithms to construct a finite state automaton for the concatenation of two given finite state automata, and for the Kleene closure of a given finite state automaton.

The availability of such operations means that a complicated language can be defined in terms of mechanical combinations of smaller, more manageable finite state automata. This is exploited in the concept of 'regular expressions': a declarative notation for regular languages. Regular expressions are used, for instance, in a variety of software tools to define string patterns. In typical implementations, such regular expressions are compiled into equivalent finite state automata.

A formal definition of finite state automata can be given as follows. A finite state automaton M is a tuple (Q, Σ, E, S, F) where Q is a finite set of states, Σ is a set of symbols, $E \subseteq Q \times (\Sigma \cup \{\epsilon\}) \times Q$ is a finite set of transitions, $S \subseteq Q$ is a set of start states, and $F \subseteq Q$ is a set of final states. (Here, ϵ denotes the empty string.) The relation $\hat{E} \subseteq Q \times \Sigma^* \times Q$ is defined inductively as the minimal relation such that:

$\hat{E} \supseteq E \cup \{(q, \varepsilon, q) \mid q \in Q\}$
If (q_0, x_1, q_1) and (q_1, x_2, q_2) are both in $\hat{E}$
then $(q_0, x_1x_2, q_2) \in \hat{E}$.

The language $L(M)$ 'accepted' by M is $\{w | q_s \in S, q_f \in F, (q_s, w, q_f) \in \hat{E}\}$.

A finite state automaton is 'epsilon-free' if none of its transitions contains ϵ. A given finite state automaton can always be converted into an equivalent epsilon-free automaton. An epsilon-free finite state automaton is 'deterministic' if it has at most one start state and the outgoing transitions of all its states have different labels. A given nondeterministic automaton can always be converted into an equivalent deterministic automaton (potentially at the cost of increasing the size of the automaton considerably). An efficient minimization algorithm

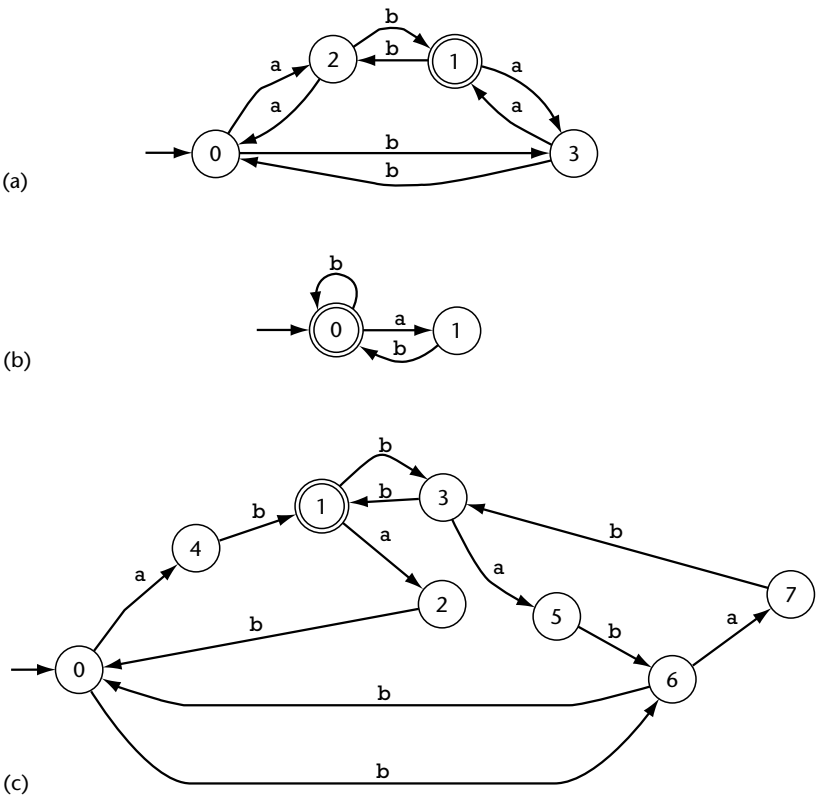

Figure 1. Examples of finite state automata. (a) In the first example, state 0 is a start state, and state 1 is a final state. The string `abbaab` is 'accepted' because there is a path $0 \rightarrow 2 \rightarrow 1 \rightarrow 2 \rightarrow 0 \rightarrow 2 \rightarrow 1$. Note that the path must start in a start state and end in a final state. The language L_1 defined by the automaton is the set of all strings over the alphabet {`a`, `b`} such that the number of occurences of `a` is odd and the number of occurrences of `b` is odd. (b) The second example defines the language L_2 consisting of all strings in which every `a` is immediately followed by a `b`. (c) The third automaton defines the language $L_1 \cap L_2$.

exists to convert a given deterministic automaton into an equivalent automaton with the fewest possible number of states (Hopcroft, 1971). This automaton is unique, ignoring the labeling of the states.

A language that can be defined by means of a finite state automaton is called a regular language. The set of regular languages is a proper subset of the set of context-free languages. There are many languages that are not regular. For example, the set of strings over the alphabet {`a`, `b`} where the number of occurrences of `a` equals the number of occurences of `b` is not a regular language. Nor is the language over the alphabet {`(`, `)`} such that the brackets are balanced. Nor is the 'copy' language $\{ww | w \in \{$ `a`, `b`$\}^* \}$.

Finite state automata are used in a variety of applications, such as the compilation of programming languages, pattern matching (not only for text, but also in other domains such as bioinformatics), and computational linguistics.

FINITE STATE TRANSDUCERS

Finite state transducers are a generalization of finite state automata, in which transitions are 'labeled' with pairs of symbols. A finite state transducer defines a mapping between two regular languages. Examples of finite state transducers are given in Figures 2 and 3.

A relation that can be defined by a finite state transducer is called 'regular' (Kaplan and Kay, 1994). Finite state transducers inherit many of the useful properties of finite state automata. The application of a finite state transducer is linear in the size of the input, although it can be exponential in the size of the transducer (it is not always possible to convert a given transducer into an equivalent deterministic transducer). Moreover, regular relations are closed under union, concatenation and Kleene closure. Same-length regular relations are also closed under intersection, complementation and difference.

The 'composition' of two binary relations R_1 and R_2 is $R_1 \circ R_2 = \{ (x_1, x_3) | (x_1, x_2) \in R_1, (x_2, x_3) \in R_2 \}$. Regular relations are closed under composition: if M_1 and M_2 are transducers for R_1 and R_2 respectively, then there is a simple algorithm to construct a transducer for the relation $R_1 \circ R_2$.

A formal definition of finite state transducers can be given as follows. A finite state transducer M is a tuple $(Q, \Sigma_d, \Sigma_r, E, S, F)$ where Q is a finite set of states, Σ_d and Σ_r are sets of symbols, E is a finite subset of $Q \times (\Sigma_d \cup \{\epsilon\}) \times (\Sigma_r \cup \{\epsilon\}) \times Q$, and S and F are sets of start and final states respectively. The relation $\hat{E} \subseteq Q \times \Sigma_d^* \times \Sigma_r^* \times Q$ is defined inductively as the minimal relation such that:

$\hat{E} \supseteq E \cup \{ (q, \epsilon, \epsilon, q) | q \in Q \}$

If (q_0, x_1, y_1, q_1) and (q_1, x_2, y_2, q_2) are both in $\hat{E}$ then $(q_0, x_1 x_2, y_1 y_2, q_2) \in \hat{E}$.

The relation $R(M)$ 'accepted' by M is $\{(w_d, w_r) | q_s \in S, q_f \in F, (q_s, w_d, w_r, q_f) \in \hat{E}\}$.

Finite state transducers can be extended with weights. Weighted transducers not only map a given string to one or more outputs, but also provide a score indicating, for instance, the likelihood of each mapping.

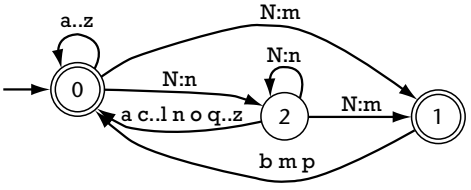

Figure 2. Example of a finite state transducer in phonology (adapted from Kaplan and Kay (1994)). N is an abstract nasal segment, which must be realized as either m (if it is followed by a labial) or n (otherwise). We use a colon to separate the labels of a label pair. We abbreviate a symbol pair s:s by writing s; and we represent intervals of symbols using ..

FINITE STATE PARSING AND HUMAN SENTENCE PROCESSING

Finite state techniques have been used widely in language processing, in particular in phonology and morphology. For instance, it has been shown that phonological models consisting of sets of context-sensitive rewrite rules are finite-state (Johnson, 1972; Kaplan and Kay, 1994). A similar result has been obtained for phonological models expressed in optimality theory (Frank and Satta, 1998).

The syntax of natural languages is generally assumed not to be finite-state (Chomsky, 1957). For instance, the recursive nature of syntactic analysis trees suggests that natural language is at least as complex as the language of balanced brackets, which is not regular. Furthermore, certain syntactic phenomena appear to require an unbounded amount of memory. An interesting example is the

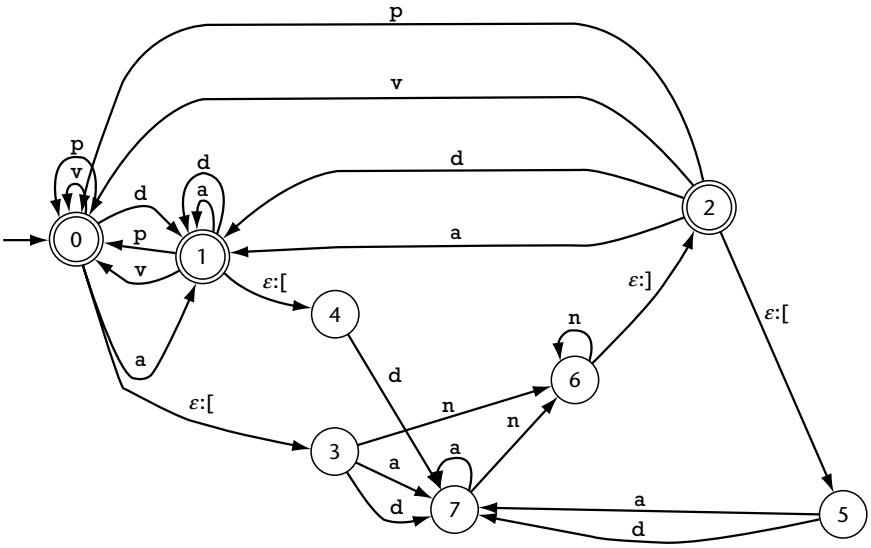

Figure 3. Example of a finite state transducer. The transducer constitutes a very simple NP-chunker. It assumes its input consists of strings over the part-of-speech labels a, d, n, p, and v, for adjective, determiner, noun, preposition, and verb respectively. The transducer places square brackets around sequences of tags in the input corresponding to noun phrases. For instance, the sentence *the quick brown fox jumped over the lazy dog* corresponds to the part-of-speech sequence daanvpdan. The transducer maps this string to [daan] vp [dan].

occurrence of crossing dependencies between verbs and their direct objects found in Swiss German (Huybregts, 1984).

However, the assumption that finite state automata are not suited to model the syntax of natural language raises the question of how the observed efficiency of language understanding by humans can be explained, because more complex language models cannot in general be processed so efficiently. Furthermore, human memory is finite; and only a fraction of it is used for language processing. Chomsky introduced the distinction between 'competence' – the speaker's and hearer's knowledge of language – and 'performance' – the actual use of this knowledge of language, including language processing. It may be that competence is modeled by more powerful means, while an efficient finite state processing model only approximates this competence model.

Interestingly, humans have problems with certain grammatical constructions, such as center-embedding, which are impossible to describe by finite state means; but which are supposed to be grammatical (Miller and Chomsky, 1963). For example, the following sentences are grammatical, but hard to understand:

I called the man who put the book that you told me about down up. (1)

The man whom the boy whom the students recognised pointed out is a friend of mine. (2)

The man the boy the students recognized pointed out is a friend of mine. (3)

The rat the cat the dog chased bit ate the cheese. (4)

Such observations suggest an underlying finite state approach, since finite state devices are incapable of describing center-embedded constructions (of arbitrary depth).

Some researchers have proposed parsing algorithms which interpret a given (nonregular) grammar, but which are restricted to operate in a small, fixed amount of memory. For instance, Resnik (1992) shows how a 'left-corner' parser, augmented with an operation of 'eager' composition, and formalized as a push-down automaton, utilizes its stack only for center-embedding constructions. Left-recursive and right-recursive structures, on the other hand, can be processed without exploiting the stack. If a limit to the depth of the stack is imposed, then the resulting model explains why center embedding cannot be processed beyond a certain complexity. In contrast, a purely bottom-up (or top-down) parser formalized in a similar fashion needs to use its stack for right-recursive (respectively, left-recursive) structures: if a limit to the stack were imposed then the model would wrongly predict that left-recursive and right-recursive structures are equally difficult. A finite state automaton can be explicitly constructed from a given grammar, on the basis of similar restrictions (Nederhof, 2000).

The distinction between competence and performance has been challenged (e.g. Abney, 1996). Rather than distinguishing between a powerful competence grammar and a finite state processing component, an alternative is to create finite state models directly. In some of these approaches (e.g. Roche and Schabes, 1997), syntactic analysis is divided into a number of levels. Each level consists of a transducer recognizing some amount of structure. For example, the first level might recognize base noun phrases, the next level prepositional phrases, the next level complex noun phrases, and so on. Such transducers are not unlike our simple example in Figure 3. They are applied in sequence; or equivalently, a single transducer may be constructed by composing them.

Generalized Quantifiers

Advanced article

Fritz Hamm, University of Tübingen, Tübingen, Germany

CONTENTS

Generalized quantifiers in logic are those quantifiers which go beyond the traditional first order quantifiers ∃, ∀. Quantifiers in natural language semantics are the denotations of determiners; generalized quantifiers are the denotations of noun phrases (NPs).

GENERALIZED QUANTIFIERS IN LOGIC AND NATURAL LANGUAGE

Both the modern logical concept of quantifier and the natural-language-semantic notion of quantifier have their historical roots in philosophical and mathematical logic.

The founding father of logic, Aristotle, introduced in his theory of syllogisms the notion of quantifier as a relation between universal terms (variables) or properties. The familiar quantifiers in the square of opposition consisting of *all* or *every, some, no*, and *not every* are binary relations Q between properties A and B; formally we write QAB. For instance, the sentence *all men are mortal* is true if the property of being a man is part of the property of being mortal.

If we presume that the extension of a one-place property, like the property of being a man, is a set, we can rephrase Aristotle's insight in modern set-theoretic terminology. A quantifier in the above sense is then just a relation between two sets. The quantifier *all*, for example, is the subset relation, and the sentence *all men are mortal* is therefore considered true if and only if the set of men is a subset of the set of individuals that are mortal.

The notion of quantifier as a variable binding operation, familiar from modern first-order logic, was first introduced much later by G. Frege (1960) and reached its full generality in the work of A. Mostowski (1957) and P. Lindström (1966). The Lindström quantifier covers nearly every instance of the notion of quantification both in logic and in natural-language semantics. (An exception will be mentioned below.)

Quantifiers in logic and most natural-language quantifiers share an important characteristic: they are both permutation-invariant (PERM), that is, only the number of elements of their argument sets determine their behavior. For example, given a universe of discourse M, a permutation π of M (i.e. a bijective map of M onto itself), and subsets A and B of M, assume $every_M AB$. This means that $A \subseteq B$. Permutation-invariance says that $\pi(A)$, the image of A under π, is a subset of $\pi(B)$. In other words, $every_M \pi(A)\pi(B)$.

There are only a few natural-language quantifiers that are potential exceptions to PERM. This contrasts sharply with the semantics of other major syntactic categories. For example, Westerståhl (1985) shows that the requirement of permutation-invariance for extensional adjectives or adverbs rules out practically all of them, leaving only the trivial ones *existent* and *non-existent*.

This suggests that natural-language quantifiers, which are usually denoted by determiners, form the logical backbone of natural-language semantics, since permutation-invariance is a characteristic logical property.

What, then, is the difference between quantifiers in logic and quantifiers in natural languages? A first, superficial, difference is in the kinds of quantifiers that are of interest to logicians and semanticists.

If L is standard first-order logic with quantifiers $\forall$ and $\exists$, then let $L(Q)$ be first-order logic augmented with an additional quantifier symbol Q. Let $Q_\alpha = \{X \subseteq M: |X| \geq \aleph_\alpha\}$ ($|X|$ stands for the cardinality of the set X).

The formula $Q_0\psi$ therefore says that there is an infinite number of elements satisfying formula ψ, and $Q_1\psi$ says that there is an uncountably infinite number of elements satisfying ψ. It is easy to show that the logic $L(Q_0)$ admits of no complete

axiomatization, but J. Keisler has shown that the logic $L(Q_1)$ does admit of a complete axiomatization. Proofs of these results can be found in Kaufmann (1985).

The quantifiers Q_α are not very interesting from a linguistic point of view. A more interesting linguistic question was posed by Keenan (1992). Keenan argues that the semantic analysis of the sentence *every student read a different book* involves a complex quantifier *every … a different*, which relates the sets of *students* and *books* and the binary relation *read* to truth values. Keenan shows that this complex quantifier is not reducible to any combination of simpler quantifiers such as *every* or *a*.

Keenan's investigations therefore raise the general question of which types of quantifiers are realized in natural languages and how their interpretation is arrived at in a compositional way. Such investigations led to new research in linguistic typology (e.g. Bach *et al*., 1995).

Another difference between quantifiers in logic and in natural languages is that the latter have a restriction set built into their syntactic realization. Thus *every* applies to, say, the denotation of the count noun *book* to produce the noun phrase (NP)-denotation *every*(*book*). In the pioneering work of Barwise and Cooper (1981) these NP-denotations were called 'generalized quantifiers'.

Even more importantly, natural-language quantifiers are contextually restricted. The sentence *every student reads Ulysses* does not mean that every student in the world reads *Ulysses*. For the sentence to be considered true, it may suffice that every student in my class reads *Ulysses*.

A still more fundamental difference between quantifiers in logic and in natural language concerns the role of semantic universals.

GENERALIZED QUANTIFIERS AND SEMANTIC UNIVERSALS

The most important semantic universal concerning the denotation of natural language determiners is 'conservativity' (CONS).

According to Montague's extensional type theory, determiners denote in $D_{<<e,t>,\ <<e,t>,\ t>>}$. Now, given a universe of discourse M with two elements, a simple calculation shows that there are 65 536 quantifiers on M. This seems to be an absurdly large number of quantifiers in a universe with two elements. Therefore, the majority of quantifiers in $D_{<<e,t>,\ <<e,t>,\ t>>}$ cannot be denoted by natural-language determiners. (*See* **Semantics and Pragmatics: Formal Approaches**)

Semantic universals ought to determine those quantifiers that are in principle denotable by natural-language determiners. This does not mean that there is no language-specific variation: some languages may have a richer system of determiners than others.

Conservativity says that the left argument of a quantifier is more prominent than the right one: formally, $QAB \leftrightarrow QAA \cap B$. Thus the sentence *a student sleeps* is true just in case the sentence *a student is a student and sleeps* is true. Neglecting intensional determiner structures, conservativity appears to be an empirically trivial requirement, in the sense that there seem to be no counterexamples. A potential counterexample that comes to mind is *only*, defined as follows: *only AB* iff $B \subseteq A$. This determiner denotation is not conservative, but it is highly questionable whether *only* is a determiner at all.

Although CONS is empirically trivial in the above sense, it has major systematic effects. Given our universe M with two elements, CONS reduces the number of quantifiers from 65 536 to 512. Of course, this result means that there are a lot of quantifiers that are not conservative. Examples from mathematical logic abound here. For instance consider the quantifier H (for Härtig), which compares the cardinalities of two sets: HAB iff $|A| = |B|$. It is clear that H is not conservative. CONS therefore not only serves as a principle that rules out the majority of quantifiers in $D_{<<e,t>,\ <<e,t>,\ t>>}$, but also helps to distinguish logical quantifiers from many quantifiers in natural language.

A further important semantic universal for determiners is 'extension' (EXT). This principle formalizes the intuition that determiners are constants, in contrast to common nouns like *farmer*. For example, we do not want to suppose that *most* can mean *every* on a universe M, *two* on a universe M' and *most* on a third universe M''. EXT excludes such situations. The principle says that for $A, B \subseteq M \subseteq M'$, $Q_M AB$ iff $Q_{M'} AB$.

Given the semantic universals CONS, EXT and PERM, many semantic facts concerning determiners can be explained.

For example, we do not find quantifiers Q satisfying the relational scheme 'asymmetry', i.e. the principle $QAB \rightarrow \neg QBA$. By contrast, there are many quantifiers Q satisfying symmetry, i.e. $QAB \rightarrow QBA$: for instance, the quantifier *some*.

Assuming CONS, EXT and PERM, it is possible to prove that no nontrivial quantifiers exist that satisfy asymmetry. Such results help to explain certain lexical gaps.

Another important class of properties of quantifiers, which are not universal but specific, are various forms of 'monotonicity'. For example, the so called Ladusaw–Fauconnier generalization (Keenan and Westerståhl, 1997) attributes the distribution of negative-polarity items such as *any* or *ever* to monotonicity properties of quantifiers. A negative-polarity item is licensed in the scope of a monotone-decreasing operator like *at most four*, but not in the scope of *at least four*, which is not monotone-decreasing. This explains why *at most four students have ever been to Munich* is acceptable but *at least four students have ever been to Munich* is not. A quantifier Q is monotone-decreasing iff whenever QAB and $B' \subseteq B$ then QAB'. For example, *no*, defined as $noAB$ iff $A \cap B = \emptyset$, is monotone-decreasing.

The most important semantic universal, CONS, has an interesting characterization, which may even be relevant to learnability issues. Keenan and Stavi (1986) show that on a given universe M the conservative quantifiers are exactly those that can be generated from a relatively small set of monotone-increasing quantifiers by applying the Boolean operators of conjunction, disjunction and negation. Therefore a person learning the possible denotations of natural-language determiners has to learn the denotations of a relatively small class of determiners, and can derive the rest by applying operations, which have to be learned anyway.

GENERALIZED QUANTIFIERS AND CONCEPTUAL SEMANTICS

In order to study in more detail the relationship between quantifier theory and conceptual semantics, it is useful to concentrate for a while on the grammatical category of (spatial) prepositions, which is a central topic in the field of conceptual semantics. (*See* **Categorial Grammar and Formal Semantics**)

Landau and Jackendoff (1993) observe a significant asymmetry between the vocabulary of object-denoting nouns and that of prepositions. An average adult native speaker of English uses about 10 000 count nouns denoting objects, but at most 100 prepositions that locate these objects in space. This seems to be a fact not only about English but about natural languages in general.

With prepositions, as with quantifiers, one observes characteristic lexical gaps. For example there seems to be no preposition *sprough* meaning 'reaching from end to end of a cigar-shaped object', which would distinguish a sentence like *the rug extended sprough the airplane* from the unacceptable **the rug extended sprough my dining room*.

The explanation Landau and Jackendoff offer for this phenomenon is that although the semantics of common nouns rests on abstractions from the objects denoted by them, the degree of abstraction is far greater in the case of prepositions. The preposition *on* in *the cat is sitting on the mat* relates the 'figure' object *the cat* to the 'reference' object *the mat*, which defines the region in which the figure object is located. Only very abstract representations of the figure and ground objects serve as arguments of the relations that propositions express. Landau and Jackendoff entertain the hypothesis that two conceptual systems, the 'what' and the 'where' systems, which determine geometries of different granularity, are responsible for the difference between object-denoting and object-locating expressions. Although the details of their proposal have been criticized (e.g. Herskovits, 1997), their basic insight seems to be correct.

If we consider the type of prepositions $D_{<<<e,t>,\, t>,\, <<e,t>,\, t>>}$ in (extensional) Montagovian type theory, we immediately get the prediction that there should be many more prepositions than common nouns, which are of type $D_{<e,t>}$. This is the opposite of what is observed. Therefore, as in quantifier theory, one would like to find restrictions on the set of possible natural-language prepositions. This is partly achieved in Zwarts and Winter (2000), where a version of conservativity adapted for prepositions plays a major role. However, this work does not account for the abstraction process inherent in the semantics of prepositions.

A device which helps to formalize abstraction has been introduced by van der Does and van Lambalgen (2000).

Conditional quantification $\exists(\varphi|G)$ is a new form of quantification. Given a set of information states G and a formula φ this form of quantification expresses the maximum information about φ on the basis of G. Therefore the meaning of $\exists(\varphi|G)$ depends on G. For a specific choice of G, $\exists(\varphi|G)$ is just the usual existentially quantified $\exists x\varphi$, but for other choices of G, $\exists(\varphi|G)$ is not even first-order-definable. Depending again on G, $\exists(\varphi|G)$ does not always bind variables in φ. This means that in general $\exists(\varphi|G)$ is not a Lindström quantifier.

Van der Does and van Lambalgen give a rough proposal for a semantic analysis of prepositions. The sentence *the book is on the table* is formalized as $\exists(B(x) \wedge \mathrm{on}(x, y) \wedge \mathrm{T}(y)|G)$, where G erases all properties of the table y except its surface and all structure of the book x except its internal axis.

(The precise description of G is a rather complex matter.)

The approach taken by van der Does and van Lambalgen therefore promises significant insights from conceptual semantics formulated in terms of model-theoretic quantification.

Government–Binding Theory

Introductory article

Howard Lasnik, University of Maryland, College Park, Maryland, USA

CONTENTS

Government–Binding theory is an approach to the study of the syntax of human languages based on an abstract underlying representation and transformations successively altering that structure. The approach posits universal principles innately represented in the mind, and simple parameters, fixed by the language learner from simple evidence, determining how languages can differ.

ORIGINS OF GOVERNMENT AND BINDING

Government–Binding (GB) Theory is an approach to the study of human language that developed out of Noam Chomsky's work in the 1970's. Like all of Chomsky's earlier work, it centered on two fundamental questions:

> What is the correct characterization of someone who speaks a language? What kind of capacity is 'knowledge of language'? (1)

> How does this capacity arise in the individual? What aspects of it are acquired by exposure to relevant information ('learned'), and what aspects are present in advance of any experience ('wired in')? (2)

Chomsky's earliest work, in the 1950's, particularly concentrated on question (1), since explicit and comprehensive answers to that question had never been provided before. Chomsky's answer posited a computational system in the human mind that provided statements of the basic phrase structure patterns of languages (phrase structure rules) and operations for manipulating these basic phrase structures (transformations). This framework, and all its descendants, fall under the general title Transformational Generative Grammar ('generative' meaning explicit, in the sense of mathematics).

In the 1960's, the focus began to shift more towards question (2). Chomsky coined the term 'explanatory adequacy' for answers to that question. A theory of language, regarded as one component of a theory of the human mind, must make available grammars for all possible human languages. To attain a high degree of explanatory adequacy, the theory must in addition show how the learner selects the correct grammar from among all the available ones, based on quite limited data. The theories of the 1950's and early 1960's made a very large number of grammars available, so the explanatory problem was severe.

Through the late 1960's and 1970's, to address this problem of explanation, more and more constraints were proposed on the notion 'possible human grammar'. For example, Chomsky's 'standard theory' of the mid- to late-1960's proposed a limitation on the kinds of transformations previously assumed to exist. Chomsky's earliest syntactic theory postulated phrase structure rules that create simple structures, 'generalized transformations' that combine separate simple structures into more complex ones, and 'singulary transformations' that alter the structures created by phrase structure rules and generalized transformations. Chomsky argued that the system should be constrained by the elimination of generalized transformations, with their work taken over by phrase structure rules themselves. He argued that since the resulting expansion of descriptive power of phrase structure rules is so slight, the resulting system is both simpler and more explanatory, in that it makes fewer options overall available to the learner. The next major move in the direction of explanatory adequacy came in the late 1960's in the form of the 'X-bar theory' of phrase structure, which proposed limitations on phrase structure rules, and further limitations on transformations, so that they no longer were responsible for derivational morphology of the *destroy-destruction* type. Such idiosyncratic relations are better captured in

the lexicon, which is, after all, the repository of all that is idiosyncratic about particular lexical items.

A human language is a systematic way of relating sound to meaning, with syntax mediating between the two. At the point in the development of the theory just summarized (around 1970), the model can be graphically represented as follows, with deep structure, the initial phrase structure representation created in conformity with the requirements of X-bar theory, connected to meaning, and surface structure, the final result of the whole syntactic derivation, connected to sound:

D(eep)-Structure – Semantic interpretation
|
Transformations
|
S(urface)-Structure – Phonetic interpretation (3)

While this was the basic architecture, it was known from the earliest work in generative grammar that some aspects of meaning depend on surface structure. In particular, while grammatical relations (subject of, object of, etc.) are most directly related to D-structure (and are opaque in S-structure), virtually all other aspects of meaning (including scope of quantifiers, anaphora, focus) relate to S-structure. For example, in his earliest work Chomsky already had pointed out that transformations often alter scope possibilities, while leaving understood grammatical relations intact, as in (4) versus (5).

Everyone in the room knows three languages (4)

Three languages are known by everyone in the room (5)

This led to a revised model (the 'extended standard theory') in which both D-structure and S-structure are inputs to semantic interpretation.

Within this model, through the 1970's, more and more restrictions were proposed on the phrase structure and transformational options assumed to be available to the child learning a language. These moves were explicitly motivated by considerations of explanatory adequacy, though general considerations of simplicity also played a role. One small simplification in the extended standard theory model was the result of a technical revision concerning how movement transformations operate. Trace theory proposed that when an item moves, it leaves behind a 'trace', a silent placeholder marking the position from which movement took place. Under trace theory, the importance of D-structure for semantic interpretation is further reduced, and ultimately eliminated. Once S-structure is enriched with traces, even grammatical relations can be determined at that level of representation. Using the term LF ('Logical Form') for the syntactic representation that relates most directly to semantics and PF ('Phonetic Form') for the one relating most directly to phonetics, we have the so-called T-model in (6), which was at the core of GB theorizing.

D-structure

PF LF (6)

Modularity

On first examination, human languages appear to be almost overwhelmingly complex systems, and the problems, for the linguist, of successfully analyzing them, and for the learner, of correctly acquiring them, seem virtually intractable. But if the system is broken down into smaller parts, the problem might likewise be decomposed into manageable components. In fact, with this divide and conquer ('modular') approach, by the GB era of the 1980's, languages began to seem much simpler. Apparently complex phenomena were seen as the result of interactions of simple modules. The phrase structure module was virtually reduced to the X-bar schema, with specific instantiations following from properties of particular lexical items. For example, the verb *prove* must be specified in the lexicon as taking a direct object, a kind of requirement called 'subcategorization' in the standard theory, since such requirements divide big categories (like verb) into smaller subcategories (like transitive verb). Given the subcategorization properties of *prove*, a specific phrase structure rule saying that a Verb Phrase (VP) can consist of a V and a Noun Phrase (NP) would be completely redundant. Further, the X-bar schema itself was extended from just 'lexical' categories (noun, verb, adjective, etc.) to 'functional' categories. It was an irony of the original formulation of X-bar theory that it excluded the most fundamental unit of syntactic analysis – the sentence. All other phrasal units were analyzed as projections of a head, but sentence was *sui generis*. GB theorizing brought sentence into the fold, by analyzing it as the projection of an inflectional head, Infl, containing tense and agreement information. In certain

instantiations of the general framework, Infl was divided into two separate functional heads, Tense (T) and Agreement (Agr).

The transformational module is also dramatically simplified in comparison with its predecessors. In the 1950's and 1960's, the transformational component of the grammar of a particular language was thought to be a long ordered list of very detailed transformations, some marked optional and others marked obligatory, specific to the language in question. In such a framework, explanatory adequacy is a very distant goal. The GB framework replaced these transformations with very general optional operations, Move α (displace any item anywhere), or even Affect α (do anything to anything). There is thus very little transformational syntax that the child has to learn. A grammar this simple and general would seem to massively overgenerate, producing countless numbers of unacceptable sentences. To deal with this overgeneration problem, GB theorists, further developing a line of research begun in the 1960's, posited general constraints on the operation of transformations (locality constraints in particular), and also conditions on the output of the transformational component (including 'filters').

PARAMETERS

The postulated universal ('wired-in') parts of the computational system are called principles. The (limited) ways in which languages can differ syntactically are called parameters. The system is fundamentally based on principles and parameters. In fact, Chomsky came to prefer the term 'principles and parameters' to 'government and binding' for the approach being outlined here, as 'government' and 'binding' are just two technical notions among many in the theory, as will be seen below. The child learning a language is pre-equipped with the principles, and needs only to set the 'values' of the parameters. The standard assumption is that there are few parameters, they are very simple, and their values can be determined by the child based on readily available primary linguistic data. One of the major parameters, the head parameter, is responsible for a significant word order difference among languages. In languages like English, X-bar heads invariably precede their complements in D-structure. For example, verbs precede their direct objects, and English has prepositions rather than postpositions. English is head-initial. Languages like Japanese are just the reverse. They are head-final. Another parameter, the null subject parameter, concerns the need for overt subjects. In languages like Spanish, a subject of a simple indicative clause need not be expressed, while in languages like English, subjects must be expressed. For all of the hypothesized parameters, simple data is expected to be readily available to the child.

θ-THEORY AND THE LEXICON

As indicated above, GB posits a highly modular organization of human linguistic ability. The X-bar schema for phrase structure is one module. The lexicon is another. These modules determine D-structure configurations via the regulation of a third module 'θ-theory'. Subcategorization properties follow, in large measure, from semantic properties. Thus, in a sentence with the verb *solve*, there is a semantic function for a direct object to fulfill, while there is no such function in the case of *sleep*. These semantic functions that arguments (direct objects, subjects, indirect objects, etc.) fulfill are called 'thematic (θ-)roles'. The verb *prove* demands a direct object since the object would fulfill a necessary θ-role determined by the meaning of the verb. Conversely, an intransitive verb like *sleep* does not take a direct object since there would be no θ-role for it to fulfill. These paired requirements on assigners and recipients of theta roles are called the 'θ-Criterion': Every θ-role must be assigned to one and only one argument, and every argument must receive one and only one θ-role.

CASE THEORY

S-structures result from the transformational component operating on D-structures. Given the generality of Move α, derivations often seem to yield ungrammatical sentences. One module reining in this overgeneration by regulating S-structure is 'Case theory'. Consider the following pair of sentences:

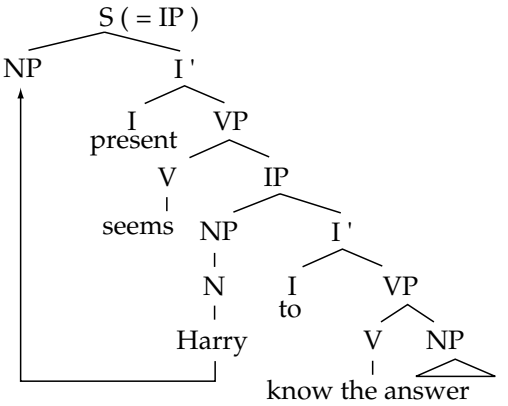
It seems Harry knows the answer (7)

Harry seems to know the answer (8)

Harry in (8) is in subject position at S-structure, but given the close semantic parallelism between (7) and (8), especially with respect to θ-relations, their D-structures (and therefore the resulting trace-augmented S-structures) are assumed to be similar. In particular, since *Harry* is the understood subject of *know the answer* in both examples, it must be in the subject position of that predicate in the D-structures of both examples. The D-structure of (7) is identical to the S-structure in relevant respects, with the subject of the main sentence *it* not

an argument, but rather, an 'expletive', a placeholder lacking semantic import (unlike the referential *it* in 'It is on the table.'). The D-structure of (8) is similar, the only differences being that the main subject position is completely empty, and the embedded sentence is an infinitive:

*seems [Harry to know the answer] (9)



(10)

To derive the correct S-structure, the NP *Harry* raises into the empty higher subject position, as indicated by the arrow in (10). The movement is obligatory in this instance. If *Harry* remains in the lower subject position, the result is ungrammatical, whether or not the expletive *it* occurs as the higher subject:

*Seems Harry to know the answer (11)

*It seems Harry to know the answer (12)

This obligatoriness of movement of the subject has been analyzed as a requirement of case. There are characteristic structural positions that 'license' particular cases, as in the following table:

Position	**Case**	**Example**
Subject of finite sentence	Nominative	*He* left
Direct object of transitive verb	Accusative	I saw *him*
'Subject' of NP	Genitive	*John's* belief that Mary solved the problem
Object of preposition	Oblique	near *him*

(13)

In many languages (such as Latin, Russian, German), these case distinctions are overtly manifested. In English, only pronouns show an overt distinction between nominative and accusative, but Case Theory posits that all NPs have abstract case (henceforth, Case), even when it is not phonologically visible. The requirement that all NPs occur in appropriate Case positions is the 'Case Filter', a well-formedness condition on the S-structure level of representation. The NP *Harry* in its D-structure position in (10) lacks a legitimate Case, since that position does not license nominative, accusative, genitive, or oblique. Movement of *Harry* to the higher subject position salvages the example, since that position licenses nominative Case. Such 'subject raising' is not possible for structure (14), where the embedded sentence is finite:

*Harry seems [*t* knows the answer] (14)

This, too, has been analyzed in terms of Case: movement of an NP from one Case position to another is prohibited. Metaphorically speaking, movement to a Case position is a 'last resort', an option taken only if necessitated by the Case Filter.

Government

The GB approach always sought regularities and generalizations. The notion 'government' is itself a generalization of the X-bar theoretic head-complement relation. The basic definition is as follows:

> A head H governs Y if and only if every maximal projection dominating H also dominates Y and conversely. (15)

By (15), a head governs its complement and also its specifier. Case licensing then is under government, with the governor licensing the governee. A transitive verb govern its direct object NP; a preposition governs its complement NP; Infl governs its specifier (the subject of the clause); and N (or D, for determiner, in a development of the theory, the 'DP hypothesis') governs its specifier, the 'subject' of the nominal expression. Thus, a Case-licensing head (transitive verb; preposition; finite Infl; possessive determiner) licenses Case on a nominal expression (DP) that it governs.

TYPES OF MOMENT

The transformational module of the theory recognizes three major subtypes of movement. 'A-movement' is movement to an argument-type position (especially subject position), as exemplified in the subject raising seen in (8), and in passive sentences, where an understood object surfaces in subject position ('Mary was elected'). In both of

these instances, the movement is to specifier of IP. 'A-movement' is movement of an XP to a non-A position. The movement of an interrogative expression as in (16) (WH-movement) is a central exemplar:

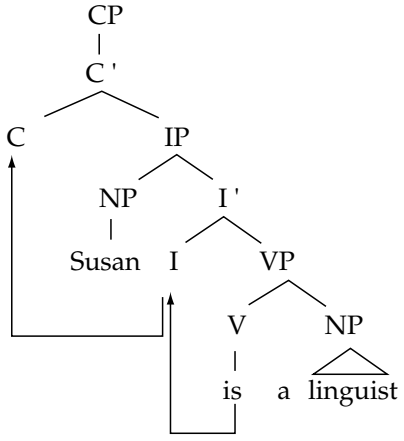
Who will they hire *t* (16)

WH-movement is standardly analyzed as movement to the specifier of CP (Complementizer Phrase), a functional projection above IP. All three types of movement are regarded as instantiations of one very general operation: Move α. The differences follow from independent properties of the items moved and the positions moved to.

Head movement and Inflection

The third major type of movement is head movement, where an X° adjoins to a higher head (the very next higher head by the Head Movement Constraint). One of the classic analyses of generative grammar was restated in the GB framework in terms of head movement. Pairs of sentences like those in (17) are related via movement of the verb *be/is* to Infl followed by movement of Infl To C, schematized in (18).

a. Susan is a linguist
b. Is Susan a linguist (17)



(18)

Similar head movement, along with WH-movement, is involved in the derivation of (16).

A major GB research topic of the late 1980's and early to mid-1990's was the parametric differences among languages with respect to the kind of head movement just illustrated. In many languages, all types of verbs can raise, but in English, only 'auxiliary' verbs (*be*, *have*, modals) can raise; 'main' verbs cannot:

a. Susan saw a linguist
b. *Saw Susan a linguist (19)

This difference shows up in negative sentences as well, as in the following contrast, under the standard assumption that the base position of negation is higher than VP and lower than Infl:

*John likes not Mary (20)

Jean (n')aime pas Marie (21)

A parametric property of Infl (or one of its components T and Agr) was argued to be responsible for the observed divergence. In languages, such as French, that allow all verbs to raise, Infl is 'strong', while in English it is 'weak'.

BINDING

The 'Binding' part of Government–Binding theory has as its core anaphoric relations, circumstances under which one expression can or cannot take another as its antecedent, that is, pick up its reference from the other. Among the imaginable anaphoric relations (relations of referential dependence) among NPs, some are possible, some are necessary, and still others are proscribed, depending on the nature of the NPs involved and the syntactic configurations in which they occur. For example, in (22), *him* can take *John* as its antecedent, while in (23), it cannot.

John said Mary criticized him (22)

John criticized him (23)

That is, (23) has no reading corresponding to that of (24), with the pronoun *him* replaced by the 'anaphor' *himself*.

John criticized himself (24)

A pronoun cannot have an antecedent that is 'too close' to it. This is Condition B of the binding theory. Conversely, an anaphor requires an antecedent quite close to it (Condition A). Compare (24) with (25).

*John said Mary criticized himself (25)

The pertinent locality is, roughly, being in the same clause (though in certain instances a more complicated notion involving government is implicated, hence Chomsky's name 'governing category' for the relevant domain).

A third binding condition (Condition C) excludes an anaphoric connection between *She* and *Mary* in (26), as contrasted with (27).

*She thinks Mary will solve the problem
[with *She* intended to refer to Mary] (26)

Mary thinks she will solve the problem (27)

THE ROLE OF LOGICAL FORM

In the core GB model schematized above in (6), LF is not distinct from S-structure. However, more and more arguments were put forward that transformational operations of the sort successively modifying D-structure, ultimately creating S-structure, also apply to S-structure, creating a distinct LF. One such operation, Quantifier Raising (QR), moves quantifiers from their surface positions to positions more transparently representing their scope, with the traces of the moved quantifiers ultimately interpreted as variables bound by those quantifiers. The ambiguities of sentences with multiple quantifiers are captured by the multiple LF representations QR makes available. For example, a sentence like (28) has the two LF representations in (29), depending on the order in which the two quantifiers are raised. Subscripts mark the association of quantifier with trace.

Some student solved every problem (28)

a. some student$_1$ [every problem$_2$ [t_1 solved t_2]]
b. every problem$_2$ [some student$_1$ [t_1 solvedt_2]]
(29)

(29a) represents the reading of (28) in which *some student* has wider scope than *every problem* (there is a particular student that solved every problem), and (29b) represents the reading in which *every problem* has wider scope (every problem was solved, but not necessarily by the same student). Unlike the transformational operations mentioned earlier, applications of QR exhibit no phonological displacement. All the expressions in (28) are pronounced in their surface structure position, on either reading. This follows from the organization of the grammar. When a transformation operates between D-structure and S-structure, it will have an effect on the phonetic output, since S-structure feeds into PF. On the other hand, a transformational application between S-structure and LF will have no phonetic effect, since LF does not feed into PF. QR in (29) is an example of the latter type of 'covert' transformational operation.

Another covert operation is the analogue of overt WH-movement. Under the assumption that overt WH-movement positions an interrogative operator in its natural position for interpretation (with the trace it leaves behind in the natural position for a variable bound by the operator), in sentences with multiple interrogatives, such as (30), at the level of LF all are in sentence initial operator position, as illustrated in (31).

Where should we put what (30)

what$_1$ [where$_2$ [we should put t_1 t_2]] (31)

(31) is then rather transparently interpreted as:

For which object x and which place y, we should put x at y (32)

One of the most powerful arguments for covert WH-movement involves constraints on movement. For example, it is difficult to move an interrogative expression out of an embedded question (a question inside another sentence):

*Why$_1$ do you wonder [what$_2$ [John bought t_2 t_1]] (33)

If (33) were acceptable, it would mean 'What is the reason such that you wonder what John bought for that reason'. In languages where WH-phrases are *in situ* (unmoved) at S-structure, such as Chinese, their interpretation apparently obeys the same constraints that the overt movement in a language like English obeys. So, in Chinese an example like (34) is possible but one like (35) is impossible on the relevant reading (the one where *weisheme* is understood as modifying the action of the lower clause):

ni renwei [ta weisheme bu lai]
you think he why not come
'Why do you think he didn't come?' (34)

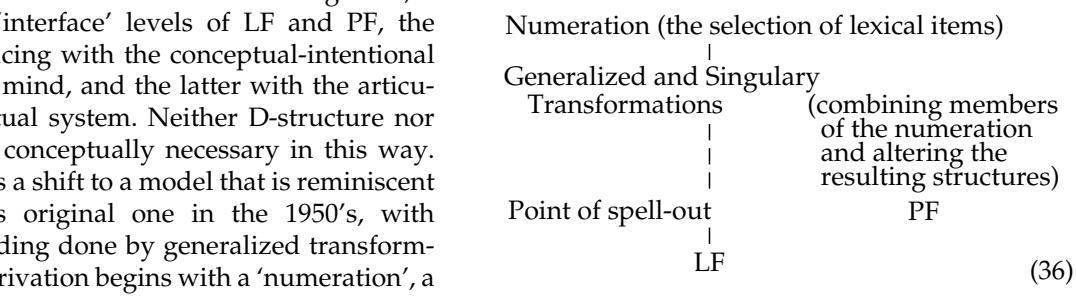
(*) ni xiang-zhidao [Lisi weisheme mai-le sheme]
you wonder Lisi why bought what
*'What is the reason such that you wonder what Lisi bought, where the purchase was for that reason?'
*'*Whatiscausingyoutowonderwhat* John bought?' (35)

This argues that even though the 'why' is not phonetically displaced, it really is moving: that is why it is obeying movement constraints. But this movement is 'covert', occurring in the mapping from S-structure to LF, hence not contributing to pronunciation.

ECONOMY AND MINIMALISM

The diminishing role of D- and S-structure in the theory suggests that neither is actually a significant level of representation. The 'Minimalist Program' for linguistics carries still further the simplifications in the theory that marked the GB framework.

If a language is to relate sound to meaning at all, it requires the 'interface' levels of LF and PF, the former interfacing with the conceptual-intentional system of the mind, and the latter with the articulatory-perceptual system. Neither D-structure nor S-structure is conceptually necessary in this way. This motivates a shift to a model that is reminiscent of Chomsky's original one in the 1950's, with structure building done by generalized transformations. The derivation begins with a 'numeration', a set of lexical items selected from the lexicon. The lexical items are inserted 'on-line' in the course of the syntactic derivation. The derivation proceeds 'bottom-up' with the most deeply embedded structural unit created first, then combined with another lexical item to create a larger phrasal unit, and so on. The 'extension condition' requires that a transformational operation 'extends' the tree upwards. Decades earlier, Chomsky had argued that eliminating generalized transformations yields a simplified theory, with one class of complex operations jettisoned in favor of an expanded role for a component that was independently necessary, the phrase structure rule component. Further, that simplification was a substantial step towards answering the fundamental question of how the child selects the correct grammar from a seemingly bewildering array of choices. Eliminating one large class of transformations, generalized transformations, was a step towards addressing this puzzle. This was a very good argument. But since then, numerous discoveries and analyses have indicated that the transformational component can be dramatically restricted in its descriptive power. In place of the virtually unlimited number of available highly specific transformations of the theories of the 1950's and early 1960's, we can have instead a tiny number of very general operations: Merge (the generalized transformation, expanded in its role so that it creates even simple clausal structures), Move, Delete. The complex apparent results come not from complex transformations, but from the interactions of very simple ones with each other, and with very general constraints on the operation of transformations and on the ultimate derived outputs. The argument can then be reversed on itself: eliminate phrase structure rules. This model, similar in some respects to the original one in the 1950's, is graphically represented in the following diagram, where the point of 'spell-out' is where the derivation splits off on one branch towards PF, ultimately phonetics, while the transformational derivation itself (the 'syntactic' portion of the derivation) continues on towards LF, ultimately semantics:



(36)

A major technical goal of the minimalist program is to reduce all constraints on representation to 'bare output conditions', determined by the properties of the systems external to the language faculty (but still internal to the mind) that PF and LF must interface with. Internal to the computational system, the desideratum is that constraints on transformational derivations will be reduced to general principles of economy. Derivations beginning from the same lexical choices (the numeration, in Chomsky's term) are compared in terms of number of steps, length of movements, etc., with the less economical ones being rejected. Lexical items are assumed to be composed of 'features', some of which need to be 'checked' in particular configurations. This is what drives movement, since, all else equal, a derivation with an instance of movement is less economical than one without. A related idea ('procrastinate') is that covert movement is less costly than overt movement. Thus, movement will be overt only if it is forced to be by some special requirement. Given that movement is driven by the need for features to be checked, this special requirement is stated in terms of special kinds of 'strong' features, features that must be checked in overt syntax. WH-movement in a language like English is then driven by a strong feature in C, while the corresponding feature in a language like Chinese is weak (under the assumption that the latter has 'covert' WH-movement). Similarly, verb raising in French is driven by a strong feature in Infl, while the corresponding feature in English is weak (although something special must be said about the fact that auxiliary verbs in English do raise overtly).

The simplifying developments in the theory leading towards the minimalist approach have generally led to greater breadth and depth of understanding of both how human languages are organized and how they are acquired by children. This success has led Chomsky to put forward the audaciously minimalist conjecture that the human language faculty might be a 'perfect' solution to the problem of relating sound and meaning, the

minimal computational system given the boundary conditions provided by other modules of the mind.

Iconicity

Introductory article

John Haiman, Macalester College, St Paul, Minnesota, USA

CONTENTS

In spite of the relative autonomy of grammar, there are many ways in which the structure of language directly reflects the structure of thought.

FUNCTIONAL EXPLANATIONS

> George Bush and his driver are out for a drive in the country. Suddenly a pig crosses their path and they run over it. 'Oh, my gosh!' says Bush. 'Go tell the farmer what's happened. I'll wait here.' An hour later, the chauffeur staggers out of the farmhouse, carrying a bottle of wine and a cigar, his clothing ripped. 'What happened?' asks Bush. 'Well, I got the wine from the farmer, the cigar from the farmer's wife, and for the last hour, their daughter has been making love to me', replies the chauffeur. 'What did you tell them?' asks Bush, astonished. 'I just said "I'm George Bush's driver, and I've killed the pig."'

Any speaker of English will realize that this scenario is linguistically impossible. The chauffeur must have uttered sentence 1, but the farmer's family could have responded only to sentence 2:

I'm George Bush's driver, and I've killed the PIG. (1)

I'm George Bush's driver, and I've KILLED the pig. (2)

In sentence 2, *the pig* is acting like a pronoun whose antecedent is *George Bush*. Speakers of English know that such pronouns are uttered more softly than the names that refer to their referents for the first time. In this respect pronouns are like copies, fainter than their originals. The minimal contrast in the two sentences above reappears in the grammars of all the languages we know: personal pronouns are generally short and unstressed, and often affixes on other words, while common and proper nouns may be either long or short, and are invariably words. The ease with which we can distinguish between sentences like 1 and 2 demonstrates that this contrast is not accidental, but systematic, and reflects the following principle:

Give reduced expression to what is already familiar. (3)

We should note that principle 3 violates a principle of grammar widely accepted in post-Saussurean linguistics, the principle of the autonomy of grammar: it invokes a system-external motivation ('familiarity') for a system-internal linguistic fact ('reduced expression').

Such 'functional' principles may be of various types. One of the most popular is the 'principle of least effort', made famous by Passy, von der Gabelentz, and Zipf. Since speakers, like all creatures, will exert themselves as little as possible to achieve their ends, they will resort to abbreviations when referring to something their hearers can already identify. Therefore, the bulk of a referring expression will tend to correlate with the novelty of its referent.

This principle seems to apply to contrasts between descriptions like *a one-eyed, one-horned flying purple people-eater* (on first mention) and *it* or zero (on subsequent mentions): it does not apply to the contrast between sentences 1 and 2, since the speaker's total energy output in these contrasting sentences is identical. One word in each sentence is uttered louder than the others: that word is *killed* when *pig* is a pronoun, and *pig* when *pig* is a noun. The stress difference directly signals a semantic contrast, rather than emerging from the speaker's tendency to minimize effort. The name is loud, as befits a novelty; the pronoun is soft, as befits a 'copy'.

External motivation of this sort (according to which 'the sound fits the sense') is known as iconicity. All external motivations violate systematicity, but iconicity in particular would seem to violate an even more fundamental grammatical assumption, the 'arbitrariness of the linguistic sign'. This assumption has been accepted by linguists since Plato's *Cratylus*, and at the word level, it is largely true. Cases of onomatopoeia, which seem to

contravene the principle, are marginal, and often language-specific.

Because system-internal explanations account so well for many linguistic facts, and because onomatopoeia is such a marginal phenomenon, iconicity has until recently received little attention as a structural grammatical principle. Yet some of the most widely recognized operative principles of language structure are iconic.

The minimal units in an utterance may be purely conventional. But the ways in which they are put together may imitate the ways in which their referents are related in our minds, as in a diagram (whether of a football sequence or of a radio wiring). Minimal elements in languages can be related to other elements both 'paradigmatically' and 'syntagmatically'. Different words that 'compete' for the same position in a message constitute a paradigm, while words that co-occur constitute a syntagm.

PARADIGMATIC ICONICITY

In the minimally contrasting pair of sentences 1 and 2, there is a paradigmatic contrast between the mutually exclusive words *PIG* and *pig*. Paradigmatic contrasts are frequently iconic.

Benveniste pointed out that the expression of the third person singular (whether as a pronoun or as a verbal affix) is often zero. The iconic motivation for this is that while the first person represents the speaker, and the second person represents the hearer, the third person represents someone who is absent. The zero morpheme represents the non-person. This is not a mere historical accident. As Watkins and others have shown, where paradigms are restructured, the third person singular is frequently reinterpreted as if it were zero.

Arguments for the autonomy of grammar often invoke the arbitrariness of grammatical categories in general. As Bloomfield asked (rhetorically): why is *wheat* a mass noun, while *oats* is a count noun? The answer is that this is an externally unmotivated, purely system-internal, fact about English. But there are a few nouns in English, like *hair*, that can belong to both categories: *nice hair* is mass, but *five gray hairs* is count. And, as any speaker of English will realize, the count form is used in exactly those cases where the hairs are thought of as individual countable objects.

Another example of an iconically exploited paradigmatic contrast is that between middle and reflexive verbs, for verbs of position, motion, and grooming, as in *I got up* (middle) and *I got myself up* (reflexive). The middle verb names only one participant. The reflexive, by naming two, suggests a mind–body duality.

Principle (3) is therefore subsumed in:

> Given a paradigmatic contrast between nearly synonymous forms, the formal difference will mirror the semantic difference. (4)

Sometimes paradigmatic contrasts with the same cognitive motivation will be frozen in the vocabulary or the grammar, like the contrast between pronouns and common nouns. In English, and in many other languages, there are minimally contrasting expressions like *kill* and *cause to die*. Where the two events of causation and result are expressed by separate words, there is the possibility that the two events are also separated in real time and space. To 'raise' a cup is usually to lift it via physical contact; to 'cause the cup to rise' is usually to effect the change of state without such contact. Lexicalization patterns will iconically reflect conceptual distinctions.

A similar contrast between levels of juncture is manifested by minimal contrast pairs like *lighthouse keeper* and *light housekeeper*: the conceptual contrast is reflected in the orthography (a 'lighthouse' is one thing; a 'housekeeper' is one person), but, as Bolinger and Gerstman demonstrated, it is also reflected in the spoken language: a pause corresponding to the word space is what makes these examples unambiguous to native listeners.

A formal-linguistic near-universal is that derivational affixes will tend to occur closer to the root than inflectional affixes, as for example in *king-dom-s*. Bybee has proposed that this principle may reflect a deeper cognitive principle, that the closeness of an affix to a root will reflect its relevance to that root. This principle may also account for the relative order of inflectional affixes, as in *child-ren-'s* (number closer to the root than case).

In English, the conceptual distinction between *my purse* and *my good name* is familiar enough, but the nature of the distinction is not clear in the grammar. But in many languages, a formal distinction is made between alienable possession (*my purse*) and inalienable possession (*my good name*). In all of those cases, the formal-linguistic distance between the possessor and the thing possessed reflects the conceptual distance between the two.

All of these examples reflect, more or less precisely, a principle which, far from being marginal, has been called (by Behaghel and Bolinger) the 'first law of syntax':

> Conceptual closeness is mirrored in formal closeness. (5)

More specifically, given two minimally contrasting expressions that differ in the relative distance between constituents *X* and *Y*, the relative formal distance between *X* and *Y* will correspond to the relative conceptual distance between their referents.

Still within the realm of paradigmatic relations is the fact of analogy as a motivation for language change. The fundamental principle of linguistic analogy is:

> The same meaning should be expressed via the same form. (6)

This principle is responsible for such familiar changes as extension (for example, almost all plurals in English are now marked with the same suffix *-s*; almost all verbs are now weak and mark the past tense with the same suffix *-ed*), paradigm coherence, and back formation. It is also responsible for the typological recurrence of motivated polysemy (for example, 'if' clauses in many unrelated languages are marked in the same way as topics – they may exhibit the same word order or occur with the same grammatical particles – because in some ways that is what they are), and for the fact that to a considerable extent grammatical categories and parts of speech correspond with conceptually homogeneous sets of things or relations in the world. The set of nouns in a language may seem somewhat arbitrary to speakers of another language, but it will include the names of most time-stable things.

SYNTAGMATIC ICONICITY

Words and linguistic expressions within a language relate to other words with which they compete, but also to those with which they co-occur in a message. Because words are uttered in order, syntagms are fundamentally asymmetrical; and it is in the asymmetrical syntagm that some of the clearest examples of iconicity occur.

Other things being equal, the order of clauses in a narrative corresponds to the order of events. Within a clause, a great deal of variety is possible, but in the majority of cases, subjects precede objects, definite noun phrases are placed earlier than the corresponding indefinites, topics are placed before comments, causes are placed before results, and in general:

> Old information tends to be placed before new information. (7)

Behaghel called this iconic principle the 'second law of syntax'.

The tendency towards systematization (driven ironically by analogy, since it is widely accepted that the drive to create analogies is iconically motivated) is undoubtedly responsible for the continual loss of iconicity in grammars. So too is the tendency to ritualization (manifested in grammaticalization), and erosion (manifested in sound change). But iconicity must be more than just what remains from 'the first language', or it would have disappeared by now. For iconicity to be as prevalent as it is, it must be a creative force contending partly against grammaticalization and erosion, each of which tends to create arbitrary structures.

Iconicity may even manifest itself in 'the dog that didn't bark in the night'. For example, many languages manifest a kind of aversion to 'accidental repetition'. This tendency is neatly illustrated by the sporadic process of haplology whereby an identical sequence of sounds is avoided: thus *haplology* might be replaced by *haplogy*. But repetition is rife in language, and is used to iconically signal repetition, plurality, and intensity at the levels of grammar and discourse. In reducing accidental repetition, haplology clears the decks: repetition is so important as an iconic signal that no iconically unmotivated repetition is tolerated.

Implicature

Introductory article

Laurence R Horn, Yale University, New Haven, Connecticut, USA

CONTENTS

Implicature is a non-truth-conditional aspect of speaker meaning that represents (part of) what is meant in a speaker's utterance without being part of what is said. What the speaker intends to convey is almost always far richer than what he or she directly expresses, as linguistic meaning radically underdetermines the communicated message. The speaker tacitly exploits pragmatic principles to bridge this gap.

THE GRICEAN MODEL

The Gricean model proposes a bridge connecting what is said (largely computed directly from the grammatical structure of the uttered sentence, but with reference resolved) with what is implicated (indirectly expressed). Implicated meaning encompasses two distinct phenomena: 'conventional' implicature, involving non-truth-conditional aspects of meaning constituting appropriateness conditions on the use of a given word or construction, and 'conventional' implicature, a relation based on a computation of speaker's intention operating from the presumption that the speaker is interacting rationally and cooperatively with the addressee.

Different types of implicature are illustrated by the pairs of sentences below, in each of which the second (primed) member is (sometimes) deducible from its unprimed counterpart by virtue of a nonlogical inferential relation:

(a) Even Bill knows it's unethical.
  (a′) Bill is the least likely [of a contextually invoked set] to know it's unethical.
(b) She has a good personality.
  (b′) She's not that attractive.
(c) The cat is either in the hamper or under the bed.
  (c′) I don't know for a fact that the cat is under the bed. (1)

Unlike an entailment or logical presupposition, the inference induced by *even* in sentence 1(a) is irrelevant to the truth conditions of the proposition: sentence 1(a) is true if and only if Bill knows it's unethical. The inference is not cancelable (one cannot say 'even Bill knows it's unethical, but that's not surprising'), but it is detachable, in the sense that the same truth-conditional content is expressible in a way that removes (detaches) the inference: 'Bill knows it's unethical too'. Such detachable but non-cancelable inferences, which are neither part of what is said (or of truth-conditional content) nor calculable from what is said, are conventional implicata, akin to pragmatic presuppositions. Indeed, along with connectives like *but*, the standard examples of conventional implicature involve precisely those particles traditionally analyzed as instances of pragmatic presupposition: adverbial particles like *even* and *too*, truth-conditionally transparent verbs like *manage to* and *bother to*, and focus constructions like clefts.

But whereas these inferences are non-truth-conditional components of an expression's conventional lexical meaning, the inferences associated with sentences 1(b) and 1(c) are non-conventional in that they are calculable from the utterance of such sentences in a particular context, given the nature of conversation as a shared goal-oriented enterprise. In each case, the inference of the corresponding primed proposition is cancelable (either explicitly by appending material inconsistent with it ('but I don't mean to suggest that …') or by altering the context of utterance) but nondetachable (given that any other way of expressing the literal content of sentences 1(b) and 1(c) in the same context would license the same inference).

Sentence 1(b) differs from sentence 1(c) in the generality of the circumstances in which the inference is ordinarily licensed. Only when the speaker of sentence 1(b) is responding to a query about the attractiveness of the referent will the addressee

normally infer that the speaker had intended to convey the content of sentence 1(b′): this is an instance of 'particularized' conversational implicature. In sentence 1(c), on the other hand, the inference – that the speaker does not know in which of the two disjoined locations the cat can be found – is induced in the absence of a special or marked context. Thus sentence 1(c′) represents an instance of the linguistically significant concept of 'generalized' conversational implicature. But in both cases, as with conventional implicature, it is not the proposition or sentence, but the speaker or utterance, that induces the relevant implicatum.

Participants in a conversational exchange systematically compute what was meant (by the speaker's utterance at a given point in the interaction) from what was said, operating from the assumption that both the speaker and the hearer are rational agents. The conversation is governed by the 'cooperative principle', which stipulates that the speaker is expected to make his or her contribution appropriate for the current purposes of the exchange. This general principle is analyzed into the four general and arguably universal maxims of conversation on which all rational interchange is grounded:

- Quality (try to make your contribution true):
  - Do not say what you believe to be false.
  - Do not say what you lack evidence for.
- Quantity:
  - Make your contribution as informative as is required (for the current purposes of the exchange).
  - Do not make your contribution more informative than is required.
- Relation (be relevant).
- Manner (be perspicuous):
  - Avoid obscurity of expression.
  - Avoid ambiguity.
  - Be brief.
  - Be orderly.

Note, however, that not all these maxims are equally important. Following Grice himself, many have posited a privileged status to 'quality', on the grounds that unless quality – or a convention of truthfulness – is observed, none of the other maxims can easily be satisfied: false 'information' is no information at all. Other researchers, working within the framework of 'relevance theory', have challenged the primacy of the principle of quality and advocated its subsumption within an all-encompassing revised principle of relevance.

SCALAR IMPLICATURE AND CONSTRAINTS ON LEXICALIZATION

Within neo-Gricean pragmatics, the starting point is the first quantity maxim, which is systematically exploited to yield upper-bounding generalized conversational implicatures associated with scalar operators. Quantity-based scalar implicature (e.g., my inviting you to infer from my use of *some* … that for all I know *not all* …) is driven by our mutual knowledge that I expressed a weaker proposition in lieu of an equally unmarked utterance that would have expressed a stronger proposition. Thus, what is said in the use of a weak scalar value like those in bold face in the sentences of Table 1 is the lower bound ('at least …'), with the upper bound ('at most …') implicated as a cancelable inference generated by (some version of) the first maxim of quantity. What is communicated in the default case is the 'two-sided reading', which combines what is said with what is implicated.

Negating such predications denies the lower bound: to say that something is not possible is to say that it's impossible; i.e., less than possible. When the upper bound appears to be negated ('It's not possible, it's necessary'), a range of syntactic, semantic, and intonational evidence indicates that we are dealing with an instance of the 'metalinguistic' or echoic use of negation, in which the negative particle is used to object to any aspect of a mentioned utterance, including its conventional and conversational implicata, register, morphosyntactic form, or pronunciation. If it's hot, it's (*a fortiori*) warm, but if I know it's hot, the assertion that it's warm can be echoed and rejected as (not false but) insufficiently informative:

Table 1. What is said vs. what is communicated in examples with scalar operators

Sentence	*One-sided reading*	*Two-sided reading*
Pat has **three** children.	'… at least three …'	'… exactly three …'
You ate **some** of the cake.	'… some if not all …'	'… some but not all …'
It's **possible** she'll win.	'… at least …'	'… but not certain …'
He's a knave **or** a fool.	'… and perhaps both'	'… but not both'
It's **warm**.	'… at least warm'	'… but not hot'

(a) It's not warm, it's hot!
(b) You're right, it's not warm – it's hot! (2)

As seen in sentence 2(b), the metalinguistic understanding typically requires a second pass, and the effect is typically that of an ironic unsaying or retroactive accommodation.

The central role played by scalar implicature in natural language is illustrated by a systematic pattern of lexical gaps and asymmetries. Consider the post-Aristotelian square of opposition defined by the logical relations among quantified expressions (ranging over non-empty sets), shown in Figure 1.

Note in particular that the assertion of either of the two subcontraries quantity-implicates the negation of the other. While what is said in 'some men are bald' and 'some men are not bald' is distinct, what is communicated is typically identical: 'some men are bald and some aren't'. Given that languages tend not to lexicalize complex values that need not be lexicalized, we might predict that *some … not* tends not to be lexicalized, and this is precisely what we find.

In a wide variety of languages, values mapping onto the **O** corner of the square are systematically restricted in their potential for lexicalization. Thus alongside the quantificational determiners *all*, *some*, and *no*, we never find an **O** determiner **nall* ('not all'); corresponding to the quantificational adverbs *always*, *sometimes*, and *never*, we have no **nalways* ('not always', 'sometimes not'). We may have

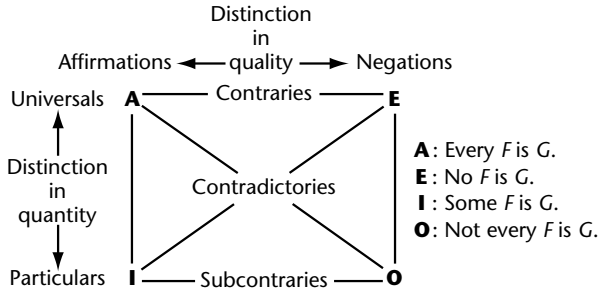

Figure 1. The square of opposition. Corresponding **A** and **E** statements are 'contraries': they cannot be simultaneously true (though they may be simultaneously false). Corresponding **A** and **O**, and **I** and **E**, statements are 'contradictories': they cannot be simultaneously true or simultaneously false. An **I** statement is the 'subaltern' of its corresponding **A** statement, and an **O** statement of its corresponding **E** statement: a subaltern is unilaterally entailed by its corresponding superaltern. Corresponding **I** and **O** statements are 'subcontraries': they cannot be simultaneously false (though they may be simultaneously true).

equivalents for *both (of them)*, *one (of them)*, and *neither (of them)*, but never for **noth (of them)* ('not both', 'at least one … not'); we find connectives corresponding to *and*, *or*, and sometimes *nor* ('and not'), but never to **nand* ('or not', 'not … and'). The missing-**O** phenomenon extends to the modals and deontics, as illustrated by the fact that the inflected negative in 'he can't go', or the orthographic lexicalization in 'he cannot go', only allows wide-scope ('**E**' vertex) negation, while the unlexicalized counterpart 'he can not go' is ambiguous. The relation of mutual quantity implicature holding between positive and negative subcontraries results in the superfluity of one of the two subcontraries for lexical realization, while the functional markedness of negation assures that the unlexicalized subcontrary will always be **O**.

Q-BASED AND R-BASED IMPLICATURE

The significance of the first quantity maxim for the form and function of natural language reflects its status as one of two cardinal principles regulating the economy of linguistic information. Setting quality aside as irreducible, we can collapse the remaining maxims and submaxims into two fundamental principles. The 'Q principle' is a lower-bounding hearer-based guarantee of the sufficiency of informative content ('say as much as you can, modulo quality and R'); it collects the first quantity maxim along with the first two 'clarity' submaxims of manner, and is systematically exploited (as in the scalar cases) to generate upper-bounding implicata. The 'R principle', by contrast, is an upper-bounding correlate of the 'law of least effort' dictating minimization of form ('say no more than you must, modulo Q'); it collects the relation maxim, the second quantity maxim, and the last two submaxims of manner, and is exploited to induce strengthening or lower-bounding implicata.

Q-based implicature is typically negative in that its calculation refers crucially to what could have been said but wasn't: the hearer infers from the speaker's failure to use a more informative or briefer form that the speaker was not in a position to do so. R-based implicature typically involves social rather than purely linguistic motivation. It is exemplified by indirect speech acts and negative strengthening (including so-called 'neg-raising', the tendency for 'I don't think that …' to implicate 'I think that not…').

R-based implicata, while calculable (as are all conversational implicata), are often not calculated

'online'; a specific form of expression may be associated with a given pragmatic effect while an apparently synonymous form is not. Thus, the question 'Can you close the window?' is generally used to convey an indirect request, while 'Are you able to close the window?' is not; 'I don't guess that …' allows a strengthened 'neg-raised' understanding in only a subset of the dialects for which 'I don't think that …' does. These are instances of 'standardized nonliterality', or 'short-circuited conversational implicature'.

The two antinomic Q and R forces interact dialectically, each appealing to and constraining the other. Thus Grice incorporates R in defining the primary Q maxim ('make your contribution as informative as is required'), while the second quantity maxim is constrained by the first and essentially incorporates relation: what could make a contribution more informative than is required, except the inclusion of contextually irrelevant material?

The opposition between the two forces may result in maxim clash. Thus an utterance of 'I broke a finger yesterday' R-implicates that it was one of my own fingers I broke, unless the common ground entails or accommodates the proposition that I am enforcer for the mob, in which case the opposite, Q-based implicature is derived.

Notice too that *finger* here conveys 'non-thumb'. In such Q-based narrowing, the existence of a specific hyponym *H* of a general term licenses the use of the general term for the complement of the extension of *H*. This is further illustrated by the development of a specific use or sense of *dog* (excluding bitches), *cow* (excluding bulls), or *animal* (excluding humans, birds, and fish). This is distinct from R-based narrowing, in which the restriction of a more general lexical item, such as *poison*, *liquor*, *drink, man*, or *undertaker*, to a particularly salient subset or exemplar of the original denotation is not prompted by the existence of a specific word preempting that portion of semantic space.

Related to Q-based narrowing is the 'division of pragmatic labor': given two coextensive expressions, a relatively unmarked form – briefer or more lexicalized – will tend to become R-associated with a particular unmarked, stereotypical meaning, use, or situation, while the use of the periphrastic or less lexicalized expression, typically more complex or prolix, will tend to be Q-restricted to those situations outside the stereotype, for which the unmarked expression could not have been used appropriately. Consider the following pairs of sentences:

(a) He got the machine to stop.
(a′) He stopped the machine.
(b) Her blouse was pale red.
(b′) Her blouse was pink.
(c) She wants her to win.
(c′) She wants to win.
(d) I am going to marry you.
(d′) I will marry you.
(e) My brother went to the church (the jail, the school).
(e′) My brother went to church (jail, school).
(f) It's not impossible that you will solve the problem.
(f′) It's possible that you will solve the problem.
(g) That's my father's wife.
(g′) That's my mother. (3)

The use of the periphrastic causative in sentence 3(a) implicates that the agent achieved the effect in a marked way (perhaps by pulling the plug or throwing a shoe into the machine); *pale red* in sentence 3(b) implicates a tint not preempted by *pink*; the selection of a full pronoun over a null pronoun in sentence 3(c) signals the absence of the coreferential reading associated with the reduced syntax; in sentence 3(d) the periphrastic form blocks the indirect speech act function of promising conveyed by the modal; the full + noun versions of sentence 3(e) imply literal motion to the specified location without the socially stereotypic connection R-associated with the corresponding institution on the anarthrous version; the double (contradictory) negation in sentence 3(f) signals a rhetorical effect absent from the direct positive; and the more complex description in sentence 3(g) suggests that the more basic and lexicalized alternative could not have been used appropriately (the referent is probably the speaker's stepmother). When a speaker opts for a more complex or less fully lexicalized expression over a simpler alternative, there is a sufficient reason, but which reason depends on the particular context.

In addition to maxim clash and the division of pragmatic labor, another area of conflict between the Q and R principles is in implicature derivation itself. If I tell you that my wife is either in the kitchen or the bedroom, I will Q-implicate that I don't know that she's in the kitchen; but I can tell you 'the kitchen is a mess' without implicating that the bedroom isn't. If you tell me that something is 'possibly' true, I will assume you don't know it's true; but if you tell me that something is true (e.g., that all bachelors are unmarried), I will not assume you don't know it's necessarily true. The use of the

weak **I** or **O** proposition licenses the inference that the speaker was not in a position to use the basic unquantified, unmodalized proposition that unilaterally entails it, as the Q principle predicts; but the use of the basic propositional form does not Q-implicate the negation of its strong counterpart, **A** or **E** respectively. Since there is no quantity- or information-based distinction between these subalternations, we must seek the source of the asymmetry elsewhere. The crucial distinction here relates not to the content (what is said) but to the form (how what is said is said): it is because the intermediate values are not only more informative but briefer than their **I** or **O** counterparts that the use of the latter will strongly implicate against the former. But the strong values, while more informative than their unmodified counterparts, are also more prolix, so quantity here is offset by manner and potentially by relation: the Q principle of informative sufficiency yields to the R principle of least effort. The richness of the pragmatic framework makes it possible to begin to develop a theory of not just what can be implicated but what will be implicated in a given context.

When degree of lexicalization is not a factor, scalar implicature normally goes through. Thus, each of the following ordered lists constitutes a Q-relevant scale in that the affirmation of any weak or intermediate value will implicate (*ceteris paribus*) that – for all the speaker knows – the value on its left could not have been substituted:

- *always*, *usually*, *often*, *sometimes*
- *and, or*
- *certain*, *likely*, *possible*
- *cold*, *cool*, *lukewarm*
- *excellent*, *good*, *OK*

But when the stronger value is less economical than the weaker one, no Q-implicature is triggered. This extends to non-quantitative 'scales' of items differing in informative strength. Thus, while the use of *finger* typically conveys 'non-thumb', it does not convey 'non-pinky (finger)', nor does the use of *toe* convey 'toe other than the big toe', although the big toe is analogous to the thumb. What is crucial is the status of *thumb* (as opposed to *pinky*) as a viable lexicalized alternative to *finger*. In the same way, *rectangle* conveys 'non-square' (i.e., 'non-equilateral rectangle') because of the availability of the lexicalized alternative *square*, while *triangle* will not convey 'non-equilateral triangle' – indeed, the prototype triangle is equilateral – because of the non-existence of a lexicalized term for a general triangle.

The model described above retains two antinomic principles along with an unreduced maxim of quality. A more radical simplification has been proposed in the framework of relevance theory, in which a redefined 'principle of relevance' is taken to be the only source of pragmatic inference required.

IMPLICATURE, EXPLICATURE, AND PRAGMATIC INTRUSION

Even for Grice, propositional content is not fully fleshed out until reference, tense, and other indexical elements are fixed. But proponents of relevance theory have pointed out that the pragmatic reasoning used to compute implicated meaning must also be invoked to fill out underspecified propositions where the semantic meaning contributed by the linguistic expression itself is insufficient to yield a proper accounting of truth-conditional content. Thus, when a news reporter observed as the jury retired to consider their verdict in the O. J. Simpson murder trial that 'It will take them some time to reach a verdict', the proposition he communicated (that it will take a long time) was, in the event, false, a fact inconsistent with a strict Gricean analysis on which the time communicated by the speaker is just an implicatum read from the underspecified content contributed by linguistic meaning alone – a trivially true existential proposition. Instead, the pragmatically recoverable strengthened communication comprises the 'explicature' or truth-conditional content. Thus, pragmatically derived aspects of meaning are not necessarily implicatures; indeed, there is substantial pragmatic intrusion into propositional content.

Such apparent intrusion is also illustrated by the temporal and causal asymmetry of conjoined event-denoting verb phrases and sentences. On the standard Gricean account, the conjunction in sentence 4(a) will typically implicate sentence 4(b) by virtue of the 'be orderly' submaxim of manner:

(a) They had a baby and they got married.
(b) They had a baby and then they got married. (4)

Arguments against a lexical ambiguity for *and* ('and also' versus 'and then') include the following.

- On the two-*and* theory, conjunction in virtually every language would just happen to be ambiguous in the same way.
- No natural language contains a conjunction *C* that would be ambiguous between 'and also' and 'and earlier' readings, so that 'they had a baby [*C*] they got

married' would be interpreted either atemporally or as 'they had a baby and, before that, they got married'.
- The same 'ambiguity' exhibited by *and* arises when two clauses describing related events are juxtaposed without an overt connective. ('They had a baby. They got married.')

If conjunctions are semantically univocal, while manner-implicating that the events occurred in the order in which they were described, the impossibility of the conjunction *C* can be attributed to the absence of any maxim enjoining the speaker to 'be disorderly'. As with scalar implicature, the asymmetric implicatum may be canceled or suspended: 'they had a baby and got married, but not necessarily in that order'. But if the 'and then' reading comes in only as an implicature, it is hard to explain its apparent contribution to truth-conditional meaning in embedded contexts, and in particular the non-contradictory nature of the three sentences below, as pointed out by L. Jonathan Cohen and Deirdre Wilson:

(a) If they got married and had a baby, their parents will be pleased; but if they had a baby and got married, their parents will not be pleased.
(b) They didn't get married and have a baby, they had a baby and got married.
(c) It's more acceptable to get married and have a baby than to have a baby and get married. (5)

One conclusion is that, while pragmatically derived, the strengthened or enriched meaning is an explicature, corresponding to what is said rather than to what is (merely) implicated.

The explicature view yields a re-evaluation of the traditional view of scalar predications, on which both one-sided and two-sided understandings of the sentences in Table 1 will be directly represented at the level of logical content. While such scalar predications are now all taken to be ambiguous, the ambiguity is no longer situated at the lexical level but has been relocated to the propositional level: what is said in an utterance is systematically underdetermined by the linguistic content of what is uttered.

Other work has challenged some of these results. Thus, while a strong case can be made for an enrichment analysis of the meaning contribution of the cardinals, it does not generalize straightforwardly to 'inexact' scalar values. Evidence for this conclusion comes from the contextual reversibility of cardinal scales and the non-implicating ('exactly *n*') reading of cardinals in mathematical, collective, and elliptical contexts, none of which applies to the scalar operators in Table 1. Note also the contrast in the exchanges below:

A : Do you have two children?
B_1 : No, three.
B_2 : Yes, (in fact) three. (6)

A : Did many of the guests leave?
B_1 : No, all of them.
B_2 : Yes, (in fact) all of them. (7)

In exchange 6, a bare 'no' answer is compatible with an 'exactly *n*' reading in an appropriate context; while in exchange 7, an unadorned negative response can only be understood as conveying 'fewer than many'. Similarly, if 'it's warm' were truly propositionally ambiguous, there is no obvious reason why a 'no' response to the question 'Is it warm?' should not be interpretable as a denial of the enriched, two-sided content and thus as asserting that it's either chilly or hot; or why the comparative in 'it's getting warmer' cannot denote 'less hot' instead of 'less cold'. This suggests the need for a mixed theory in which cardinal values may demand a relevance-theoretic pragmatic enrichment analysis, while other scalar predications continue to submit to a standard neo-Gricean treatment on which they are lower-bounded by their literal content and upper-bounded, in default contexts, by Q-implicature.

IMPLICATURE VERSUS IMPLICITURE

The arguments we have been reviewing rest on the tacit assumption that whatever is communicated but not said must be implicated. Some have argued from this assumption that implicatures can affect truth-conditional meaning after all, given cases like the asymmetric conjunction in sentences 4(a) and 4(b); others have argued instead for the notion of explicature; i.e., pragmatically determined content. But if there can be implicit components of communicated meaning that are not implicatures, these aspects of meaning – such as the bracketed expansions below – need not be considered part of what is said:

(a) I haven't had breakfast {today}.
(b) John and Mary are engaged {to each other}.
(c) They had a baby and they got married {in that order}.
(d) Robin ate the shrimp and {as a result} got food poisoning.
(e) Everybody {in our pragmatics class} solved the riddle. (8)

In each case, the bracketed material cannot be derived as an implicature, but neither can it be part of what is said, since it is felicitously cancelable ('John and Mary are engaged, but not to each other'). It may be regarded instead as an 'impliciture', an implicit weakening, strengthening, or specification of what is said. This approach, urged by Kent Bach, permits an intuitive characterization of propositional content, a conservative mapping from syntactic structure to what is said, and an orthodox Gricean conception of implicature, albeit as a more limited construct than in much neo-Gricean work. At the same time, the standard view that every sentence expresses one and only one proposition must be abandoned, as it is typically, and in some cases only, the impliciture – the expanded proposition conveyed but not directly expressed – that is assessed for truth or falsity.

With a fuller understanding of the interaction between pragmatics and propositional content, we see that while the explanatory scope of conversational implicature may have been reduced from that of the original Gricean program, this program and the pragmatic principles motivating it – rationality, common ground, and the distinction between implicit and explicit components of utterance meaning – continue to play an essential role in the elaboration of dynamic models of context. As recent work on language acquisition and on lexical change has further demonstrated, a suitably sharpened notion of implicature remains at the heart of communicated meaning.

Innateness and Universal Grammar

Introductory article

Stephen Crain, University of Maryland at College Park, Maryland, USA
Paul Pietroski, University of Maryland at College Park, Maryland, USA

CONTENTS

In linguistics, the Innateness Hypothesis is the claim that all children have, by virtue of a common biology, a 'Universal Grammar' that defines a space of possible human languages. Children explore this space, influenced by the environment, until they stabilize on grammars that are equivalent to those of adult speakers in the linguistic community.

INTRODUCTION

Human beings speak languages, so children must have the capacity to speak languages. In order to understand this capacity, theorists often focus on a cluster of observations about how language develops in children. (1) While languages differ in certain respects, the capacity to speak a language is universal in our species, such that any normal child can acquire any human language. (2) This capacity is manifested at an early age, and it appears to be independent of other cognitive abilities. (3) Despite considerable variation of experience within the same linguistic community, all normal children in that community converge on (more or less) the same grammar. (4) There is a dramatic gap between the linguistic experience available to children and the kinds of linguistic competence that children achieve as a matter of course.

These observations are noteworthy because they are hallmarks of innateness: facts which suggest that speaking a language is a property human beings have, at least in large part, by virtue of their biological endowment – much like the property of having a liver or being able to see. Of course, it is always possible that a trait bearing the hallmarks of innateness will turn out to be acquired (by all children) through experience. And it is a truism that each individual's properties stem from interactions of her particular genetic heritage with her environment. But our common biology presumably plays the major role in explanations for why human beings have livers, even though different people have different livers (which are affected by diet).

There has, however, been resistance to the very idea that our common biology plays the major role in explanations for why human beings speak languages. So it bears emphasis, first, that no one proposes that the capacity to speak a particular language, say English, is innate. Children who acquire English have obviously been influenced by their environment, in a way that differs from how children who acquire Japanese have been influenced by their environment. The Innateness Hypothesis is the proposal that all children have, by virtue of their common biology, a property one might call 'having Human Language'; and this 'Universal Grammar' (UG) interacts with each child's linguistic experience to determine the specific language(s) that the child will acquire. From this perspective, linguists try to find the common core of human grammars, that is, the universal principles that underlie any language that human children can acquire.

PRINCIPLES AND PARAMETERS

Linguists are also in the business of explaining how and why specific human languages differ. According to one active line of research, called the Principles and Parameters approach, even the possible dimensions of variation among human languages are innately specified, at least to a large extent. To take a simple example, direct objects precede verbs in many languages, so many children will encounter strings of words like 'Chris rice eats'. This differs from the corresponding experiences of American children, who encounter verbs preceding direct objects, as in 'Chris eats

rice'. This word-order variation is explained by a parameter. The idea is that subject–object–verb experiences interact with Universal Grammar to produce languages of one sort, while subject–verb–object experiences interact with Universal Grammar to produce languages of another sort. So while the environment has an effect, the number of options available – and thus the range of possible languages the child can acquire – is severely constrained in advance of any experience. To the extent that the relevant parameter can be 'set' by simply detecting features of linguistic experience (without significant computation or extrapolation), talk of 'learning' will be unhelpful.

Linguists who argue for the innate specification of linguistic principles and parameters typically have nothing to say about how our genes give rise, in the normal course of events, to the biological structures that underlie human linguistic capacities. Rather, linguists argue that certain features of human languages are determined by innate aspects of the human mind/brain, as opposed to being determined by aspects of human environments. The argument rests on two main observations. First, children encounter a finite and haphazard collection of expressions, each of which presumably conveys a single meaning in its conversational context. Yet children internalize grammars that go beyond these experiences along several dimensions. Children can produce and comprehend an unlimited number of novel expressions. They can discern paraphrase and ambiguity relations among linguistic expressions. Second, children attain knowledge of linguistic structures for which they have no corresponding experience. For example, children are not systematically informed that certain linguistic expressions are unacceptable in the local language, but this knowledge emerges in the course of language development.

POVERTY-OF-THE-STIMULUS PROBLEMS

Examples of knowledge not drawn from experience – illustrations of the 'Poverty of the Stimulus' – are offered in (1) and (2). Examples (1a,b) indicate that the verbal elements *want* and *to* may sometimes be contracted to form *wanna*. In fact, contraction of *want* and *to* is licensed in general; the deviance of (1d), which is the exceptional case, is indicated by '#'. If children were to generalize on the basis of examples like (1a,b) using standard principles of induction, children would be inclined to produce linguistic expressions like (1d), which are unacceptable for adults.

a. Who do you want to beat?
b. Who do you wanna beat?
c. Who do you want to win?
d. #Who do you wanna win? (1)

Similarly, examples (2a,b) show that contraction of the copula, *is*, is optional in certain linguistic expressions. Again, contraction is licensed in general; (2d) is the exception. So, learners who acquired language by means of general induction principles, or analogy, would be tempted to allow *is*-contraction in expressions like (2d). If human children do not produce expressions like (2d), they evidently must know (unconsciously) that contraction is held in check by some linguistic principle.

a. What is that in the tree?
b. What's that in the tree?
c. Do you know what that is in the tree?
d. #Do you know what that's in the tree? (2)

A single linguistic principle has been advanced to explain both the *wanna*-contraction and the *is*-contraction facts. On this account, *want* and *to* cannot contract in (1d) because there is an unpronounced element between them. This 'empty' element, labeled 'e' in (1d′), is associated with the question word *who*.

who do you want **e** to win (1d′)

Turning to (2), *is*-contraction is prohibited whenever an empty element follows *is*, as in (2d′), where the empty element *e* is associated with the question word *what*.

do you know **what** that is **e** in the tree (2d′)

This means that *is* contracts to the right, as in (2b′), orthographic conventions notwithstanding:

what is that **e** in the tree ⇒ **what** s′ that **e** in the tree (2b)′

But the linguistic constraint is the same for *wanna*-contraction and *is*-contraction: contraction is blocked by an empty element. Contraction is permitted in (1b) and (2b) because in these examples the empty elements associated with *who* and *what* do not interfere.

No one tells children that expressions like (1d) or (2d) are unacceptable; yet all English-speakers somehow know this. This illustrates the poverty-of-the-stimulus problem: linguistic knowledge that is demonstrably not acquired by attending to input data. The emergence of a property in the absence of environmental input is one hallmark of genetic

prespecification. This invites us to ask about other hallmarks: universality and early emergence. The prohibition against contraction across an empty element is a universal phenomenon, as far as we know. Using an experimental technique known as elicited production, it has also been shown that as soon as children can be tested, they manifest adult competence with regard to *wanna*-contraction and *is*-contraction. That is, children prefer to contract *want* and *to* when this option is licensed in the local language, but children never contract these verbal elements when this is not tolerated by adults, as in (1d). Similarly, children prefer to contract *is* (to the right), but they never produce reduced expressions like (2d), where linguistic theory posits an empty element to the right of *is*. In short, children converge on generalizations that govern the local language, but do not generalize in many other (perfectly coherent) ways; and this is so, even though children's linguistic experience would lead them to generalize in ways that speakers of the local language do not, if children were to adopt general principles of induction.

The linguistic principle blocking contraction emerges in the absence of decisive evidence in the primary linguistic data available to children, and children respect this constraint from the earliest stages of language development. Because the relevant linguistic principle bears all the hallmarks of innate specification, it is a likely candidate to be part of Universal Grammar. We noted earlier that linguistic parameters, such as word-order parameters, are also candidates for inclusion in Universal Grammar. If so, we would expect such parameters to be set by children early in the course of language development. Indeed, this seems to be the case for word-order parameters, and also for parameters involving the inflectional system. We would not expect the same acquisition scenario for more peripheral phenomena, however, which do not closely track the natural seams of human languages. Phenomena on the periphery of human languages, such as irregular forms of rare verbs, are more likely to emerge late and may be subject to individual differences.

THE CONTINUITY ASSUMPTION

In debates about the Innateness Hypothesis, the *details* of linguistic theory matter: linguists first identify principles that characterize human grammars, *then* they ask which aspects of these grammars are plausibly learned from experience, and which are more likely to be innately specified. The nativist claim is not that language must be innate since children say things they do not hear. The argument is, rather, that many aspects of language are innate, since human languages seem to exhibit features (such as the constraint on contraction) that children could not 'pick up on' given their linguistic experience. Correspondingly, although poverty-of-the-stimulus problems are superficially similar to 'induction problems' that arise in any domain where knowledge is logically underdetermined by data, there are important differences between the study of human languages and the study of other aspects of human cognition. One difference is the expectation that children may try out various linguistic options that are available in human languages, but are not attested in the primary linguistic data available in the local language. This is the 'continuity assumption'.

According to the continuity assumption, while children will not entertain linguistic hypotheses that extend beyond the boundary conditions imposed by Universal Grammar (UG), children might well entertain linguistic hypotheses with features found in languages elsewhere on the globe, despite the absence of any evidence for such hypotheses in their primary linguistic data. An example of a non-adult (but UG-compatible) production is the 'medial-*wh*' phenomenon observed in many 3- and 4-year-old children of English-speaking parents. Such children are observed consistently to insert an 'extra' *wh*-word in questions like (3) and (4):

What do you think what pigs eat? (3)

Who did he say who is in the box? (4)

These expressions are presumably not responses by children to their environment, since medial-*wh* expressions are not produced by adults in English-speaking environments. However, structures similar to (3) and (4) are attested in many languages, such as Irish, Chamorro, and in dialects of German. Given a Principles and Parameters theory that includes the continuity assumption, this is noteworthy but unsurprising: children are not born knowing if the local language allows medial-*wh* questions; so until the relevant parameters are set, children may speak a dialect of 'Human Language' that differs from the local language. This kind of mismatch between child and adult language may constitute the strongest argument for an innate universal grammar, and against models according to which children construct linguistic hypotheses based on experience.

THE NATURE VERSUS NURTURE DEBATE

The 'nature versus nurture' debate continues, as various poverty-of-the-stimulus arguments are challenged or supported by developments in linguistic theory and empirical investigations of child language. Opponents of nativism view language acquisition as an induction problem of the same sort that arises in other domains where the knowledge achieved is underdetermined by the learner's experience. This perspective highlights the 'cues' that are available in the input to children, as well as children's skills in extracting relevant information and forming generalizations on the basis of the data they receive. Nativists counter with evidence showing that children project beyond their primary linguistic data in ways that the input does not even suggest, as illustrated by the facts about *wanna*-contraction, *is*-contraction, and the medial-*wh* phenomenon. Instead of viewing language acquisition as a special case of theory induction, nativists posit a universal grammar, with innately specified principles of grammar formation. From this perspective, innate linguistic principles define a space of possible human languages – a space that children explore, influenced by the environment, until they stabilize on a grammar equivalent to the grammar(s) used by adults in the linguistic community.

Intonation

Introductory article

Sun-Ah Jun, UCLA, Los Angeles, California, USA

CONTENTS

Intonation is the melody of a sentence or a phrase. It marks a grouping of words or the prominence relations among words, and reflects the syntactic structure and the semantic and pragmatic meaning of a sentence.

WHAT IS INTONATION?

Traditionally, intonation has been defined as the melody of a sentence or a phrase. A melody is, in a general sense, a pattern of pitch changes. Some parts of a sentence are produced with higher or lower pitches than other parts of a sentence, and the overall pitch pattern of a sentence delivers the speaker's intention as well as certain aspects of the meaning of the sentence or sentence type. However, intonation involves more than just the global changes in pitch over the course of a sentence. The overall pitch pattern has an internal structure. Intonation marks groupings of words and defines a hierarchy for these groupings. This means that, while the acoustic realization of pitch is continuous, intonation is not in fact an undividable whole – instead it is decomposable into subcomponent pitch events. Some pitch events mark the boundaries between groupings of words, either small boundaries or large, and others mark the prominence relations within a group of words.

The boundary of a group of words, marked by pitch patterns called boundary tones, is sometimes also marked by duration. For example, syllables at the end of a group of words are often substantially lengthened, and this is known as preboundary lengthening. Further, prominent words that are marked by pitch are also often characterized by higher intensity and longer duration. In this way, pitch patterns carry the tune or melody of a sentence or a phrase and, together with intensity and duration, they also convey the prominence relations among the words in a phrase. Thus, intonation, whether it marks a phrase boundary or prominence relations, is comprised not only of pitch changes but also of other prosodic features such as intensity and duration. For this reason, the terms 'intonation' and 'prosody' are often used interchangeably. In sum, intonation has an internal structure, and the structure is cued by pitch, intensity, and duration. (*See* **Prosody**)

Intonation can change the meaning of a sentence but not the meaning of a word. In this sense, it is different from (lexical) pitch accent or tone, both of which can change the meaning of a word. In a pitch accent language, such as Japanese or Swedish, each word has a distinctive pitch pattern. That is, words with different pitch patterns do not have the same meaning, even when the words have the same sequence of consonants and vowels. For example, in Japanese, 'kami' means 'God' when high pitch occurs on the syllable 'ka', but the word means 'paper' when high pitch occurs on the syllable 'mi'. Similarly, in a tone language such as Mandarin, each syllable of a word has a distinctive pitch pattern. For example, one syllable 'ma' can mean 'mother' when it is produced with a high pitch, 'horse' when it is produced with a low rising pitch, 'hemp' when it is produced with a high rising pitch, and 'scold' when it is produced with a falling pitch. In languages such as these, where pitch is distinctive at the word level, pitch variations at the phrasal level, i.e. intonation, are not as easily observable as they are in nontonal and/or nonpitch accent languages such as English, French, or Korean. Still, all languages have intonation, and intonation conveys the structure and meaning of a sentence as well as the speaker's intention.

Though there are certain features of intonation that are similar across languages, many attributes of the intonation patterns found within a given language are determined on a language-specific basis. For example, in most languages pitch rises at the end of a yes–no question and falls at the end of a statement. However, in Chickasaw, an American Indian language of the Western Muskogean

language family spoken in south-central Oklahoma, the reverse pattern is found. That is, pitch falls at the end of a yes–no question and rises at the end of a statement. Languages also differ in terms of sentence-medial pitch patterns. This depends on the intonational groupings within a sentence and the types of pitch movement permitted within a word in the language. For instance, in English, the stressed syllable of a word can be realized with several different pitch patterns (e.g. high, mid, low, rising), and the edge of an intonational grouping can be marked by either a high or a low pitch. On the other hand, in Seoul Korean, pitch patterns are not linked to specific syllables within a word. Instead, they are linked to certain locations within a phrase. The phrase initial syllable can be either high or low, but the phrase final syllable is almost always high. This suggests that the pitch patterns of sentences within a given language reflect the prosodic system of that language, i.e. the intonational structure of that language and whether the language has stress, tone, pitch accent, or none of these.

Finally, the pitch categories that appear in descriptions of intonation, such as high tone or low tone, are not absolute but are in fact relative. They are relative to adjacent pitch values within the sentence or phrase and are relative to the speaker's pitch range. In a given speaker's production, a syllable can be said to have a high tone intonationally if its pitch is higher than that of the immediately preceding syllable within the same prosodic phrase or if the pitch is realized at the top of the speaker's current pitch range. On the other hand, the interpretation of pitch categories in intonation is not gradient but categorical. The categorical nature of intonation is determined by the categorical nature of its component pitch events. If a statement ending in a low pitch is interpreted as a declarative, the absolute lowness of the pitch at the end of the sentence does not influence the degree of 'declarativeness' of that statement. It simply is or is not declarative. This contrasts with the paralinguistic features of speech which convey a speaker's emotional state (e.g. angry, fearful, joyous) and his or her attitude towards the listener (e.g. friendly, appeasing, aggressive). The interpretation of paralinguistic features is gradient. So, for instance, the higher the absolute pitch or intensity in a word or a phrase, the angrier or more aggressive the speaker is likely to be. In this article, we will discuss the categorical properties of intonation, and in the following sections we will show the role of intonation in grammar, especially with respect to its role in prosodic grouping, its relation to syntactic structure, and its semantic and pragmatic functions. (*See* **Emotion**)

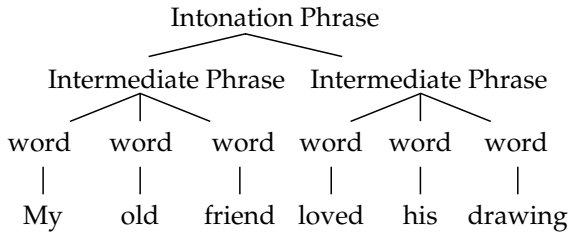
PROSODIC CONSTITUENCY

When we produce a sentence, we tend to form subgroups of words within the sentence. This grouping reflects how close adjacent words are in terms of their meaning and function relative to one another. The degree of juncture or distance between each word is not always equal. Words belonging to the same group are closer together, i.e. have smaller juncture between them, than words belonging to different groups which have a larger juncture between them. The degree of juncture between words and groups of words is abstract and subjective, but studies have found that native speakers of the same language generally agree on the degree of juncture between the words in a given utterance. This is because the abstract entity termed 'juncture' reflects the organizational structure of the spoken utterance and is realized by consistent acoustic features such as pauses, preboundary lengthening, and other intonational attributes. (*See* **Prosody**)

The grouping of words within an utterance is called prosodic grouping or phrasing. There is typically more than one level of grouping within an utterance, reflecting the different degrees of juncture. That is, there are subgroupings within various groups within an utterance. For example, a sentence such as 'The lady with flowers loves John's brother' could be divided into two large groups, (The lady with flowers) and (loves John's brother), but the degree of juncture among the four words in the first group is not equal. The juncture between the first two words, 'the lady', or the next two words, 'with flowers', is smaller than the juncture between the second and the third word, 'lady with'. This shows that a whole utterance can be divided into groups which in turn can be divided into smaller groups, and so on. The hierarchical structure of groupings within an utterance is called the prosodic hierarchy, and each group in the prosodic hierarchy is called a prosodic constituent.

In English, investigators disagree on exactly how many levels of prosodic constituents there are above the word. We will not discuss the different proposals or the differences among the proposed levels here except to say that there are in general two prosodic levels above the word. The higher of the two is often called an intonation phrase and the lower one is called an intermediate phrase (or a

phonological phrase), and these are marked by intonation. The prosodic grouping for an example sentence is shown in (1). The whole sentence forms one intonation phrase, and is further divided into two intermediate phrases. Each intermediate phrase includes three words. This is one of many possible phrasings for this sentence.



(1)

Words can also be subdivided into prosodic constituents such as the foot (a sequence of strong and weak syllables), the syllable, and the mora. However, in this article we will focus on the prosodic constituents above the word level, since prosodic constituents below the word level are not directly related to intonation.

Experiments have shown that prosodic constituency and the hierarchical structure are psychologically real. This means that these abstract entities are part of native speakers' tacit knowledge about their language. Phonetic studies on speech production have shown that prosodic constituents are phonetically cued so as to mark the prosodic hierarchy. For example, the duration of a single sound segment is longer in the initial position of a higher prosodic phrase than it is in the initial position of a lower prosodic phrase, which in turn is longer than that in the initial position of a word occurring somewhere in the middle of a lower prosodic phrase. The same pattern is found for the duration of phrase final sounds. That is, the higher the prosodic constituent is in the prosodic hierarchy, the greater the degree of lengthening is at the edges of this prosodic constituent. (*See* **Phonetics**)

Psycholinguistic experiments have also shown that native speakers of a language are sensitive to the boundaries of prosodic constituents when they are processing sentences of their language. For example, when English speakers listen to sentences such as the one in (2) below, the processing time, i.e. the time taken to understand the meaning of the sentence, is shorter if the prosodic phrasing (marked by acoustic features such as preboundary lengthening, boundary tones, and pause) matches the syntactic or semantic grouping of the sentence (see next section for more detail). Thus, English speakers process (2a) more quickly than (2b) because there is a match between the prosodic phrasing and the syntactic/semantic grouping in (2a), while there is a mismatch between the prosodic phrasing and syntactic/semantic grouping in (2b). (*See* **Sentence Processing: Mechanisms**; **Sentence Processing**)

Sentence: When George left the house, it was dark.
a. expected prosodic phrasing: (When George left the house) (it was dark)
b. unexpected prosodic phrasing: (When George left) (the house it was dark) (2)

In sum, utterances are prosodically divided into large and small phrases, and these prosodic constituents are hierarchically structured. Furthermore, native speakers phonetically cue the prosodic hierarchy in speech production by manipulating pitch, duration, and intensity, and they are also able to perceive these cues when processing a sentence.

RELATION TO SYNTACTIC STRUCTURE

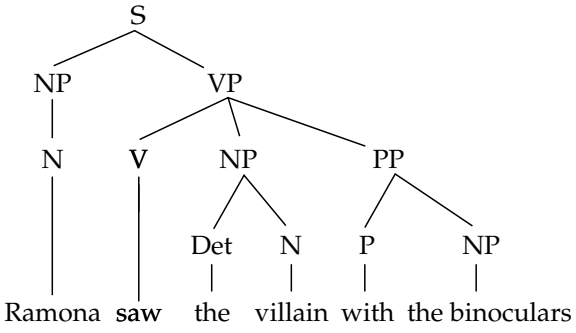
We have seen that sentences, when produced, are divided into intonational phrasings, or prosodic groupings, marked by intonation. (Thus, the term 'prosodic phrase' is used interchangeably with 'intonational phrase' below.) However, a sentence can be phrased in various ways depending on multiple factors such as syntax, the location of a focused word within the sentence, speech rate, and/or the length of the words and phrases. Therefore, prosodic phrasing does not always match the syntactic phrase of a sentence but is heavily influenced by syntax. In this section, we will show how the intonational phrasing is influenced by the syntactic structure of the sentence. (*See* **Syntax**)

Though there are many ways to phrase a sentence prosodically, prosodic phrase boundaries cannot be placed at random but are constrained by syntactic constituents. Specifically, there are certain syntactic constituents that tend to trigger phrase boundaries and others that do not. For example, speakers generally put a prosodic phrase boundary at a sentence-internal clause boundary (e.g. the sentence 'When you are tired, it's better to rest' is phrased as '(When you are tired) (it's better to rest)'), at the boundary of a parenthetical phrase (e.g. 'Disneyland is, Jane said, the most popular place to visit in LA' is phrased as '(Disneyland is) (Jane said) (the most popular place to visit

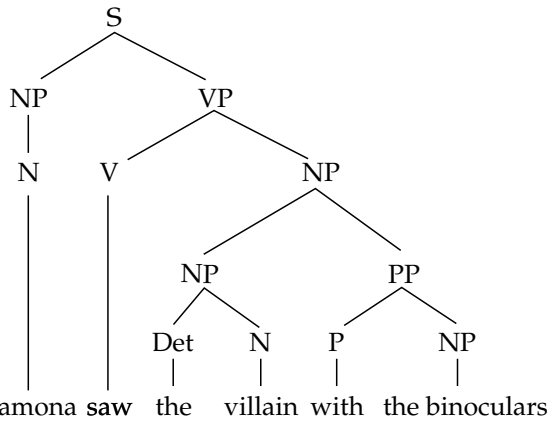
in LA)'), and before a tag question (e.g. 'He will win, won't he?' is phrased as '(He will win)(won't he)'). Similarly, speakers generally put a prosodic boundary between two words if the two words belong to two different syntactic phrases unless each syntactic phrase has only one word (e.g. between subject noun phrase and verb phrase).

On the other hand, speakers do not in general put a prosodic phrase boundary between words if they belong to the same syntactic phrase, unless the phrase is too long or each word is emphasized or produced very slowly. For example, it is very unlikely that a determiner and the following noun (e.g. 'a book', 'the teacher'), or an adjective and a noun (e.g. 'pretty girl', 'last year'), or a possessive pronoun and a noun (e.g. 'my book') would belong to two different prosodic phrases. For the same reason, it is unlikely for speakers not to put a prosodic boundary between two words if each belongs to a different syntactic phrase and the second syntactic phrase has other component words. For example, for the sentence 'The child with asthma outgrew the condition last year', combining 'asthma' and 'outgrew' together in the same prosodic phrase while putting a phrase boundary after 'outgrew' is not likely (i.e. *(The child) (with asthma outgrew) (the condition) (last year)). In sum, this suggests that prosodic phrasing reflects the syntactic grouping of the words.

Psycholinguistic and phonetic studies have shown that speakers disambiguate a syntactically ambiguous sentence by producing different prosodic phrasings for each syntactic structure. For example, the sentence 'Ramona saw the villain with the binoculars' can mean two things. Namely, Ramona could have used the binoculars to see the man, or Ramona could have seen the man who possessed the binoculars. For the first meaning the prepositional phrase 'with the binoculars' modifies the verb 'saw', as shown in (3a), and for the second meaning the prepositional phrase modifies the preceding noun phrase, 'the villain', as in (3b).



(3a)



(3b)

It has been found that speakers may produce the sentence differently depending upon which of the two syntactic structures is intended. For the structure in (3a), a prosodic phrase boundary is placed between 'the villain' and 'with the binoculars', i.e. (Ramona saw the villain) (with the binoculars), while for the structure in (3b), no such boundary is produced. Figure 1a shows a pitch track for the utterance with the first meaning, i.e. (3a), and Figure 1b shows a pitch track for the utterance with the second meaning, i.e. (3b). The horizontal axes in the figures show the time in milliseconds and the vertical axes show the pitch in hertz (Hz). A higher value in Hz indicates higher pitch. Above the pitch tracks, waveforms are presented which indicate the amplitude (vertical axes) over time (horizontal axes). Each word of the sentence is written over the waveforms, and a vertical line marks the end of each word or phrase. (The same format is used in Figure 2.) The word 'villain' in Figure 1a is longer than the same word in Figure 1b. This is because the word in Figure 1a is the final word in the prosodic phrase, but it is not in Figure 1b. The word in Figure 1a also shows a falling and slightly rising pitch, indicating a phrase boundary after the word.

Psycholinguistic studies have also found that native speakers perceive these disambiguating intonational and timing cues in ambiguous sentences and that these acoustic cues help native speakers process the sentences to arrive at the intended meanings. This shows that syntax imposes some constraints on the production of prosodic structure and that the prosodic structure is parsed or accessed by native speakers together with the syntactic structure when processing a sentence.

In sum, intonation can help cue the syntactic structures of a sentence, although not all syntactic structures are cued by intonation. Additionally, intonation plays a further role in conveying the

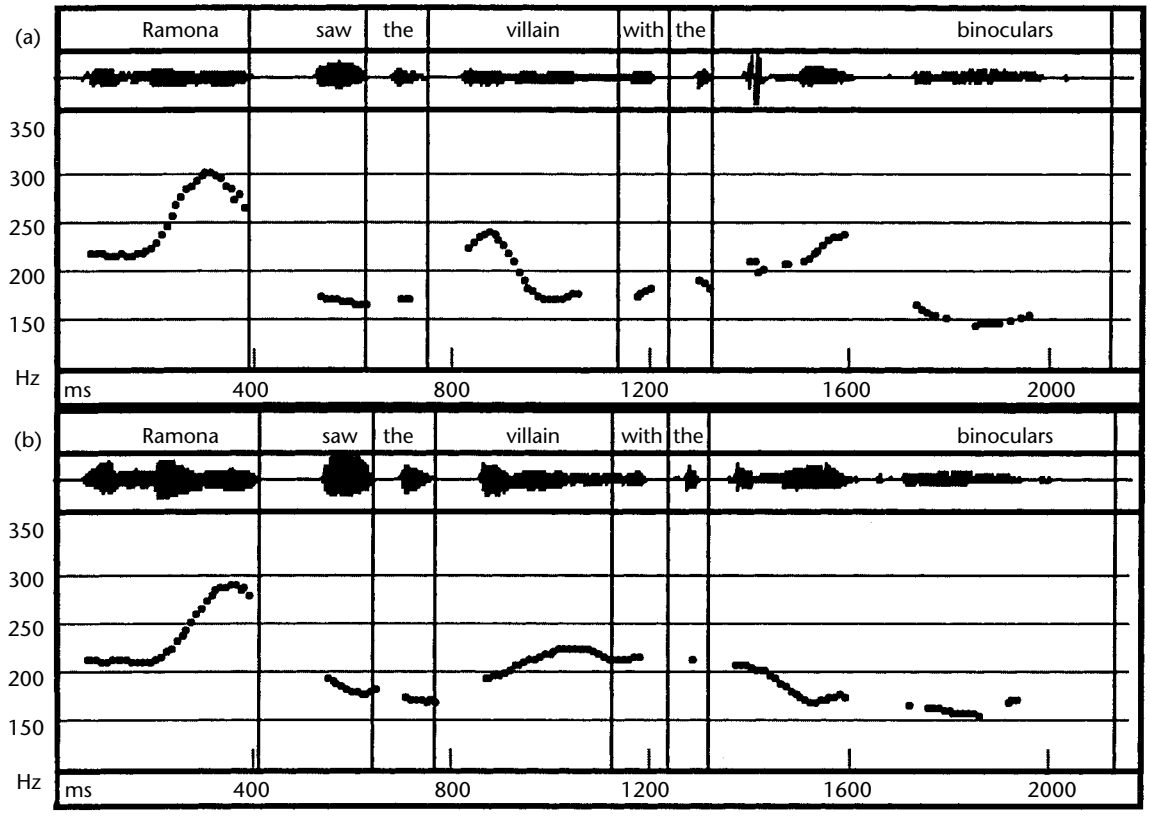


Figure 1. (a) A pitch track of a sentence with (3a) structure, and (b) the same sentence with (3b) structure.

semantic and pragmatic meaning of a sentence, and this will be discussed in the next section.

SEMANTIC AND PRAGMATIC FUNCTIONS

It is well known that native speakers emphasize or focus an important word within a sentence by means of pitch, intensity, and duration. For example, in English a focused word is realized with a sharply rising pitch and has longer duration and higher intensity than a nonfocused word. Listeners interpret the focused word by comparing it with other items belonging to the same category as the focused word. For instance, the sentence 'John only introduced Bill to Mary' can mean different things depending upon which word is focused. If 'Bill' is focused ('John only introduced BILL to Mary'), the sentence is true only when John introduced exactly one person to Mary and that person was Bill. On the other hand, if 'Mary' is focused ('John only introduced Bill to MARY'), the sentence is true only when John introduced Bill to exactly one person and that person was Mary. Thus, it can be seen that focus intonation changes the truth conditions of the sentence, suggesting that the semantic interpretation of a sentence is influenced by intonation. (*See* **Semantics and Cognition**; **Pragmatics, Formal**)

Intonation can also influence the relationship between words within a sentence. For example, the sentence 'Mary didn't approach them because they were yelling' can have two meanings depending upon how the sentence is produced. It can mean either that Mary did not approach them and the reason was because they were yelling, or it can mean that Mary approached them not because they were yelling but for some other reason. For the former meaning, 'not' modifies the verb 'approach', while for the latter meaning, 'not' modifies the word 'because'. Example pitch tracks for this sentence conveying these two different meanings are presented in Figure 2. (These are not the only possible intonation patterns that would convey these two meanings.) The utterance in Figure 2a conveys the former meaning and that in Figure 2b conveys the latter meaning. There is a phrase boundary after 'them' in Figure 2a, but not in Figure 2b. (Note the lengthening on 'them' in Figure 2a.) Further, the sentence ends with a falling boundary tone in Figure 2a, but with a rising boundary tone in Figure 2b. These

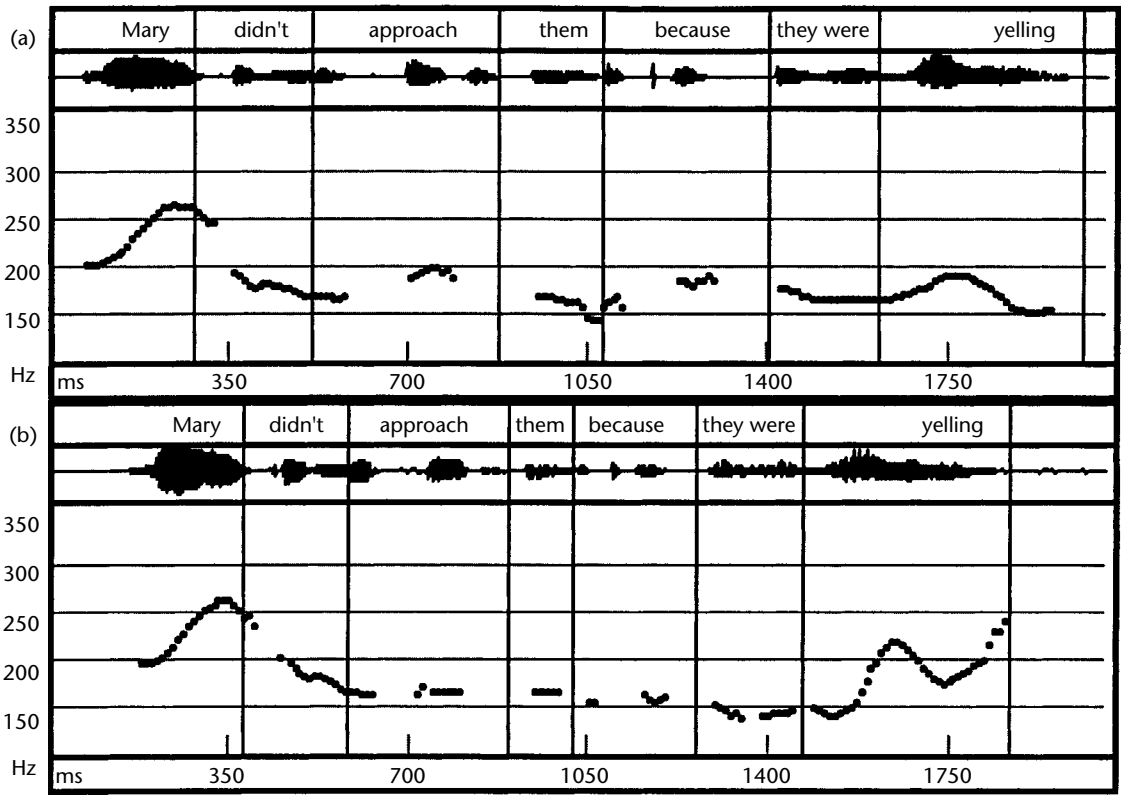

Figure 2. A pitch track of the sentence meaning (a) 'Mary did not approach them and the reason was because they were yelling' and (b) 'Mary approached them not because they were yelling, but for some other reason'.

examples illustrate that intonation can change the modification relations between words.

Furthermore, intonation reflects the structure of a discourse and the relative informativeness of words or constituents in a sentence (e.g. new versus old information). Words or constituents of a new topic or new information become prominent by pitch range manipulation or by getting pitch accent. In order to cue a discourse structure, a pitch range is manipulated in such a way that sentences with a new topic are produced with an expanded pitch range while those with an old topic (or a nonmajor topic as in parenthetical phrase) is produced in a reduced pitch range. That is, the pitch peak is higher at the beginning of a paragraph introducing a new topic than in the middle of the paragraph, and the pitch valley is lower at the end of the paragraph finishing a major topic than in the middle of the same paragraph.

Similarly, in English, a word with new information is produced with pitch accent, and a word that is repeated or 'given' in the discourse does not get pitch accent. When the sentence 'I don't read German' is produced with broad focus, the sentence final noun, i.e. 'German', would receive pitch accent. However, when this word is repeated and becomes old information, it does not get any accent, as in (4B). Here, the verb 'read' is accented and the object noun 'German' is deaccented. Deaccenting is also found in word(s) after contrastive focus. For example, when the word 'John' is contrastively focused (for example, against 'I') as in (5), it will get pitch accent and the rest of the sentence will get deaccented. Thus, accentedness reflects the relative semantic weight and the informativeness within a constituent.

A: I found an article for you in a German journal.
B: I don't READ German. (4)

JOHN reads German. (5)

This relationship of semantic weight versus accent, however, is not universal. In Italian and Romanian, for example, a word with given information still receives accent, and in French and Korean, which do not have lexical stress, new

versus given information is delivered by phrasing, not by accenting. A word with new information begins a new prosodic phrase, while a word with old information is dephrased, i.e. does not begin a new phrase but belongs to the preceding phrase. Thus, beginning a new phrase in French and Korean is equal to receiving pitch accent in English.

To conclude, we have seen how intonation is related to prosodic structure, syntactic structure, and the semantic and pragmatic meaning of a sentence. Intonation marks a structure as well as prominence relations among words. It also conveys semantic and pragmatic meaning. It is related to all subareas of grammar and is psychologically real. Thus, intonation is a crucial part of a native speaker's knowledge of his or her grammar, and it is also essential for effective communication between the members of a speech community.

Language Acquisition and Language Change

Intermediate article

David W Lightfoot, Georgetown University, Washington, DC, USA

CONTENTS

Under a cognitive view of language, a mental system emerges in the mind/brain of an individual child; linguists study the acquisition of that system, a 'grammar', which characterizes the individual's mature linguistic capacity. If a different system develops in another child in the next generation of speakers, then we have grammatical change, and that change reflects differences in the acquisition process.

INTRODUCTION

Language acquisition and change are intimately related: ideas about acquisition influence models of change, and vice versa. For example, children are sometimes viewed as input matchers: they acquire a grammar, which generates the set of primary data to which they are exposed in the first years of life, matching the input. This view of acquisition was promulgated in Chomsky (1965) and persists in recent work (Gibson and Wexler, 1994; Clark and Roberts, 1993). It entails stability and one would not expect languages or grammars to change except through major disruptions such as invasions or transfer of populations. Indeed, Keenan (1994) and Longobardi (2001) have argued for an 'inertia', under which languages do not change structurally. On the other hand, if children are not input matchers but converge on a grammar by identifying abstract 'cues', then minor shifts in experience may entail identifying a different distribution of cues, hence the development of a different grammar (Dresher, 1999; Lightfoot, 1999). This view leads one to expect to find catastrophic changes when a new grammar emerges, changing substantially the kinds of expressions found in historical texts.

The explanatory schema adopted by generative grammarians who study natural language with a view to learning about human cognition is shown in (1), where (1a) has general biological terminology and (1b) the corresponding linguistic terms.

a. triggering experience (genotype → phenotype)
b. Primary Linguistic Data (Universal Grammar → grammar) (1)

A child's triggering experience causes the genotype to develop into a phenotype; exposure to a range of utterances in, say, French allows the genetically prescribed Universal Grammar (UG) to develop into a particular mature grammar. A child develops a grammar by setting the open parameters of UG in the light of her particular experience.

CHANGE: SOCIAL AND COGNITIVE

Changes take place in two ways. First, there are changes in the primary linguistic data, some of which have no effect on the grammars which emerge. No two children have identical triggering experiences; children do not hear the same set of expressions in the same order and in the same context, but they may none the less converge on the same abstract system. Consequently, variation or change in the primary linguistic data does not necessarily entail a different grammar. One may study variation and change at this level ('change' is just variation taking place over time) and it may be minor, piecemeal, chaotic, and gradual. This variation, what one may call 'language change', is influenced by social factors and may spread through population groups in the course of time. Briscoe (2000) offers a computer simulation of such variation and the way it may affect acquisition.

Second, change may also take place in grammars, resulting from prior changes in the primary linguistic data, and here particular theories of UG become relevant. If one works with a theory of UG with a significant degree of abstraction, a single change at the grammatical level may proliferate through the system and have 'catastrophic' effects, that is, simultaneous change in several superficially

unrelated phenomena. Grammatical change is often bumpy: the set of expressions occurring in texts change significantly in a short period. By examining the clusters of simultaneous changes and by taking them to be related by properties of UG, we discover something about the nature of grammars; the time and conditions of grammatical change may illuminate the relevant trigger experiences. In this perspective, work on grammar change informs work on variation and acquisition: the set of parameters postulated as part of UG explains the unity of the changes, why superficially unrelated properties cluster in the way that they do.

AN EXAMPLE OF CHANGE

English modal auxiliaries such as 'can', 'could', 'may', 'might', 'will', 'would', 'shall', 'should', and 'must' differ from verbs in their distribution. A modal auxiliary is fronted in a question, but a verb like 'understand' is not, as in (2); a modal occurs to the left of a negative particle, unlike a verb (3); a modal does not occur with a perfective (4) or progressive (5) marker, unlike a verb; a modal does not occur in the infinitival complement to another verb (6), nor as the complement of another modal (7); and no modal occurs with a direct object, unlike some verbs (8). (Asterisks indicate non-occurring forms.)

a. Can he understand chapter 4?
b. *Understands he chapter 4? (2)

a. He cannot understand chapter 4.
b. *He understands not chapter 4. (3)

a. *He has could understand chapter 4.
b. He has understood chapter 4. (4)

a. *Canning understand chapter 4, . . .
b. Understanding chapter 4, . . . (5)

a. He wanted to understand.
b. *He wanted to can understand. (6)

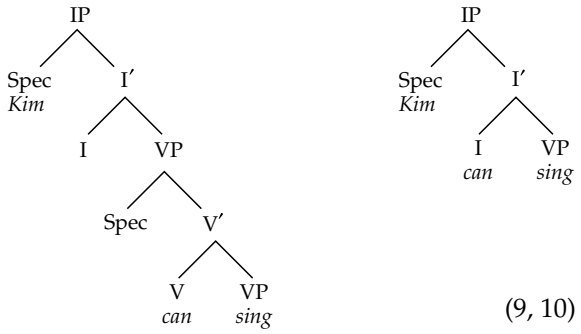
a. He will understand.
b. *He will can understand (7)

a. *He can music.
b. He understands music. (8)

The distribution of these modal auxiliaries is peculiar to Modern English. Sentences along the lines of the nonexistent utterances of (2)–(8) were well formed in earlier English. If the differences between Old and Modern English were a function of separate features with no unifying factor, we would expect these features to come into the language at different times and in different ways. On the other hand, if the difference between Old and Modern English reflected a single property, a categorical distinction, then we would expect the trajectory of the change to be different. If the differences between 'can' and 'understand' in (2)–(8) were a function of the single fact that 'understand' is a verb while 'can' is a member of a different category, Inflection (I), then we are not surprised to find that: (2b); (3b); (4a); (5a); (6b); (7b); and (8a) dropped out of people's language in parallel, at the same time.

If we attend just to changing phenomena, the change consists of the *loss* of various forms, not the development of new forms; people ceased to say things which had been said in earlier times. Before the change, all of the utterances in (2)–(8) might have occurred in a person's speech, but later only those forms not marked with an asterisk. That fact alone suggests that there was a change in some abstract system. People might start to use some new expression because of the social demands of fashion or because of the influence of speakers from a different community, but people do not cease to say things for that sort of reason. Changes involving only the loss and obsolescence of forms need to be explained as a consequence of a change in an abstract cognitive system.

If one focuses on the disappearance of the relevant forms, one sees that they were lost at the same time. The most conservative writer in this regard was Sir Thomas More, writing in the early sixteenth century. He used many of the asterisked forms in (2)–(8) and had the last attested uses of several constructions. His grammar treated 'can', etc. as verbs in the old fashion (see (9)), and the fact that he used *all* the relevant forms, and his heirs none, suggests that his grammar differed from theirs in one way, not that the grammars differed in unrelated features. The uniformity of the change suggests uniformity in the analysis. There was a single change, a change in category membership: 'can', etc., formerly verbs which moved to I in the course of a derivation, came to be analyzed as I elements, as in (10). The fact that there was a single change in grammars accounts for the bumpiness: several phenomena changed simultaneously. The notion of change in a grammar is a way of unifying disparate phenomena, taking them to be surface manifestations of a single change at the abstract level. The change in category membership of the English modals explains the catastrophic nature of change, in that phenomena changed together but not in the sense that the change spread through the population rapidly.



(9, 10)

Linguists have also studied the spread of changes through populations. Anthony Kroch and his associates (e.g. Kroch, 1989) have done interesting work on the replacement of one grammar by another, enriching grammatical analyses by describing the variability of individual texts and the spread of grammatical change through a population. Niyogi and Berwick (1997) have offered a dynamical systems model for describing the spread of new grammars; a key idea is that a new grammar acquired by one speaker entails new primary linguistic data for the community, which in turn is more likely to trigger the new grammar in other children. Yang (2002) also has an interesting model in which grammars may coexist, with one eventually winning out.

The cause of the grammatical change in English was two earlier changes in primary linguistic data (here we discuss a result of these earlier changes; *their* cause is another story). First, the modal auxiliaries became distinct morphologically, the sole surviving members of the preterite-present class of verbs. There were many verb classes in early English and the antecedents of the modern modals were preterite-presents. The preterite-presents were distinct in that they never had any inflection for the third person singular, although they were inflected elsewhere: 'þu cannst', 'we cunnan', 'we cuþon'. They did not change in this regard, but a great mass of inflectional distinctions disappeared and, as a result, the preterite-presents were isolated; they looked different from other verbs in lacking their one morphological feature, that *-s* ending. That property, insignificant when there were many classes of verb inflection, took on a new importance when present tense inflection consisted of only one property.

Second, the morphological distinctiveness of the surviving preterite-presents, the new modals, was complemented by a new opacity in their past tense forms. The past tense forms of the preterite-present verbs were phonetically identical in many instances to the subjunctive forms and, when the subjunctive forms were lost (part of the general loss of inflections just alluded to), past tense forms survived with subjunctive-type meanings rather than indicating time reference. While 'loved' is related to 'love' in terms of time reference in present-day English, the relationship between 'can' and 'could' sometimes has nothing to do with time; 'might' is never related to 'may' in terms of time in Modern English. So 'might', 'could', 'should', etc. came to take on new meanings which had nothing to do with past time, residues of the old subjunctive uses.

The preterite-present verbs came to look different from all other verbs in the language. UG provides a small inventory of grammatical categories, and elements are assigned to a category on the basis of their morphological and distributional properties. Morphological changes entail new primary linguistic data, which may trigger new category distinctions. In this case, we know that, following the morphological changes, the surviving verbs of the preterite-present class were assigned to a new grammatical category, and that change was complete by the early sixteenth century.

There were two stages to the history of English modal auxiliaries (Lightfoot, 1999, chap. 6). First came a change in category membership, whereby 'can', etc. ceased to be treated as verbs and came to be taken as manifestations of the Inflection category; this change affected some verbs before others, but it was complete by the sixteenth century. Second, English lost the operation moving verbs to a higher Inflection position (e.g. in (9)). This change was completed only in the eighteenth century. At this point, sentences with a finite verb which had moved to some initial position (2b) or to the left of a negative (3b) became obsolete and were replaced by equivalent forms with the periphrastic 'do': 'Does Kim understand this chapter?' 'Kim does not understand this chapter', etc.

Gradual, piecemeal changes in primary linguistic data (such as loss of verbal inflections) sometimes cross a threshold such that they entail changes in people's grammars (e.g. category membership), part of their cognitive make-up. Such grammatical changes need to be explained through the mechanisms of acquisition and consequently they may illuminate the properties of Universal Grammar, including the nature of grammatical categories. Taking grammars to be elements of cognition has been productive for work on language change and helps to inform theories of grammar and of acquisition.

CONTENTS

Language acquisition by animals is concerned with how the acquisition of linguistic skills by nonhuman animals compares to language acquisition in humans. Although language acquisition by nonhuman animals is not claimed to be identical, or even approximate, to language acquisition by humans, researchers in this area are concerned with the specific cognitive skills of nonhuman animals that are necessary in the productive use and understanding of symbols.

INTRODUCTION

Animal language acquisition research has produced important data and, at times, led to highly contentious debate. The importance of animal language research is more than just to better understand how human language may have evolved. It is also important to demonstrate exactly what language does, and does not, involve. Language research with nonhuman animals allows us to identify processes in humans that may derive from general rather than specialized cognitive structures. Additionally, animal language research sheds important light on the role of the environment, the role of early experience, and the impact of cultural variables on cognitive factors influencing the exchange of information. This article outlines briefly the recent history of attempts to 'speak' with the animals, some of the more important issues in animal language research, and the major findings in this research area.

APE LANGUAGE ACQUISITION

Early Attempts

The earliest recorded attempt to teach an ape language involved training an orangutan to produce speech sounds. Furness (1916) observed an orangutan that acquired a number of different speech sounds that were produced voluntarily and apparently in appropriate contexts. The attempt to teach language to apes was the continued focus of research by both Kellogg and Kellogg (1933) and Hayes and Hayes (1951). The Kelloggs observed a chimpanzee named Gua. The chimpanzee was raised with the Kelloggs' own son, named Donald, for the first nine months (from the time the chimpanzee was 7 months to 16 months), and Gua proved the more capable student in the realm of locomotor behavior and navigation. However, although both the chimpanzee and the child began responding to spoken requests appropriately at around 12–14 months of age, the human soon exceeded the chimpanzee in comprehension of these spoken requests. When Hayes and Hayes began their research with a chimpanzee, the emphasis was returned to speech production, but the chimpanzee, Vicki, also provided much insight into the psychology of the ape mind. Vicki was given formal speech training, in which she was required to produce voluntary sounds in order to be rewarded. Eventually, Vicki produced a small number of different speech sounds that sounded like the words 'Papa', 'cup', 'up', and 'Ma Ma'. However, there was no evidence that Vicki used these words symbolically to refer to those items.

The next major scientific studies examining language-related skills in apes began in the 1960s and 1970s (Gardner and Gardner, 1969; Patterson and Linden, 1981; Premack and Premack, 1983; Rumbaugh, 1977; Terrace, 1979), and as the field evolved from that time period, its emphasis and methods changed considerably. Initially, the emphasis in ape-language research during the 1960s

and 1970s was on production of ordered sequences of symbols as well as on vocabulary acquisition and the meaningfulness of symbols, reflecting the issues of productivity and rule-generation emphasized by Chomsky in the then-emerging field of linguistics. The chimpanzees Washoe, Sarah, and Lana were conditioned to produce single symbols or strings of symbols through extensive training, and their combinations of the symbols in novel ways was examined.

Washoe was taught American Sign Language by the Gardners. Because chimpanzees had anatomical limitations that prevented production of the sounds of human speech, the Gardners decided that speech production was not a useful method for examining language in chimpanzees. Thus, only signs were used around Washoe, and signing was a part of every daily activity. Additionally, Washoe was trained to make and use various signs, and by three years of age she had become proficient in making many signs. This research program was continued by Fouts with Washoe and other chimpanzees. Additionally, Patterson studied sign language with gorillas, and Miles studied sign language acquisition by an orangutan. All of these studies confirmed that apes learned to use signs more readily than they had been able to produce speech.

Premack's work with a chimpanzee, Sarah, was with a different symbol system. Plastic tokens were used as representations for various items, actions, and concepts. Sarah was presented with various 'problems' that she had to solve through recourse to her symbol system. Rumbaugh also began working with a female chimpanzee, Lana, using special symbols called lexigrams. These lexigrams were geometric symbols representing English words or phrases, and they were located on a large computer-monitored keyboard in Lana's housing area. Lana communicated with her human caretakers and they communicated with her exclusively through use of this computerized system. This computer was important because it helped to standardize the interactions with Lana and to control for many of the cuing problems that had been evident in earlier projects with apes. Lana was taught to string symbols together to form various stock sentences (e.g. 'Please machine make window open'), and she came to exhibit flexible and appropriate use of her symbols in novel situations.

These early ape-language studies produced data indicative of rudimentary language or language-like skills in these apes. The initial conclusion made by those involved in the research was that the chimpanzees had learned many skills associated with language and that the language use of these chimpanzees was similar to that of human children.

Associative Language versus Representational Language Learning in Apes

Terrace had conducted research with a chimpanzee, Nim, in an attempt to replicate the work of the Gardners. However, Terrace analyzed the signing of Nim and concluded that Nim's utterances were simply imitations of the sign language utterances of his human caretakers. Analyses of the signing of Washoe produced the same conclusion: Washoe was simply imitating the signs of those around her. Lana's sentences also were attacked by Terrace and his associates who claimed that her system was not syntactic, but rather was the result of a series of chained associative responses that could be interchanged at various points. Additionally, it was claimed that Lana had learned only to associate certain things with certain lexigrams, and this associative language did not lead to true understanding of the meanings of lexigrams. However, Lana was able to complete sentences started by others with appropriate lexigrams, and she even 'erased' sentence beginnings that were intentionally produced in incorrect sequences by an experimenter. This indicated that Lana was not simply performing a chained sequence of associative responses. Later reports from Rumbaugh's team also showed that Lana only infrequently imitated her human companions' lexigram strings, and her productions were not to be accounted for by an appeal to her memory of recent experimenter-initiated utterances of lexigram symbols.

As issues of competence became apparent, ape language researchers placed emphasis on understanding whether the 'words' apes used really contained the same set of underlying representations for them as they did for humans. Psychologists came to recognize a clear difference between associative naming, such as that learned by Lana, and representational language, which indicates a true understanding of what words mean. Child language studies in the 1970s and 1980s were guided by the 'semantic revolution'. Emphasis was placed on acquisition of single words and the meaning of symbols that precedes grammatical competence. 'Reference' (the notion that symbols such as lexigrams, manual signs, or printed words represented real-world items, actions, and ideas) became an important concept in the nonhuman language

debate. Production was still the primary focus of inquiry. However, the tide was turning towards recognition of comprehension as a vital part of language acquisition.

At the Language Research Center in Atlanta, Georgia, the learning environment of a second generation of apes, Sherman and Austin, was substantially richer than that of Lana in that they experienced a greater variety of daily activities in a more open environment (e.g. they were allowed to go for walks outdoors), and their communications were directed to humans or to each other rather than exclusively to a computer (Savage-Rumbaugh, 1986). Human caretakers communicated with Sherman and Austin using the lexigram keyboard as well as through spoken English statements and various context-specific gestures. Sherman and Austin were trained to use lexigrams under a paradigm that relied on discrete-trial operant conditioning. Training sessions were distinct from other activities, and symbols were, initially, restricted to the training context. The use of spoken English was of only secondary importance in the interactions of the caretakers and the chimpanzees during these training sessions, as demonstrating comprehension of spoken English by the chimpanzees was not the goal of the project. There was no indication that these chimpanzees understood spoken English. Savage-Rumbaugh later determined through work with bonobos that exposure to human speech at an early age was critical in the subsequent comprehension of human speech by apes.

The processes by which the apes learned were different in many ways from those experienced by children; in fact, children learn more than these apes did without any formal training at all. This left the work open to criticism that there was no homology between what the apes were learning and children's early language skills. However, through their training, Sherman and Austin did master referential functions that are considered an important part of symbolic competence, allowing at least an argument of analogy to be made with regard to some aspects of human language competency. The two chimpanzees made statements about their future actions and then carried out those actions, they requested items from each other so as to accomplish tasks, and they responded correctly to each other's appropriate requests whereas they refused to respond to inappropriate requests. None of these behaviors were evident in other language-trained apes. Sherman and Austin (but not Lana) demonstrated metalinguistic ability when they categorized lexigrams into functional categories. The apes were first taught to place items into either the category 'food' or the category 'tool'. The apes then learned to categorize photographs of those same items into the two categories, and finally the lexigrams for those items were categorized correctly. Most importantly, when novel lexigrams (i.e. lexigrams that the apes had never before categorized but had learned as symbols for real-world items) were presented, Sherman and Austin correctly categorized those lexigrams as 'foods' or 'tools' on the very first trial. This clearly demonstrated that these lexigrams functioned as symbols for the apes, and that these lexigrams had semantic meaning for them. Another way of demonstrating that these symbols had meaning for Sherman and Austin was through showing that they could perform symbol-based cross-modal matching. When presented with the lexigram for an object, the chimpanzees could reach into a box and find the object which that lexigram represented without ever having seen the object itself. As in the categorization study, the lexigrams represented things that were not present, and this is the essence of semantics: it is word meaning.

Language Learning, Speech Comprehension, and Early Rearing

In the early 1980s, the developing knowledge base relevant to ape and child language radically changed the approach to teaching language skills to apes as well as to the evaluations of what the apes were capable of learning (Savage-Rumbaugh and Lewin, 1994). Savage-Rumbaugh began work with an adult female bonobo (*Pan paniscus*) in an attempt to replicate the findings with Sherman and Austin. During these training sessions, the bonobo's son, Kanzi, remained in the area but was not taught to use the lexigrams or even to attend to them (he was thought too young to learn the symbols). The adult female proved unsuccessful at learning the symbols, and after some time she was separated from Kanzi so that she could breed. At this time, it was discovered that the infant had learned not only to appropriately use and respond to others' use of lexigrams but also to comprehend English speech. Apparently, being immersed in the daily routines of lexigram use and speech use by the humans around him, Kanzi had gleaned the meanings of these symbols and spoken words. This occurred with no training, but through observation of a structured series of daily situations.

After the young bonobo Kanzi surprised his caregivers with untrained symbol use, subsequent apes participating in language studies have been

immersed in a language-structured environment or culture throughout much of their infancies – much as human children are. The apes in these studies were not trained in formal repeated-trial training sessions. Rather, they participated in daily life and observed the behavior and communications of others as they did so. For example, the apes traveled through a forest each day during which time there was much discussion by human caretakers (through both speech and lexigram use) about what was going to occur or what had occurred already. These structured interactions and routines provided a framework from which the apes learned the meanings of lexigrams and large numbers of spoken words. And most importantly, this lexigram use and speech by caretakers was important to the apes as it informed them about events and items of interest to them.

The initial route to language competence in these apes was through comprehension of speech and lexigram use starting very early in infancy, and this generalized to production of symbols without explicit training by one to two years of age. These studies coincided with improvements in measuring early comprehension in children and the realization of its importance to natural language acquisition. Also, at this time there emerged a new emphasis on the process and context of language acquisition as a social phenomenon, with examination of the social support systems that facilitate communicative competence in children. These apes came not only to understand the meanings of lexigrams, but also to comprehend spoken English in a variety of contexts. For example, strict experimental testing showed that the bonobo Kanzi comprehended spoken requests and statements in highly controlled situations with hundreds of novel sentences. This comprehension included a sensitivity to word order, such that Kanzi responded appropriately to both 'Pour the Coke in the lemonade' and 'Pour the lemonade in the Coke' (Savage-Rumbaugh *et al*., 1993). Kanzi's productive competence was comparable to that of an 18-month old human child, and analyses of Kanzi's use of lexigrams indicated that he used grammatical rules of his own invention and rules modeled after those of his human caretakers (Greenfield and Savage-Rumbaugh, 1991). For example, Kanzi always used lexigrams before gestures within the context of combining an agent gesture with an action lexigram. When Kanzi produced two-element utterances with action lexigrams, regularities that reflected preferred action orders in social play were evident (Rumbaugh and Savage-Rumbaugh, 1994).

Three of the four apes who have been reared in this way and who comprehended spoken English have been bonobos. The one chimpanzee, Panzee, who also was raised in this enriched environment, demonstrated that *Pan troglodytes* is capable of learning to understand spoken English as well as use a large number of lexigrams communicatively without explicit training during the first few years of life. This chimpanzee and her bonobo companions have learned to use lexigrams to fulfil many communicative functions, to understand another's communicative intent when that other individual touched lexigrams, and to understand spoken English sentences and words as well. At age three, Panzee was able to select the correct lexigram when presented with 79 different spoken English words, and her comprehension of English today stands at more than 120 words for which she has lexigrams. Today, these apes have a functional understanding of even more spoken English words than are represented with lexigrams, as the lexigram keyboard has trailed behind the spoken word comprehension vocabularies of these apes as they are exposed to new objects, foods, people, and activities.

PARROT LANGUAGE ACQUISITION

At nearly the same time that Savage-Rumbaugh was investigating Kanzi's language competence, Pepperberg was training the African gray parrot, Alex, using what she called the 'model–rival' approach (Pepperberg, 1999). Alex observed linguistic interactions between two people, who served alternatively as 'models' and 'rivals' for Alex. The model/rivals talked about and exchanged objects that they hoped would interest Alex. When Alex entered the conversation through emitting vocalizations, he was rewarded by having the humans respond as if he 'meant' what he had said. For example, if he had made a request, it was honored. Alex could observe and enter the conversation at will, and he eventually learned to ask for, choose, and describe the color, shape, and materials of the objects with which he was familiar. As with the animals at the Language Research Center, it was assumed that Alex really did want whichever item he requested. Further, Alex had the opportunity to observe the way in which his human model/rivals interacted with each other. This ideal situation in which to learn relationships was important in the language acquisition of Alex, and it resembles the contextual way in which human infants learn human language both by interacting with parents and by observing parents and others interacting

with each other. Note also that these contexts are designed so that Alex can respond spontaneously. A broad range of different responses is available, rather than the single responses that have for so long been the standard in the typical classical or operant conditioning experiment.

From this approach, it was found that the parrot learned many names for items, and he used those names appropriately in a variety of contexts. Additionally, Alex learned to respond to the spoken requests of his caretakers. Alex could be queried on the names of items, the quantity of items in an array, the color of items, and even the substance of which an item was made. Even complex questions of multi-item, multicolor, multisubstance arrays could be answered correctly, indicating that Alex understood the entire sentence and could decompose the request into relevant subcomponents so that the correct category and answer within that category could be determined. To do this, the parrot must not only understand word meanings but also perform tasks involving recursive processing in many instances. Alex can interpret spoken requests and statements and respond appropriately based on conceptual understanding of those requests. Thus, linguistic abilities in nonhuman animals are not limited to apes. The research with Alex further demonstrates that rearing and teaching methods are important to the competencies that emerge in nonhuman animals.

DOLPHIN LANGUAGE ACQUISITION

Language acquisition research with dolphins centers around the work of Herman who taught two dolphins two different artificial language systems (Herman *et al*., 1984). One dolphin, Akeakamai (Ake), was taught to respond to the hand and arm gestures of humans, whereas the other dolphin, Phoenix, was taught computer-generated vocal sounds. The words in each of these artificial language systems referred to objects, actions, properties, and relationships. These words could be combined into meaningful sentences that the dolphins could interpret. Some sentences were relatively simple and required an action to be done to an object; other sentences, however, were more complex and involved relations between words within the sentence as well as multiple relevant item words. Using the same words, multiple sentences with multiple meanings could be constructed, and this required that the dolphins learn not only the semantic meaning of the symbols, but also the syntactic rules governing the combinations of those symbols.

Herman believed that comprehension of this language system was a more important route to investigate than production (as was used in the early ape-language studies) because he claimed that investigations of productive use of language in apes had revealed no convincing evidence for the understanding or use of syntax (although, as already noted, Rumbaugh believed that Lana did show evidence of grammatical understanding). Additionally, Herman (and Savage-Rumbaugh) noted that language comprehension precedes language production in human children, and thus is a more likely place to start an investigation of language in nonhuman animals. Therefore, Herman was interested in the ways in which his dolphins responded to different types of linguistic statements by humans.

In addition to responding appropriately to commands in this linguistic situation, the dolphins also answered questions pertaining to the status of named objects (such as HOOP QUESTION to ask whether a hoop was present in the tank). Herman conducted numerous studies of this language system with the dolphins, including investigations into how Ake would respond to anomalous gestural sequences (the dolphin discriminated anomalous sequences from normal sequences and rejected the anomalous ones or completed only the part of the gesture sequence that 'made sense'). Additionally, the dolphin responded appropriately to gestures that were videotaped and even substantially degraded in the clarity of the image. In both symbol systems, the dolphins demonstrated an understanding of both the syntactic rules and the semantic content of the symbols in their system; they responded appropriately not only to the meaning of individual gestures and signals, but also to the relation of those gestures and signals to each other within a sentence. Syntactic understanding was shown through responses to semantic contrasts in sentences in which word order was reversed, to syntactically anomalous sentences, to novel sentences, to sentences in which one word modified the meaning of another, to interrogative sentences, and to sentences with variations in the placement of modifiers.

Despite the data indicating language comprehension by these dolphins, there is a lack of any productive language data. Unlike with the work with bonobos, in which both comprehension and production of lexigram use, as well as comprehension of spoken English (including for syntactic structure) was investigated and demonstrated, the work with dolphins has remained tied to the realm of comprehension. Therefore, little is

known about what the dolphins would 'say' if they had the means to produce linguistic output that was comprehensible to humans (dolphins use a seemingly complex communicative system of whistles among conspecifics, and this points even more to a need to look to productive language use in the dolphin).

THE FUTURE OF ANIMAL LANGUAGE RESEARCH

With the advances made since the late 1970s, nonhuman animal language studies have become established within the fields of biology, psychology, and anthropology. Nonhuman animal language acquisition is now an established phenomenon that has been documented in numerous species and through numerous symbol systems. That said, what is (and should be) the future of this research area?

First, it is necessary to expand the scope of such studies to include other species that have the requisite skills and abilities needed for this kind of research. These species may include elephants, whales, dogs, and even other nonhuman primate species. However, we believe the most interesting and informative data will continue to come from the great apes. In particular, recent studies show that the chimpanzee brain and the human brain are much more closely related in morphology than previously thought (Gannon *et al*., 1998), and it will be important to look for homology in brain processes during language-related activities to understand further the specific evolutionary course of language-like skills in our human ancestors. With the advent of brain imaging technologies such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), it will be important to determine what role the chimpanzee brain plays in comprehension of human speech, in symbol use, and in species-specific vocal communicative utterances. We also hope such studies can be conducted with other species and their respective symbol systems or natural communicative capacities.

Additionally, we believe it will be important to define further the role of the environment in the language acquisition of nonhuman animals. In particular with chimpanzees and bonobos, we must examine the extent to which language competence in these animals affects, and is affected by, the cultural variables that make up the environment in which these animals live and are raised. One cannot learn language in a vacuum, at least not in the sense of using it for its intended purpose of communication. Language is necessary only within the social and cultural context in which it is learned and employed. Therefore, studies of language acquisition and use are intricately tied to studies of culture and social interactions with nonhuman animals.

Finally, we would note that language acquisition is an example of an *emergent* (Rumbaugh *et al*., 1996). Emergents are forms of silent learning that, in many cases, are acquired through social observation. They are not reinforced via training regimens, but are established through induction by the organism, and they are noted for their appropriateness to novel situations. We believe that the language acquisition of Kanzi (and the other apes raised in a manner similar to Kanzi) demonstrates perhaps the clearest example of this form of learning. Further research into nonhuman animal language will continue to provide data that force us to reconsider our views of early rearing, the role of culture, the uniqueness of human language, and the principles of learning as they are manifest in intelligent nonhuman animals.

Language Acquisition

Introductory article

Michael P Maratsos, University of Minnesota, Minneapolis, Minnesota, USA

CONTENTS

Language acquisition comprises the developmental processes by which children develop into competent users of words and sentences in their native language, to express themselves, and to influence and cooperate with others.

INTRODUCTION

Children do not need to be taught language; they formulate it themselves. In school, children and adolescents are taught the underlying rules and principles of complex systems, and given examples to flesh out the general rules. In learning a language, the child only hears the examples – particular utterances used by others – and is expected to deduce the underlying rules and principles independently.

BEHAVIORIST VIEWS OF ACQUISITION

A half-century ago it was largely taken for granted that in acquiring language, children showed no distinctive talent. Rather, it was thought that learning a language, like learning everything else, was a relatively simple process of experience 'stamping in' specific behaviors. Skinnerian psychologists believed that children spontaneously give off sound productions. Those that are appropriate are rewarded, by mechanisms such as parental approval, and are thus shaped and strengthened by experience. Inappropriate responses are suppressed by mechanisms such as parental disapproval. Learning theorists who emphasized imitation added that children could acquire responses by imitation, without contingent reward or punishment.

Inadequacies of Behaviorist Theories

Behaviorist views proved inadequate on a number of grounds, some empirical, some theoretical. Empirically, it was shown that in most known cultures, parents do not approve and disapprove on the basis of how well-formed sentences are. A child's sentence like 'her curl my hair', though ill-formed, would be approved of if it were factually accurate, disapproved of if were factually inaccurate, in most cultures that have been studied (although in one culture, the Kaluli of New Guinea, adults do in fact overtly disapprove of poorly formed sentences). Also, many children simply do not imitate very much in general, at least overtly.

Theoretically, the behaviorist view of language as a set of particular memorized or previously reinforced responses is wrong. A competent speaker of a language can and does produce new utterances that the speaker has never heard or given forth before, that are nevertheless appropriate and communicative. That is because in acquiring a language, a speaker formulates a set of rules and principles that underly the particular utterances that are heard. These rules and principles can then be used to generate new appropriate sequences of words and morphemes from these underlying rules and principles.

What is meant by this? To illustrate with a non-linguistic example, suppose one heard and learned a set of number sequences: 1–2–4, 8–16–32, 121–242–484. A reasonably intelligent person, having learned these particular sequences, would soon figure out a more general underlying pattern or rule that generated the sequences: any first number x is followed by $2x$, which is then followed by 2 times $2x$. One could then generate new sequences that follow the same underlying patterns, e.g. 3–6–12, 14–28–56, 3000–6000–12 000, and so on.

As simple as this case is, what is done here is indescribable in strict behaviorist terms. One has not just acquired a set of imitated (or reinforced) particular responses. One has gone beyond this to generate a set of underlying mental rules, which can then generate new examples. Notions such as

'rule' or 'underlying mental rule' were unacceptable in behaviorism, which forbade theorization of mental entities like mental rules, feelings, plans, goals or other things inside the organism. In fact, we might better say the problem-solver above formulated a set of rules from the input, rather than 'learned the rules', which implies that experience presented the rules directly, which it does not – experience only provided data for the formulation of the rules.

Acquiring a natural language, of course, does require a good deal of acquisition of specific knowledge, some of it basically imitative, such as acquiring the sound sequences of particular words. However, it also requires the formulation of a heterogeneous set of underlying rules and principles of many kinds. Experience can supply particular data points, examples of speech, for doing this, but it cannot directly supply the underlying rules and principles themselves. Even if parents did approve well-formed utterances and disapprove badly formed ones, this would only tell a child about the validity of specific examples; it could not supply the underlying system for the child.

COGNITIVIST AND NATIVIST VIEWS OF LANGUAGE ACQUISITION

Noam Chomsky, a linguist, used these and other arguments about the nature of language and its acquisition in an influential set of criticisms of the behaviorist view. In general, in the 1960s, most of those who believed humans formulate underlying rules and principles, like Jean Piaget, believed that they construct these structures by the use of a general, intelligent set of constructive and inductive mechanisms which could be used to analyze causality, number and space, as well as language. We can call this a 'cognitivist' approach.

Chomsky, however, proposed a far more radical view. He believed that the underlying structures and rules of natural languages, especially those of syntax (sentence structure) are too particular in nature, and too far removed from the input data, to be derived by a general cognitive device. Rather, he proposed that to acquire language, children must know a good deal of its specifically linguistic nature in advance: they must have considerable innate knowledge. In Chomsky's view, we should try to postulate mechanisms that make language acquisition more like instantaneous perception, rather than slow, cumulative acquisition and construction. This innate knowledge would not be particular knowledge of particular languages. Rather, it would be like a child who innately knew the general principles of architecture, who was to analyze the structure of particular buildings encountered later. Chomsky's hypothesis was both radical and skilfully argued, and set the central issues for language acquisition in the decades to come. Indeed, nearly all work in the field, even if not strongly relevant to his hypothesis, is referred to the basic nativist–antinativist controversy.

In reality, most of the work in language acquisition is not strictly relevant to Chomsky's particular claims, though investigators generally try to make references to issues of nativism and nonnativism. Whatever the explanation, empirical work does show surprisingly competent acquisition of complex language systems and knowledge, even if some of this complexity in fact has a strong non-Chomskyan cast. While acquisition of a language covers many domains, the central areas remain phonology (sound systems), semantics (word meaning) and grammar (sentence structure and structurally realized meaning). The accumulated empirical findings of some decades, from many languages, resist adequate summary; a selective survey of key findings and arguments is given instead.

EMPIRICAL FINDINGS AND KEY ARGUMENTS

The First Year and Phonology

Phonological acquisition means acquiring the meaningfully distinguished set of sounds used in one's language (ranging from about 30 to 60 in various languages), the sets of rules for how these sounds can be combined into words, intoned in phrases, varied across related forms of words, and other related acquisitions. Currently the best-known results have arisen in studies of infants. Generally, we can say that infant babbling creates many different sounds. Then, around the age of 1 year, a smaller set of sounds is used to make initial words. This initial set expands at different rates in different children, with highly variable rates of error in pronunciation.

More exciting than the study of what children produce, however, has been the experimental study of how they perceive sounds. At birth, children can discriminate – apparently – all or virtually all the sound distinctions employed by the world's languages. At first it was believed these innate auditory abilities might be specific to humans acquiring language, but it was found that minks, chinchillas and monkeys can discriminate the same sounds (at least when tested).

Even at birth, from womb experience, children prefer to hear characteristic sound sequences of their own language. Over the next months, further language-specific adjustments take place. For example, the /o/ of English and Swedish is somewhat differently centered in sound. By 6 months, infants have a properly centered set of preferences for the 'o-center' of their own language. Rhesus monkeys do not seem to revise their basic sound perception system similarly with similar experience, so this sound-center learning ability might be specific to humans. Infants also lose the ability to discriminate sounds not characteristic of, or not distinguished meaningfully, in their own languages. For example, English-language infants can discriminate various sounds used in Hindi at 6–8 months, but lose this ability by 10–12 months of age, probably because the relevant sound differences do not make meaningful differences in English although they do in Hindi.

Perhaps most surprising are infants' abilities to analyze sequences of sounds. By the age of 6 months, infants prefer sequences containing whole-phrase intonation patterns, over recordings of broken-up phrase patterns chained together. Ten-month-old infants hearing new words read to them in a passage can differentially recognize these new words in a later passage. Surprisingly, if one plays to them sound sequences in which some sound transition sequences are more likely (e.g. /r/ followed by /a/ followed by /l/) than others, it appears that they learn something about these probabilistic transitions, an ability thought relevant to isolating word-sequence patterns in the sound input. This is startlingly well-developed sequential analytic ability; in fact, it is learning from experience, the analysis of large amounts of data to find statistical sequential probabilities.

Word Meaning Acquisition

Before first words

The first recognizable word appears around the age of 10–12 months. This initial utterance rests on much previous preparation; by the time it appears, an average child probably comprehends some meaning in around 50 words. Some evidence indicates that children can manually sign words earlier, so it is likely that the difficulty of reproducing sounds itself presents an obstacle. Also, it is likely that children gather information about the use of a word for some time before using it, rather than quickly venturing its use.

Fast mapping

Many competences probably feed into word meaning: the understanding that others have minds and intentions, and the ability to tell where the attention of others falls. Beyond this, there is the problem that a word is just a sound sequence used in a situation, and in any situation there are many possible meanings to assign. Yet once 50 words have entered the spoken vocabulary, acquisition proceeds at the rate of six or seven words a day. Furthermore, on the whole, children's word meanings are accurate, though some errors of use occur.

One theoretical response to this combination of quickness and accuracy has been to posit various 'fast mapping' strategies and heuristics children might use to deduce a word meaning – or a great deal of it – quickly from a single exposure. For example, it has been proposed children are biased to guess that a new word refers to an unnamed object, that each object has only one name, and that words refer to categories rather than individuals. Furthermore, it is proposed that there are natural 'basic categories' for children to guess as the meaning of an object-word, a category defined roughly by the highest distinctive shape common to groups of objects: that is, certain categories of objects, like chairs, cups and birds, fall together naturally in the mind, and so their meanings are easily assigned to words. Indeed, across languages, word meanings for basic object-word categories tend to remain constant, which supports a natural conceptual-semantic analysis.

Slow mapping

So far, it is fast-acting strategies for basic object-words that have been most successfully proposed. Other kinds of meanings often vary across language communities, so a 'fast guess' good in one community would be a poor guess in another. For example, suppose a child hears a new word, *gib*, while someone is eating a tortilla, and guesses that it refers to the action. We might think it natural for the child to encode this in the action-category English speakers encode with 'eat', meaning to 'ingest solid food'. Yet in Tzetal, there is one verb for eating very solid (crunchy) foods, another verb for eating softer solid foods (like fruit), and another for eating tortilla and bread-like foods. So if the child guessed that 'gib' meant the same as the English 'eat', the child would apply it too broadly, and make many errors. In Korean or Navajo, as another illustration, various verbs of handling or moving objects bundle meaning differently from English. One Korean verb, for example, applies to

removing objects from a tightly contained or supported place, while another applies to removing objects from loose containment or support. Another commonly used verb refers to placing an object long in dimension (long or tall) on a support surface. Surely the child learning Korean would not luckily guess just these right meanings immediately. Yet young children's uses of these Tzetal and Korean terms are accurate. Such acquisition requires, it seems, 'slow mapping' – that is, the child must collect detailed information across time on the situations for which a word is used, and from this information analyze the correct situational elements. 'Slow mapping' is a form of learning from experience.

Furthermore, the meanings discussed above are all relatively concrete objects or actions. Still other mechanisms must obtain for the learning of internal emotion words, or words referring to past, present, future, possible, and many other kinds of nonconcrete meanings. Word meanings cover the entire human conceptual sphere, and no single set of procedures can be expected to be adequate for all.

The Acquisition of Grammar: Morphology

Grammar (competence in sentence structure) is usually divided into two major parts: syntax and morphology. Morphology relates to the composition of words from morphemes, defined as the smallest sound sequences that have independent meaning. In English, morphology is used to express notions such as number on nouns ('dog+s') or tense on verbs ('push+ed') or possession on persons ('John's', 'the boy's'). Morphology is used in many languages to express not just these meanings, but also notions expressed by syntax in English. In Turkish, for example, any of 'John-u helped Ann', 'Ann helped John-u', 'helped John-u Ann' and so on constitute an acceptable way of saying, 'Ann helped John.' The accusative marker '-u' on 'John' marks John as the direct object of 'help', the one helped, and thus Ann as the helper. In morphologically rich languages like Turkish, morphological combinations in a single word may represent the first grammatical utterances.

The 'wug' test and productive grammatical knowledge

Morphological knowledge has most simply shown the productive, nonimitative nature of finished grammatical competence. For example, a preschool child is shown a picture of a man doing something novel, and is told, 'This man is nissing.' The experimenter continues, 'Yesterday the man did the same thing. Yesterday he …', leaving a pause in which the child can fill in 'nissed'. 'Nissed' follows from the general English morphological pattern of adding '-ed' to verbs to express past tense. It could not have been previously learned by imitation or reinforcement, because 'niss' has only just been introduced. Only the speaker's previous formulation of general rules, including the appropriate formulation of categories such as verb, makes it available. English-speaking children also produce overregularized past forms like 'runned' and 'breaked', not heard from parents, which show their analysis of a general 'ed-past' pattern.

Morphological acquisition

Children's skill in acquiring complicated morphological rules provides one of the most striking findings of current acquisitional work. For example, in Turkish, the accusative case marks direct objects such as 'John' in English 'Ann helped John', or 'the dog' in 'the cat chased the dog.' Yet only definite direct objects are so marked; indefinites corresponding to English 'a cat' or 'something' are not so marked. Furthermore, there are four accusative markers, rounded and unrounded '-oo' and '-ee' (rounded versus nonrounded lips during pronunciation), which are used according to the back-front and rounded-unrounded qualities of the stem vowel of the noun. None of this, of course, is told to the child, who just hears markers used on nouns sometimes and not others. One might expect long-drawn-out, error-filled acquisition of this complex set of contingencies. Yet instead, competence in production and listening are generally complete by the age of 2 years, with no errors of applying a marker wrongly. Acquisitional findings from other languages offer similarly impressive early, error-free pictures.

Slow mapping again

It should be obvious here that a child could not just hear such a marker used once and luckily guess just the right rule for its use. The child must store a great deal of information about the use and nonuse of each of these morphological markers, across many speech situations, to ferret out the right controlling properties. Since some hundreds of properties may affect morphological marking in different languages, sifting through hundreds of such candidate properties appears necessary to achieve the right analysis. This kind of hugely impressive grammatical acquisition, like nothing else currently known in general cognitive development,

supports some kind of special acquisitional systems for language. Nevertheless, like much discussed above, it does not correspond to the 'quick perception' mode of Chomskyan nativism, even if some kind of special adaptations for language learning may be present.

Syntactic Acquisition and Constraints

Syntax is the appropriate ordering of whole words to say what one intends. 'Helped John Mary' is simply not a possible syntactic ordering of English. 'John helped Ann' is possible, but is wrong if one intended to say Mary was the agent (i.e. helper). Syntax is partly controlled through meaning, and partly through nonmeaningful formal properties of word categories. In syntax-dominated languages such as English, children's initial grammatical combinations appear to be controlled by meanings such as agency, possession, location, negation and others. For example, an English-speaking child would say 'mommy go' (actor followed by action) or 'daddy chair' (possessor before possessed object).

While there is a fairly good map of how syntactic constructions are added over time, their underlying descriptions remain controversial. For simple-looking early speech, for example, theoretical descriptions range from highly specific word-centred descriptions, to general semantic-structural formulas, to essentially adult-like semantic-formal rules which are described as being reduced in production by children's memory restrictions. Indeed, the most striking aspects of normal syntactic acquisition lie in certain complex constructions which are rarely actually found in children's speech or even in that of adults, yet have central places in linguists' theoretical analyses, and play central roles in Chomskyan nativism. The major paradox lies in the interaction between the highly general rules that languages use in conjunction with highly specific, abstract constraints that restrict their generality. For example, in English, a highly general pattern is that where there is a form in which a wh-expression is part of a sentence, like 'You will talk to who(m)?' there is a corresponding form in which the wh-expression is placed at the front of a clause, e.g. 'Whom will you talk to —?'. Various evidence indicates there is indeed a gap understood where the wh-expression would 'normally' go.

The initial wh-expression may be very far from its 'gap', which may be hierarchically embedded as well, e.g. 'Which theory does John say that Mary claims that the current government will force you to talk about—?' The simplest rule for the input children hear would be that a wh-expression can leave a gap anywhere later in the sentence. Yet this is not true. One cannot say, corresponding to 'John really admires doctors who can cure *which diseases*?' the wh-question *'*Which diseases* does John really admire doctors who can cure—?'

Similarly, a noun expression like 'John' and a coreferential pronoun like 'he' or 'his' can appear in many different relative positions in sentences, e.g. the pronoun can follow the noun expression, as in 'John-i thinks he-i is right' or precede it, as in 'Mary says he-i would flee because John-i is a coward.' Yet the pronoun cannot precede its noun expression sometimes, as in *'He-i thinks that people don't like John-i', where 'He' and 'John' cannot refer to the same person (in English and many other languages).

In all these cases, something constrains these apparently general patterns from applying with complete generality. One cannot say people have not heard 'sentences just like these' before, because people can generally produce and accept an unlimited number of sentences which are new in some of their properties. So what makes the particular 'new properties' of these unacceptable uses so conspicuous – especially when speakers have no conscious knowledge of the relevant properties? Chomskyans would say that speakers have a limited range of settings for certain types of properties, and watch carefully to see where the input sets them for their own language. The properties are quite abstruse, such as how many types of syntactic boundaries of what type, the 'path' between a wh-expression and its 'gap' can cross, or abstruse structural relations between pronouns and noun expressions. Speakers would never know to pay attention to just these unless they were innately set to do so. Yet knowledge of what they are, and how they can work, in turn would require innate knowledge of large amounts of other grammatical equipment.

What is stated here briefly is a set of arguments that in reality, some months of linguistic training would probably make fully sensible. Yet the basic argument is simple: people have strange quirks in how they interpret the input data, and it is hard to get these quirks out of general, nonlinguistic cognition. Unless it can be shown that such quirks can be acquired naturally from more general cognition (as some linguists are attempting to do), the Chomskyan case, though based on uncommon (indeed unheard) sentences, has considerable general strength.

Yet little is known about children's acquisitional patterns in dealing with such constructions, and

what is known is inconsistent. Sometimes they appear precocious in dealing with such constraints, sometimes they do not, and for the most part, we do not know. It is not clear Chomskyans in the end would care about empirical acquisitional patterns, however. They might well say that the ability to formulate such constraints properly, without overt instruction, is the main point.

FINDINGS FROM 'NON-USUAL' POPULATIONS

Unclear Findings from Brain Localization

In attempting to test the innateness hypothesis, acquisition of language under 'non-usual' conditions has been prominent. Much of this work, especially work on children with particular retardation syndromes, or work on children and adults with damage in various parts of the brain, was initially used to argue for a biologically specific 'language faculty' housed in particular parts of the brain. However, the work has turned out to be ambiguous or puzzling at best. Indeed, some of the findings fit into no straightforward theory at all. For example, children with hydrocephalus have an excess of spinal fluid in their brains. Current treatment is to insert a shunt into the spine to drain the liquid immediately. Decades ago this was not done, however, and the result was extensive, near-total destruction of cerebral cortex tissue, the tissue believed critical for higher thinking. Yet a good many of these children turned out to be average or even well above average in developing normal language and cognition. Absolutely no current theory of brain localization or recovery can accommodate such data. In general, the brain injury data show surprising robustness of language, without giving straightforward answers to questions of language innateness.

'Home Sign'

From the nativist point of view, perhaps the most exciting 'non-usual' acquisitional work has concerned deaf children raised with little language input who seem nevertheless to devise and develop their own sets of signing symbols, which they may combine into simple propositions. Unless very generous analyses are made, these propositions seem so far to have simple structure far from the complexities at the heart of Chomskyan analysis, but the phenomena still point to a basic symbolic and propositional 'set' in human children.

Chomsky's particular nativist hypotheses remain unproved. However, when he proposed nativist explanations some forty years ago they were radical proposals, whereas now they are generally viewed as at least plausible. Beyond this, Chomsky's work pointed out the complexity of language under any reasonable analysis, making language acquisition the most impressive mental accomplishment that is widespread and sturdy throughout the human species.

Language and Brain

Introductory article

Merrill F Garrett, University of Arizona, Tucson, Arizona, USA

CONTENTS

The major structural features of language systems are systematically reflected in specialized neural systems of the human brain. Evidence for this conclusion derives from patterns of language breakdown and from physical measures of brain activity made during normal language use.

INTRODUCTION

What questions are addressed in studying brain and language relations? And why are they of scientific interest? A broader context suggests some answers. The objective in all brain and behavior studies is to understand how specific abilities can be physically realized, given the capacities and limitations of nervous systems. Beautifully detailed accounts of such relations exist for neural representations of sensory and motor capacities in human and nonhuman systems. The step to higher order mental capacities (cognitive systems), however, presents difficult additional problems. Cognitive systems involve abstract levels of representation that do not have direct links to physical features of the world. The principles that link abstract representations to neural activity are not well understood as compared to, for example, sensory transduction and early stages of perception. Language provides a superb means to attack this issue. Although it is a very specialized behavior, it supports communication across the range of human thought. It therefore contains components that are language specific and those that are not. Language is a truly central capacity that ties together many different mental systems. Studying its brain organization can indicate how in the general case the complex, multicomponent processes of human cognition are realized in neural systems.

Language and brain study is historically tied to language deficits (aphasias and related disorders) that result from brain injury and disease, or from surgical interventions to treat neurological problems. Those data have been enriched in recent years by brain imaging measures. These assess neural activity during behavior, showing which brain regions support different mental processes. Imaging is complemented by electrophysiology, which monitors changes in the brain's electrical activity to distinguish among types of mental processes and to indicate when they occur. Combining these sources provides an intricate mosaic of brain data that can be linked to the complex structure of language processing.

This work requires careful distinctions to be made among types of language processes. Everyone who has undertaken the study of a foreign language becomes acutely aware that many different skills must be acquired – 'proper' pronunciation, rapid word retrieval, syntactic details absent or different from one's native language, and different ways of thinking about the meanings of individual words. All these (and more) must be fluidly combined in order to use a language as normal communicative exchange demands. The intuitions developed from such experiences are an informal expression of ideas that drive scientific investigations of language in linguistics and psycholinguistics. The studies reviewed here draw on those sciences. Figure 1 gives a summary of relations among language structures. Broadly speaking, language is studied at the levels of sounds *(phonetics, phonology, and prosody)*, words *(morphology and lexicon)*, sentences *(syntax)*, and meanings *(semantics)*. Theories of language model the mental processes that generate and recover such structures in real time (i.e. while listening or speaking).

Figure 1 displays major classes of relations among language structures: those within a structural type

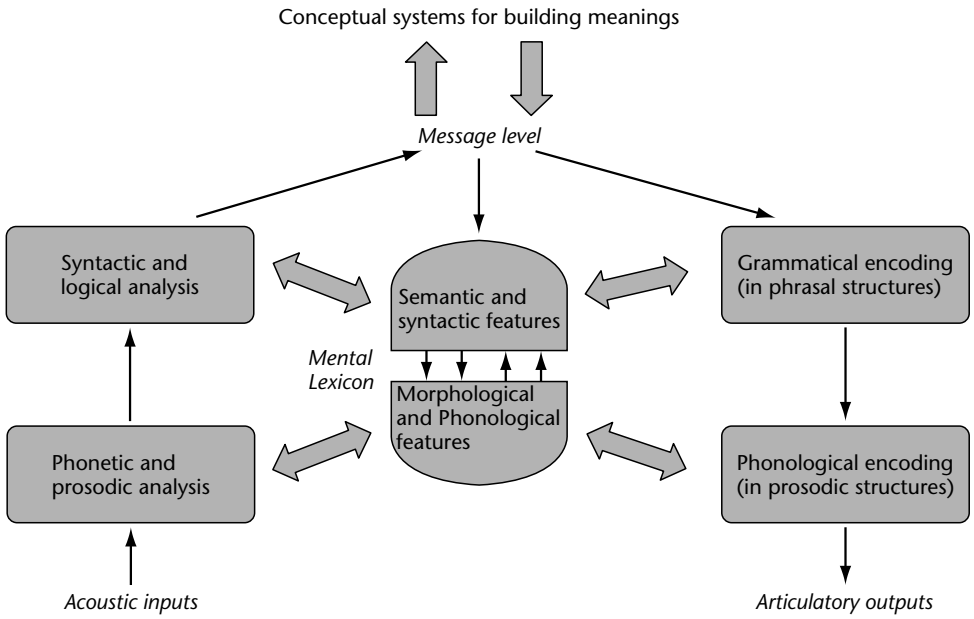

Figure 1. The major structural systems of language and their relations in processing. Sound systems include phonetic, phonological and prosodoc structure: phonetic categories of language connect to sensory and motor data by primary speech perception/production processes. In turn, the information represented by phonetic distinctions is linked to the more abstract categories of phonological and morphological structure in systematic ways. The phonological and morphological structures are systematically associated with the inventory of words in a language (the lexicon). In the lexicon, the form of every word must represented so that it can be identified or pronounced. Lexical representations are also associated with sets of syntactic and semantic features. These reflect the syntactic and semantic regularities of a given language. Systems for syntax and meaning use lexical codes to develop phrasal structures and coordinate them with semantic interpretations.

and those between types. These define the set of functions needed for a comprehensive theory of language. The study of language and brain targets the neural processes that are correlates of mental systems that assign such structures to sensory inputs (comprehension), or generate such in response to conceptual inputs (production).

LOCALIZATION OF LANGUAGE FUNCTIONS

What is the localization question? At first glance, it seems fairly easy. Are distinct neural systems associated with the processing of the major classes of linguistic structure? Broadly speaking, the answer is 'yes'. Processing for sounds, words, syntax, and semantics activates distinguishable brain areas. But the fuller story requires additional distinctions.

Some General Issues in Localization

Several related ideas animate localization claims. First, localization need not mean there is just one place where all activity related to the processing of, for example, sounds, or syntax, or semantics is done. Keep in mind the organization of Figure 1. In particular, different effects may appear for *system internal* processes (e.g. relations of sounds to sounds, or syntactic categories to syntactic categories, etc.) as compared to interface processes that relate sounds to words, or word forms to meanings or syntax, etc. System internal processes do pose the question of whether brain regions select for one type of structure. But brain responses that combine two or more structural types are also to be expected, and identifying which combinations of structure are associated with specialized brain activity may reflect system interfaces. Still another question is this: if there is a brain region for function X, is it specific to language – i.e. is it dedicated to language *per se*, or does it also serve other mental systems? It is perfectly possible to find a positive outcome for association of brain regions with specific structural types, and a negative outcome for specificity to language *per se*. Current evidence does not provide definitive answers for all variants of localization questions. There is good reason to claim brain specialization for language processing, with localization for syntactic aspects

most sharply defined. The possibility that some regions of specialization for language may also serve other mental functions remains open.

An Overview for Brain and Language Relations

As preliminary orientation, the regions of brain implicated by discussion in later sections are outlined in Figure 2. Localization questions arise at two levels. One is lateralization (hemispheric specialization). Many observations show differences between left and right hemispheres for the support of language. The second level of localization claims is finer grained. It associates focal areas of the left and right hemispheres with different language functions. A word about variability regarding localization is in order before proceeding further, however.

Discussion here assumes the dominant patterns of localization, but two exceptions should be kept in mind. First, some left-handers (about a third) have reversed lateralization. This is complementary to the pattern in almost all right-handers and the majority of left-handers. In reversed dominance, right hemisphere regions homologous to left hemisphere regions support language processing. This systematic variation poses no great theoretical problem. A second exception is more challenging. There is evidence for significant individual variability in language areas. Such variation in expression does not itself invalidate the idea of functional localization. It does highlight the need for precise accounts of mechanisms that produce localization and how they account for variability. This issue is not well understood and is a matter of active research. With these reservations in mind, significant generalizations can be summarized. Despite the variability just discussed, the association of major language functions with particular brain regions is robust.

Figure 2 shows the left hemisphere as the major focus of language activity. The notion that left and right hemispheres support different cognitive and perceptual functions is widespread in popular culture. Left brain thinking versus right brain thinking is a cliché. But, clichés sometimes reflect important truths, and that is so here. Many specializations of the hemispheres exist and that for language is among the most compelling, but here too there is indication of the brain's dissection of language: not all of language is strongly lateralized. Interpretive functions and lexical representation are more distributed between the hemispheres, and aspects of speech perception are bilaterally represented as well. By contrast, the structural core of morphology and syntax supports the clearest claims for lateralization. Aphasia patterns and split-brain patients' performance reflect this. That evidence is complemented by brain imaging and electrophysiology studies. Historically, perisylvian areas of the left hemisphere (Broca's area and Wernicke's area) were identified as the primary language areas on the basis of aphasic disturbances. More recent evidence using better tools for the identification of lesion site and effects, coupled with imaging data from normals, has broadened the regions of language-responsible tissue in the left hemisphere and implicated some right hemisphere activity.

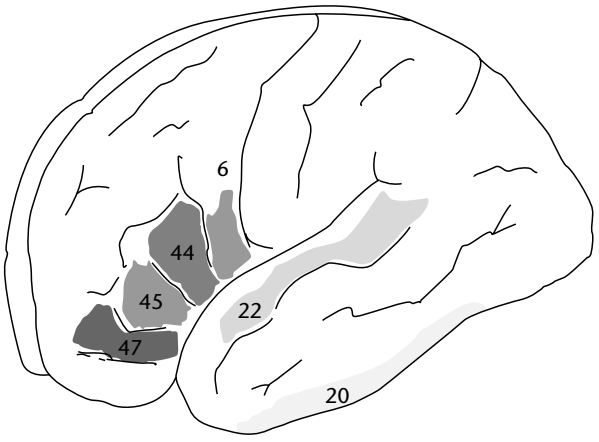

Figure 2. Left lateral view of the brain, labeled for cytoarchitectonic areas (viz., Broadman's areas: BA 20, BA 22, BA 44, etc) referred to in the text. Contrasting colors indicate areas responsive to distinguishable language processing activities as discussed in the text.

- BA 20: inferior temporal gyrus
- BA 22 Anterior portion; posterior portion of area 22 is in the region called Wernicke's area
- BA 44: Pars opercularis; in the region called Broca's area
- BA 45: Pars triangularis; in the region called Broca's area
- Area 6: anterior Rolandic operculum

THE APHASIAS: PATTERNS OF BREAKDOWN IN LANGUAGE FUNCTION

Aphasia is the general term for language-specific deficits caused by brain injury. The plural form 'aphasias' signals the fact that many subvarieties of language compromise exist. Brain injury usually causes multiple cognitive problems, but some deficits can be quite selective – features of sound structure, word structure, sentence structure, and meaning all seem isolable. Brain damage can pick

out a particular piece of the language repertoire and leave the rest largely intact.

Some History

How can such a variety of language impairments arise? The relevant history begins with two pioneers whose names survive as labels for the constellations of symptoms they reported: a French physician, Paul Broca ('Broca's aphasia') and a German physician, Carl Wernicke ('Wernicke's aphasia'). In 1861, Broca identified patients with damage to fronto-temporal areas (Broca's area, Figure 2) who showed hesitant speech ('nonfluent') marked by omission or reduced use of certain grammatical classes (verbs and some classes of function words and inflections); comprehension was relatively well preserved. A few years later, in 1874, Wernicke reported a contrasting pattern for patients with damage to posterior regions of the temporal lobe (Wernicke's area, Figure 2). Their speech remained fluent and superficially grammatical but had frequent errors for phonological and semantic features of words; comprehension was seriously impaired.

These patient groups differ in almost every way. Nonfluent Broca patients, with relatively good comprehension, have impaired production of syntactic structures (described as agrammatism). By contrast, the fluent Wernicke's patients, with poor comprehension, produce syntactically complete structures but make semantic errors in word selection (described as paragrammatism). The losses seem complementary and arise from very different lesion sites. These contrasts were interpreted for a long period in terms of a model that identified posterior language zones with comprehension and the anterior language zone with production. Other aphasic patterns were linked to damage to underlying fibers (the *arcuate fasiculus*) linking the two areas. The resulting model (the Wernicke–Lichtheim Model) and its variants provided the classic account of aphasia until about three decades ago. Several findings then began to erode confidence in the presumed functions of Broca's and Wernicke's areas.

Problems for the Classic Account: Behavioral Inconsistencies

An influential series of studies in the 1970s demonstrated that many agrammatic aphasics have comprehension limitations that mirror their production problems. When such patients must rely on syntactic cues (of the sort missing from their speech), comprehension is impaired. Their successful comprehension relies on lexical semantic cues. So, they understand sentences like 'The flowers were watered by the girl' based on (preserved) knowledge of plausible relations between objects and events in the world; but such knowledge is not decisive in sentences like 'The boy was pushed by the girl' – syntactic detail is essential. In these circumstances, agrammatics perform poorly. This fostered the idea that basic syntactic capacity resides in Broca's area.

This idea did not survive long. Very shortly, patients were reported who displayed agrammatic speech but had no comprehension problem. Moreover, still other patients showed comprehension deficits but no agrammatic symptoms. Even more perplexing, other tests of agrammatics showed they could correctly judge the grammaticality of the very sentences that they could not interpret. They showed a syntactic loss in one domain, but not in the other. All this rules out an exclusive association of Broca's area with syntactic capacity – and it begins to suggest problems in processes that integrate different types of structures as opposed to loss of a specific structural type. Other complications exist, but these suffice to illustrate the difficulties in explaining language deficits with the components of the classic aphasia theory. A richer set of assumptions about brain and language is required.

Other Problems for the Classic Model: Lesion Data

The perisylvian areas of the left hemisphere are undoubtedly central to language function, but saying precisely how has been a vexed matter for aphasia. Careful examination of large numbers of patients with contemporary methods of observation has revealed a poor fit between Broca's aphasia and classic lesion sites. One finds patients with agrammatism but no lesion in Broca's area and patients without Broca's aphasia with a lesion in Broca's area. Moreover, other areas (area 22, anterior portion Figure 2) are statistically better linked to Broca's aphasia than Broca's area itself.

The evidence conflicts in some respects. Why? Does it invalidate the idea that focal areas for language exist? Not necessarily. There are other good reasons for variability in the lesion data. First, lesion site is only a part of the story. Lesions also vary in size and character. Moreover, reduced activation in adjacent tissues is known to be important, but has been hard to evaluate in patient populations. Recent imaging studies have verified

and clarified this factor: the observable lesioned area does not fully identify the regions of compromised neural function. When this fact is coupled with variability of localization across individuals noted earlier, it helps explain why the lesion landscape is so hard to interpret.

Variable lesion data complicates inferences about specific brain areas and language functions. But, a salient fact remains: the existence of many highly selective language deficits is not open to serious question. Thus, although one may have difficulty in saying exactly which region of brain is the locus of an effect, the inference that there are specific brain regions for language functions seems correct. The isolability of language processes regarding brain activity is attested even if the physical base is uncertain on lesion evidence.

Other Important Performance Issues: The Modes of Language Exercise

Attention has so far focused on types of structure, but modality is also important. Modalities include speaking and listening, reading and writing, and spoken versus signed languages. These modes of language may be independently affected in aphasia. Production and comprehension may be separately affected, with loss of a structurally defined capacity in production and its preservation in comprehension (and vice versa). Written language (at several levels) can be affected independently of spoken expression (and vice versa). Moreover, some aphasic disorders are mirrored in acquired reading problems ('dyslexias') – structural contrasts for language compromise appear across modality.

Visual/manual-based languages, such as American Sign Language (ASL), are of special significance. The basic grammatical structure of ASL is like that of spoken language, and aphasias in ASL show similar structural bases to those of spoken languages. In ASL, gestural systems can be selectively impaired in ways that mirror spoken language deficits (while preserving nonlinguistic gestural capacity). This is a striking result, given that important visual processes are specialized for right hemisphere function, but careful study of ASL users with brain damage indicates that language functions are left lateralized in ways comparable to spoken language users.

Moral: the many subsystems for implementing language are represented in the brain in ways that allow selective interference from physical damage, and do so in similar ways across domains of performance. On any account of language disorders, the affinity of phonological, morphological, and syntactic language functions for a relatively circumscribed set of areas in the left hemisphere remains a central explanatory challenge for brain and language theories.

DISORDERS OF SEMANTIC MEMORY AND LEXICAL ACCESS

Lexical structures are an essential resource for sentence level processes. Knowledge of the structures peculiar to individual words guides language generation and comprehension. Is X a noun, a verb, a quantifier? Does it have morphological parts? How is it pronounced? What does it mean? Such information must be accessible in different ways. To talk, the words that express a thought must be picked from all the words a speaker knows. Experimental study of normal language processing indicates that this is a two-stage process, one meaning based and one form based. The initial step links a lexical concept with a word representation that provides only its semantic and syntactic characteristics. A second step connects this abstract representation to sound structures for pronunciation. Similar ideas apply in access for comprehension (See Figure 1). How is such lexical processing represented in the brain?

Dissociations of Meaning, Syntax, and Form

Various errors of meaning (e.g. saying 'sword' for 'arrow') and form (e.g. saying 'sympathy' for 'symphony') are frequent in language pathologies (and not uncommon in normal speech and reading). One finds well-attested cases of patients whose errors primarily involve meaning relations or primarily word form failures, and this dissociation can arise either for production or for comprehension. Aphasic patterns demonstrate that meaning-based and form-based systems of lexical recognition and retrieval can be separately affected by brain injury.

Outright retrieval failures are also common in aphasia. 'Anomia' is the cover term for word finding difficulties – well-known words are not available for utterance. A similar phenomenon in normal language users is the 'tip of the tongue' (TOT) state. The sharp pang of failure to recover a well-known word is a universal subjective experience. Indeed, naming failures in anomic patients have parallels to those of normal speakers in TOT states: dissociations of semantic, syntactic, and phonological levels of word description are observable in both groups. To illustrate: anomics usually

have detailed semantic and conceptual information about a target picture they cannot name. But syntactic features of blocked words may also be available. Tests of anomic patients in languages with gender marking systems (e.g. Italian, German, Spanish) show this. Grammatical gender is tested because it is a feature of syntax that can be distinguished from conceptual and semantic covariates. So, for example, in Italian, different varieties of pastas may be masculine, feminine, or neuter, as are rocks of varying size (pebble, stone, bolder), etc. Italian anomics can report the grammatical gender of a target word with high accuracy even when unable to provide any information about its pronunciation. Similar dissociations arise for normal speakers in TOT states. All this demonstrates that sound structures for words are distinguished from their meaning and syntax in both brain and behavior.

Syntactic Lexical Disorders

Lexical deficits can also pick out syntactic categories. Nouns can be selectively impaired in anomic patients. Striking cases of this are seen in patients who speak in fluent, syntactically well-organized and communicatively appropriate sentences but do so with greatly diminished ability to recover contentful nouns. These are replaced by pronouns or nonspecific nouns ('thing', 'place', 'stuff', etc.). Verbs, by comparison, are specific and appropriate. Interestingly, a contrast with this pattern is typical for many Broca's aphasics for whom verbs are more compromised than nouns.

A second kind of syntactic loss was earlier remarked in discussion of agrammatism. It involves failure to recover function words and some word affixes (e.g. inflections for number, tense, and aspect). This set is sometimes labeled the 'closed class vocabulary' to call attention to its stability – new nouns and verbs are invented as the need arises, but new function words and affixes are rare in language change. This stability makes sense. Closed class words are tied to enduring structural properties of a language. They convey grammatical relations and functions rather than referring to objects, events, and properties. Broca's aphasics show a diminished capacity for such words. Certain reading disorders (deep dyslexia) are also marked by much poorer ability to read closed class words as compared with major category words.

These patterns are robust, but their explanation in terms of storage or processing theories of the lexicon, or relations to brain structure, is not well understood. Localization accounts based on lexical representations seem unlikely for such broad ranging category effects. General computational mechanisms for syntactic analysis and composition are more likely candidates.

Category-Specific Semantic Deficits

Selective semantic losses are also found. Aphasia research has yielded several reports of word losses restricted to particular meaning classes: such as inability to name pictures of animate objects while succeeding with pictures of inanimates, or relative success with all word classes except, for example those referring to fruits. These category-specific lexical losses are not the consequence of conceptual level impairments. Such patients may make accurate non-linguistic judgments about a problematic word and provide detailed information about its reference ('it's small, you use it for cutting paper; it's made of metal…') while unable to name it if it is an artifact. The same patient may succeed with tests on animate objects, naming even rather exotic animals. The reverse pattern has also been reported. Deficits may be quite circumscribed: body parts, foods, flowers, vegetables, musical instruments, and tools are among other reported examples.

What about brain areas linked to these deficits? The lesion data are variable – some cases arise for diffuse damage, and others are more localized. Multiple brain mechanisms are likely to be implicated across the affected categories. Moreover, the numbers of patients showing well-defined losses is not large. Not surprisingly, controversy surrounds accounts of category-specific losses, but that discussion is beyond the scope of this article. However, studies that combine aphasia information with brain imaging do give some helpful insights. A good example compares brain areas for patients with losses in one or more of these sets: famous faces, animals, and tools. In one such study of naming by aphasics, impairments for these three categories were associated with lesions in different parts of the left temporal lobe but outside the usual perisylvian language areas (area 20; see Figure 2). The results were complemented by a positron emission tomography (PET) study with normals showing activation of these areas during picture naming for the categories. Do these selective losses reflect localization driven by meaning features for words? Analysis of the deficits for faces, animals, and tools suggests not. Some patients showed mixed losses – two categories impaired, but not the third. Not all combinations occurred. Faces and animals did coincide, but tools and faces did not. Why? One might

first suppose the similarity of the semantic representations is at work. People have faces and people are animals. Tools and faces should contrast, and indeed, they did not co-occur. But the third pairing does not fit this picture: animals and tools did co-occur. Furthermore, lesion data and the PET study showed the tools area separated from faces by the animal area, so two isolated infarcts would be required to get tools and faces while preserving animals. The effect seems to reflect spatial distribution, not meaning similarity.

HEMISPHERECTOMY AND SPLIT-BRAIN RESEARCH: DETAILS OF LATERALIZATION

Surgical procedures undertaken to alleviate otherwise untreatable neurological conditions turn the spotlight on right hemisphere (RH) language functions. 'Split-brain' patients reveal RH language capacities in adult brains with established left lateralized language prior to surgery. By contrast left hemispherectomized patients reveal the potential for language development by infants who must rely only on RH. The implications are complementary: the split-brain research shows significant RH language capacity even in left lateralized brains, while hemispherectomy research shows sophisticated language processes can be acquired in RH. The flip side is that both classes of data also suggest that some language capacities are specific to the LH and that these involve aspects of the syntactic organization of sentences.

Split-Brain Patients

Certain medical conditions require a surgical procedure that severs the channels of communication between left and right hemispheres (the corpus callosum). When the callosal fibers are cut, each hemisphere operates independently. The hemifield structure of the visual system allows selective stimulation of LH or RH (inputs to the left hemifield of each eye project only to RH and vice versa for the right hemifield of each eye). Thus, procedures that project words to one or other hemifield can test individual hemispheric capacity, to judge, for example the suitability of lexical targets for given syntactic or semantic environments. In such tasks, the RH supports accurate semantic decisions about words and can process the syntactic structure of simple sentences. Complex syntactic structures are beyond its apparent capacity.

What interpretation should be put on this? Should LH/RH contrasts be seen as exclusive specialization and the limited success of RH a residual but irrelevant capacity (low-level redundancy) with regard to normal language use – perhaps left over from early stages of development during which left dominance is established? Or does the RH provide useful language support that is normally invisible because the LH controls overt language expression? Some hints favor the latter perspective. Speech processing illustrates this. Both hemispheres are involved in the translation of acoustic inputs to phonetic structures, but recent research indicates different functions for the hemispheres. Speech perception maps a complex set of acoustic cues onto phonetic categories. RH and LH appear sensitive to different classes of these cues (steady state versus transient). There is hemispheric asymmetry, but it is complementary rather than competitive. The extent to which this perspective should be generalized is not clear, but there is other suggestive evidence. For example, reaction time studies of word priming (e.g. word 1 of a successively presented pair of words facilitates decisions for word 2) show a complementary sensitivity of RH and LH to associative relations (e.g. fire/hydrant, fossil/fuel) versus semantic relations (e.g. categorial relations: plant/flower, horse/dog). RH performance emphasizes the former, and LH the latter. A potentially related effect arises in studies of lexical ambiguities: RH may support recovery of nondominant senses of ambiguous words.

Hemispherectomy Patients

Surgical intervention for a congenital neurological disorder (Sturge–Weber syndrome) requires removal of the entire LH ('hemispherectomy'). Infants who undergo this procedure (in the first year of life) develop apparently normal communicative language capability. The RH can, if the process begins early in life, assume major LH language functions. A similar conclusion derives from observations of childhood aphasia. Effects of brain damage are dramatically different in very young children compared to adults. Children rapidly recover normal language function after injuries that would leave an adult with an enduring deficit. Language functions are apparently taken over by nearby LH brain areas or by RH regions homologous to the LH language areas.

These observations suggest early equipotentiality for language in left and right hemispheres, with a commitment of left hemisphere tissue that becomes increasingly fixed with age. But, there is an important caveat: adult syntactic performance in hemispherectomy patients is not fully comparable to normal performance. Complex syntactic structures

are more difficult for such patients to comprehend or produce. This limitation indicates a LH priority in language development. Evidence from a quite different source supports the same conclusion.

Another Learning Perspective

Developmental research supports the idea of sensitive periods in language acquisition. Success in attaining nativelike performance by second language learners depends on when exposure to the second language begins. Experimental tests have shown detection of grammatical violations (e.g. word order or agreement errors) to be less accurate for those who learn a second language 'late' (after about 5 years old) compared to those who learn earlier. The effects are graded (systematically poorer performance is associated with increasing age of first exposure). Is this sensitive period linked to hemispheric specialization? Brain imaging effects suggest so: early learners displayed sharply lateralized LH brain activation when they heard syntactic violations. But learners whose exposure to the target language was delayed by a few years had RH activation as well as left. By contrast, tests of semantic violations in the same groups did not show a sensitive period. Early and late acquiring groups showed similar brain responses for words that did not fit the meaning of test sentences. These and related findings indicate localization depends on the stage of brain development at which processing is acquired. Further, the consequences of lateralization seem most sharply focused on the syntactic devices of language. This developmental picture thus fits neatly into the framework that emerges from aphasia, hemispherectomy, and split-brain research.

BRAIN IMAGING: MEASURING ACTIVATION DURING LANGUAGE PROCESSING

Imaging approaches compare neural activation in different brain areas during mental activity. A prominent example is PET, which measures variation in blood flow to different brain regions as indexed by the concentrations of a weak (harmless) radioisotope injected prior to observation. Another example is fMRI (functional magnetic resonance imaging), which measures blood flow based on changes in the magnetic properties of red blood cells. These and related measures have been the focus of intense activity over the past two decades, and the 1990s saw extraordinary advances in their reliability, precision, and availability.

Imaging Studies Contrasting Semantic and Syntactic Processes

Many imaging studies have used the strategy of comparing semantics and syntax, and distinct patterns for syntactically and semantically based judgments have been repeatedly observed. In one such study, listeners had to judge whether two sentences had the same meaning. One experimental condition varied content words, and so judgment required a lexical semantic process. A second condition varied ordering of phrases, and so required a syntactic process. Activation areas differed: syntactically driven judgments produced activation in a *subpart* of Broca's area (pars opercularis), while semantically driven judgments activated an area below Broca's area (Figure 2, area 47). Several other imaging studies requiring semantic processing have also showed activation in this latter area and area 45. From study to study, regions in or near Broca's area appear as a focus (see Figure 2), but there is some variation in the detailed activation patterns. The variation may reflect differences in tasks and materials, along with possible individual subject differences.

The preceding example highlights a semantics and syntax contrast in anterior language regions. Semantic responses occur elsewhere in other imaging work, including more posterior areas. Earlier discussion of semantically specific lexical losses also cited areas outside the classic language zones associated with identification of persons, animals, and tools. Moreover, split-brain research indicates significant RH lexical competence. Imaging outcomes support this as well. In general, imaging work shows lexical representations and meaning-based processing broadly distributed in the left hemisphere, with both anterior and posterior regions represented and right hemisphere activation commonly observed.

Syntactic Responses in Brain Imaging

A preoccupation of aphasia research has been the relation of syntactic deficits to Broca's area. Imaging studies that vary syntactic complexity amplify the aphasia work. As syntactic processing demands increase, activation levels in responsible areas should increase. A contrast in relative clause structures illustrates this. Compare: 'The dog the boy teased bit him', versus 'The dog bit the boy who teased him'. These two make the same set of claims about the world – they mean the same thing – but the organization of information differs. Behavioral measures show the first (with a

center-embedded relative clause) is more difficult for normal listeners than the second (a right-branching relative clause). Moreover, agrammatic aphasics have difficulty with center-embedded structures when they lack semantic cues that tell who did what to whom. When syntax load varies but semantic content does not, what is the imaging result? PET studies showed selective activation in Broca's area. In some studies, a subpart of the area called 'pars opercularis' (Figure 2, area 44) was again singled out. Other imaging experiments, using fMRI measures, have also manipulated syntactic complexity. These too reveal activation in Broca's area, though with some variation for locations within the region. A related observation that does not rely on complexity *per se* is that differential responses to open and closed class vocabulary also implicate a part of Broca's area. Given the association of this vocabulary contrast with syntactic processes, the result makes sense, but it is not clear how it should be linked to the work involving complexity. Overall, this work affirms a syntactic role for Broca's area, though it leaves open questions about what aspects of processing are involved and how they relate to each other.

To this mix, a modality factor must be added. A few imaging studies have tested syntactic processing in production rather than comprehension. Recall that the initial characterization of Broca's area in aphasia assigned production processing as its primary function. That claim is not supportable for the full range of aphasia observations. What does imaging research contribute? Recent imaging studies show selective activation for syntactically structured as compared to unstructured word strings in a production task. These were equated for the conceptual input that drives encoding, but activation was not in Broca's area. It was immediately adjacent (Figure 2; left anterior Rolandic operculum). There is, thus, good reason to locate multiple language functions in or near Broca's area and these include several structural types and modes of processing.

ELECTROPHYSIOLOGY: LANGUAGE PROCESSING SYSTEMS

Measurements recorded from scalp electrodes (electroencephalography) have been used to study perceptual processes for many decades, with wide applications in health-related areas. An adaptation of those techniques (event-related potentials: ERP) can be used to study cognitive processes. Recordings are time-locked to presentations of a specific class of stimuli and the signal averaged across many examples to extract regularities associated with a stimulus type. The onset and duration of a brain response to different language structure types can thus be estimated and compared. Characteristic response patterns are defined in terms of scalp location of recording electrodes, time course, and polarity of the electrical signals. The sources of these electrical changes (generators) are difficult to pinpoint precisely from scalp recording, but different patterns at quite separate electrode sites indicate different underlying brain processes. Moreover, there is substantial correspondence between variation in ERP recording sites and imaging results regarding the general locales for different classes of processes.

Semantic and Syntactic Contrasts in Electrophysiology

A classic study of language using ERP methods revolves around responses to semantically incongruous words in sentences. A characteristic waveform (N400) is robustly triggered by the appearance of an unexpected word, as, for example 'socks' in 'She spread the warm bread with *socks*'. The N400 label reflects the characteristic negative polarity and latency of this response to reach peak amplitude. The pattern of activity is similar across several electrode sites – it is not tied to a narrow range of recording locations. It is virtually absent at anterior sites, bilaterally represented at most posterior sites, and often more prominent at right hemisphere locations. Discovery of this regularity was a milestone in language study and generated many studies that explore semantic processing, most specifically aspects of integrating the meanings of individual words into the overall interpretation of a sentence.

Note, however, that an N400 is not elicited by syntactic deviations (as agreement errors or grammatical category violations). Thus, the imaging results mentioned above, showing distinct regions of activation for semantic and syntactic tasks, have a corresponding contrast in electrophysiological measures.

Syntactic Contrasts in Electrophysiology

Work in several languages (English, Dutch, German, Italian, and others) shows two classes of syntactically driven ERP patterns. These are the P600 and various anterior negativities in the 200–400 millisecond range. Though all have syntactic triggers, there are important differences in the conditions that elicit them.

Many studies have demonstrated a sustained positive polarity shift that normally peaks around 600 ms following a syntactic violation site (P600). This response is broadly distributed, as is the N400, but it is very different in polarity and latency from that associated with semantic violations. P600 shows effects both of syntactic acceptability and of relative probability of syntactic analysis. When two analyses are syntactically possible partway through a sentence, a P600 can be triggered by a word that requires the less preferred (less frequent) of the two.

A rather different complex can also be triggered by syntactic violations, but as compared to P600 the conditions that elicit it are more restricted. These responses involve negative polarity shifts at anterior recording sites. They range in latency from 200 ms to 400 ms and contrast with semantically driven responses in recording sites and latency. They are strongly lateralized to the left in some studies and bilateral in others. Sentences with memory requirements tied to moved elements (e.g. question forms and center branching relatives) have been shown to produce a bilateral anterior negativity around 400 ms after the element that signals the movement (e.g. the relative pronoun or question word). More strongly lateralized response patterns have been observed for syntactic violations involving phrase structure and morphological errors of inflection. Latencies vary from 200 to 400 ms for these responses across studies from different languages and task variables. Moreover, among the strongly lateralized left anterior responses, several studies indicate an ERP signature for closed class words (N280). This latter finding has a rough parallel in the imaging work showing a left anterior locus for contrasts of open and closed class vocabulary.

Comparison of these two classes of syntactically driven ERP responses suggests interesting processing interpretations. The strongly left lateralized anterior negativities arise only for syntactic violations rather than syntactic preferences or interpretive strategy. By contrast, P600 is also modulated by multiple nonsyntactic influences (task strategies and syntactic preferences both syntactic and semantically driven). The differences are thus suggestive of early and late stages of sentence integration, with early reliance on relatively inflexible automatic processing routines, while later stages show accommodation to multiple constraints on the final analysis and interpretation of a sentence.

SUMMARY

Several conclusions supported by evidence from aphasia and brain injury are refined and extended by contemporary measures of brain activity. In the process the early aphasia-based picture of localization has been extensively redrawn. Several findings are instructive.

First, imaging studies confirm the involvement in language processing of the major regions of perisylvian cortex identified on the basis of lesion data from aphasia study. But, regions associated with various lexical and interpretive processes are widely distributed. Imaging and ERP data have made it clear that there is more RH activity during language processing in left lateralized brains than was supposed. Regions associated with syntactic integration are more circumscribed but nevertheless represented at more than a single site. More particularly, however, imaging studies show multiple regions within Broca's area and immediately adjacent areas that are associated with distinguishable processing tasks. These include both syntactic and semantically based processes and include comprehension and production modes. In short, the language-responsible tissue in the perisylvian areas of the frontal, temporal, and parietal cortex shows a structure more in keeping with a co-ordinated multicomponent system than a monolithic segregation into meaning-based comprehension processes and form-based production processes.

Electrophysiology shows distinct semantic and syntactic processing systems but also evidences of semantic and syntactic integration systems. Within the systems triggered by syntax, there is a contrast between processors sensitive to a limited range of morphosyntactic and phrasal variables and processors responsive to a broader range of syntactic processes. These latter reflect interactions between syntactic structures and semantic constraints. Though localization issues for electrophysiological signals measured at the scalp are problematic with regard to underlying brain regions, the general distributional features of the scalp recording sites for the several different ERP patterns are broadly compatible with the distribution of language-responsible areas revealed in brain imaging.

Sound systems, syntactic systems, and semantic systems are all complex. None of them are 'one thing'. And they interact with each other in diverse ways. The newer information sources emphasize the need to provide accounts of how different information classes in language systems interact to yield the rapid and highly accurate performance profiles of human language use. The specificity of response measurable with contemporary tools of observation now has the potential to discriminate the details of sophisticated accounts of structure and

processing provided by linguistic and psycholinguistic theory.

CONTENTS

Language comprehension processes are those by which people extract meaning from texts, whether written or spoken. Researchers have developed a variety of experimental methodologies in order to study these processes.

INTRODUCTION

The term 'cognitive science' has come to represent a wide variety of disciplines, each with its own methods and objectives. However, cognitive scientists as a whole are working towards the same ultimate goal – to discover how the complex processes of the mind operate. Given the somewhat enigmatic nature of human mental processes, one problem faced by researchers has been how to measure the activity of the mind. An early solution was to use introspection, wherein subjects were presented with a stimulus and were simply asked to relate their subsequent thoughts and feelings to the experimenter. Unfortunately, although some facts regarding the human mind may be ascertained through introspection, introspection alone proved to be largely uninformative. Introspective data tended to be: (1) highly variable across subjects; (2) frequently invalid; and (3) often strongly biased by individuals' preconceptions. What's more, many mental processes occur too quickly to be measured by conscious report, and some processes occur without any conscious awareness at all.

Given the early failure of introspection, cognitive scientists began to develop a number of tasks and paradigms – both generalized and specialized – in order to observe, record, interpret, and predict the activity of the mind. In this article we will discuss a number of such tasks and paradigms that have been utilized by researchers in order to study language comprehension processes. Specifically, we will delineate how each has been used to examine how people extract meaning from both written and spoken language. Since most of these techniques have been shown to have both strengths and weaknesses, we will also discuss some of the limitations inherent in various tasks.

REACTION TIME MEASURES

Reaction time measures are arguably the most common procedure for tapping into comprehension processes, and cognitive scientists generally use such measures to examine the relative time course of a process. In general, reaction time (RT) is defined as the interval between the presentation of a stimulus and the onset of the subject's subsequent response. This interval is typically measured with a high degree of precision (e.g. in milliseconds), and response types may vary from simply naming the stimulus to making a more complex decision, such as deciding whether two words are related in meaning to one another.

Naming and Lexical Decision

In the naming task, subjects are simply asked to articulate a word (or a pronounceable nonword) and reaction times are measured from the presentation of the stimuli to the onset of the named response. By contrast, in the lexical decision task, subjects are asked to decide whether a letter string is a word (e.g. DESK) or a nonword (e.g. DOSK), with reaction times measured from the presentation of the letter string to the onset of the word/nonword response. In the past, the most popular

usage of these tasks has been to determine the time course of visual word identification. For example, when extraneous factors such as word length and syntactic class are controlled, naming and lexical decision times for high frequency (more common) words are shorter than those for low frequency (less common) words. However, one problem with such tasks is that overall response time is not simply a measure of word identification, since both naming and lexical decision times also include the time it takes a subject to formulate and initiate the appropriate response for the task (i.e. an articulation or a manual button-press). Furthermore, it is not clear whether such responses even require the subject to identify the stimulus. The naming task, for example, simply requires the subject to pronounce a string of letters based upon grapheme-to-phoneme conversion rules without necessarily requiring that word meaning be accessed (e.g. most people can formulate a pronunciation for BLICKET, although no corresponding meaning exists in the lexicon). Similarly, in the lexical decision task, subjects may be able to judge whether a letter string is a word by simply basing their decision on the familiarity of the letter string rather than on the actual identification of the word. This does not necessarily mean that these tasks are insensitive to semantic properties of words – quite the contrary, naming and lexical decision tasks have been shown to exhibit effects of word frequency and familiarity, which would be unlikely unless some aspect of word meaning was accessed. Despite these limitations, response times in these tasks may be used to classify the upper limits of the time course for word recognition. However, many researchers have used naming and lexical decision tasks in conjunction with other tasks to determine whether the patterns of reaction times converge (see Taft, 1991).

Priming and Masking

Two methodologies have emerged which are often used in conjunction with naming and lexical decision. One paradigm, priming (Meyer and Schvaneveldt, 1971), typically involves the presentation of a sequence of two words: a prime followed by a target. Subjects are then asked to make a decision regarding the target word, and the researchers measure how quickly they are able to respond. One early finding that emerged from priming studies is that when the prime is semantically related to the target (e.g. DOG followed by CAT), subjects respond more quickly than when the prime is not semantically related to the target (e.g. PEN followed by CAT). This indicates that the relationship between prime and target words influences processing time on the target.

A second paradigm, masking, also examines word identification time by limiting the exposure of a stimulus. For example, the word DOG may be presented for 60 ms, at which time DOG disappears and is replaced by a pattern mask consisting of either a series of X's or of random letters. As with many reaction time measures, the masking paradigm has been useful in allowing researchers to examine the time course of lexical processing. Studies utilizing masking, for example, suggest that subjects may extract information from words which are presented for even very brief durations (e.g. 30 ms).

More recently, a paradigm which combines priming and masking procedures, masked priming, has been used to shed light on the early stages of word comprehension. In this paradigm, subjects look at a fixation target and a mask is presented followed by the brief presentation of a prime word which is then followed by a target word (presented for about 200 ms) which is in turn followed by another mask. Although subjects are generally unable to identify the prime word, it still has an effect on their report of the target word.

Dual Task

The dual task paradigm is often used to study attentional processes, and it follows two basic assumptions: (1) that subjects have a limited processing capacity, and (2) that different cognitive activities may make use of different processing resources. For example, subjects may be asked to read sentences while listening for a tone. If response times are slower when performing two tasks simultaneously as compared to performing a single task (e.g. simply reading sentences), this would be evidence that both tasks are drawing upon the same cognitive resources. Further, the rate of slowdown may also indicate the degree of resource utilization.

One example of the dual task paradigm is phoneme monitoring. Most often, phoneme monitoring is used to study speech comprehension, and it involves listening to auditorily presented sentences while monitoring for a particular phoneme (e.g. to detect the /ba/ sound while listening to the sentence 'The emperor went to the royal baths'). Thus the two tasks are to comprehend the sentence and to press a button when the target phoneme is detected. The idea is that if contextual or lexical processing prior to the target word (*baths* in this

example) is difficult, it should take subjects longer to detect a target phoneme. For example, subjects are slower to detect a phoneme when the target word is preceded by an ambiguous word.

Researchers utilizing this task are often interested in determining the basic units of speech perception or in studying the processing complexity of sentence contexts, lexical ambiguity, and attentional issues. However, the data emerging from phoneme monitoring tasks are often affected by a number of extraneous variables such as the frequency of targets across sentence stimuli, the discriminability of the phoneme, target word length, and the frequency of the target word in which the to-be-detected phoneme is located.

Speed–Accuracy Tradeoff

In addition to the dual task paradigm, another technique puts subjects under various types of speed constraint. For example, one variation of the technique involves training subjects to respond immediately upon the presentation of a signal that occurs at various times after the end of a sentence (which the subject reads and presses a button to indicate completion of reading). Accuracy of a decision made about a sentence increases as the response deadline increases. The manner in which reaction times and errors trade off against each other as the response deadline increases (or decreases) can therefore reveal information about processing activities. The major concern with this technique is that it may induce strategies that are specific to the demands of the task.

PROCESSING TIME AND OTHER MEASURES TO ASSESS COMPREHENSION

The reaction time measures discussed above are most commonly used when the unit of interest is a single stimulus (e.g. a word). Researchers interested in examining readers' comprehension of larger units, such as sentences or sentence phrases, may use one of a variety of processing time methodologies. By manipulating characteristics of the text, researchers can infer selected attributes of comprehension processes. In these tasks, subjects may be asked to read a paragraph/sentence while elapsed reading times are recorded (so that paragraph reading time or sentence reading time is measured). Similarly, subjects may be given a limited amount of time to read a portion of text while error rates are recorded.

Self-paced Reading

Sometimes, if an experimenter is interested in how long it takes a subject to read a segment of text, measuring overall reading times for sentences or paragraphs may be too imprecise. In the self-paced reading task, the experimenter controls the amount of text that the subject can see at any one time, and the size of the segment (e.g. a word or a clause) available to the subject is generally a function of the topic under investigation. When the subject has finished reading one segment, they push a button and the next segment of text is presented. When only one word at a time is presented, this procedure yields a processing time measure for each word in the text. A variation of this task is called the *makes sense* task, in which subjects advance word-by-word through a sentence as long as it makes sense. However, when the sentence no longer makes sense, or becomes ungrammatical, subjects push a different button.

One problem with the self-paced reading task is that it does not mimic natural reading. Reading times in the self-paced reading paradigm are slower (about half as fast) than those in more natural reading tasks since subjects must press a button to read subsequent segments of text. Since it takes longer to manually press a button than it does to move the eyes, words stay on the screen for about 400 ms in this task, as compared to average eye fixation times of approximately 250 ms in natural reading. Given that reading in the self-paced paradigm is slower in general, one possibility is that subjects may develop different comprehension strategies. It should also be noted that self-paced listening paradigms have been used to study speech perception. Similar concerns regarding strategic effects also apply to this paradigm.

RSVP

Natural silent reading involves moving the eyes to successive segments of text – hence the reader controls how quickly text is read. By contrast, in the rapid serial visual presentation (RSVP) task, the experimenter controls the rate at which text is presented. In this paradigm, the subject sits in front of a computer screen while new words are presented one at a time for various durations (e.g. 50 to 400 ms). Studies utilizing this technique have found that readers can comprehend short passages of text which are presented at rates of up to 1200 words per minute, with a new word being presented every 50 ms. Interestingly, when each word

is presented for 250 ms, reading comprehension in the RSVP task is often better than in natural reading.

This paradigm has several limitations. First, although comprehension performance is high for short passages of text, as the amount of text increases, comprehension begins to suffer. This is partially because RSVP reading disallows regressions back to previously read text, thus preventing readers from looking back at 'misunderstood' portions of text (during normal reading, readers make regressions on approximately 10 per cent of all fixations). Moreover, RSVP reading is also mentally taxing for subjects, as it requires their constant attention to text.

Phoneme Restoration

The self-paced reading and RSVP tasks described above are generally utilized to measure higher-order cognitive comprehension processes in reading. In contrast, the phoneme restoration effect has most commonly been used to measure lower-order, perceptual processing. The phoneme restoration effect is an auditory illusion that arises when part of an utterance is either deleted or replaced by an extraneous sound such as a cough or white noise. In such instances, listeners often perceptually fill in (restore) the missing phoneme and report that they heard the complete utterance. When utilized as a dependant measure in cognitive science, the phoneme restoration paradigm is used to examine the activation of sublexical phonemic structures (see Samuel, 1996 for a brief review of the literature). Early studies using this method found that psychoacoustic factors related to the nature of the replacement sound (e.g. amplitude, frequency) affected the probability of detecting the missing phoneme. Subsequent studies have shown that the restoration effect is also influenced by word length, lexical neighborhood size, and sentence context. More generally, subjects' ability to discriminate between an intact utterance and one in which a phoneme has been replaced by an extraneous noise is a function of perceptual processing difficulty – as the demand for processing resources increases, discriminability decreases.

Effects emerging from the phoneme restoration paradigm are typically replicable and valid, but the paradigm is sensitive to small changes in methodology. For example, differences in effects may arise between studies when experimenters utilize different forms of extraneous noise, even if the same independent variable is manipulated in both studies. Hence, experimenters need to take care in selecting the nature (e.g. cough, noise), phonemic class (e.g. vowels, stops), and position (e.g. initial, medial, final) of the replacement sound.

EYE MOVEMENTS

With the continuing development of technological innovations, some researchers have begun to replace (or supplant) reaction time and processing time paradigms with eye movement measures. In a typical eye-tracking experiment, subjects read sentences presented on a computer monitor while their eye movements are recorded. Researchers then look at patterns of readers' eye movements noting, for example, how long readers' eyes remain fixated on words or phrases within sentences, how far readers' eyes move from fixation to fixation, or how frequently readers' eyes regress back to reread text.

Eye movements have been utilized to study a variety of language comprehension processes, and data gleaned from eye-tracking studies have been found to reflect moment-to-moment cognitive processes. One early finding was that where readers look and how long they look there is directly related to the ease or difficulty of cognitive processing. For example, when extraneous factors are controlled, fixation times are longer for lower frequency words, which are less likely to be encountered during reading, as compared to higher frequency words, which are more likely to be encountered during reading. Eye movements have also been used to examine the effects of lexical ambiguity, morphological complexity, discourse processing, semantic relatedness, phonological processing, syntactic disambiguation, and the perceptual span (see Rayner, 1998 for an extensive review of the eye movement literature).

A number of methods have emerged within the eye-tracking paradigm including the development of the *eye-movement contingent display change* paradigm. In this paradigm, text displayed on a computer screen is manipulated as a function of where the eyes are fixated. As readers' eyes move across a line of text, letters or words may be modified in foveal, parafoveal, or peripheral locations, thus allowing the experimenter to control the nature and amount of information available to the reader. One variation of the eye-movement contingent paradigm is the moving window paradigm. In this paradigm, as readers move their eyes across the text, upon each fixation, text is exposed within an experimenter-defined 'window' while all text outside the window is altered in some way (e.g. all letters might be replaced by X's). Wherever the

reader looks, the text within the window is available. The logic of the paradigm is that when the window is as large as the region from which information can normally be obtained, reading will proceed as smoothly as when there is no window (normal text). Using this technique, the size of the perceptual span in reading has been determined.

Another variation is the boundary paradigm, in which characteristics of a target word in a particular location within a sentence may be manipulated. For example, in the sentence 'The man picked up an old map from the chart in the bedroom', when readers' eyes move past the space between *the* and *chart*, the target word *chart* would change to *chest*. In this manner, researchers can examine the types of information (e.g. orthographic, phonological, semantic) that readers obtained from the target word prior to fixating upon it.

A final variation is the fast-priming paradigm, in which a prime word is briefly presented for a very short duration (i.e. less than 50 ms) and is immediately replaced by a target word. Primes may be related in meaning to target words, but they may also be phonologically related (e.g. BAT-CAT) or orthographically related (e.g. BENCH-BEACH). This paradigm has been used to examine the time course of word processing.

One advantage of using eye movements over reaction time and processing time measures is that it allows researchers to study comprehension processes in a more natural setting. As mentioned previously, one disadvantage of reaction time and processing time measures is that they may result in the formulation of task-specific strategies or may simply slow the reading process. In the eye-movement paradigm, readers are free to read text as they would during normal reading. Moreover, eye-movement measures are flexible, allowing researchers to examine both fine-grain and coarse-grain language comprehension processes.

Finally eye-movement recording techniques have been utilized in the context of speech understanding. It has been demonstrated that when subjects listen to a narrative while a scene is presented in front of them which depicts objects in the narrative, their eyes tend to move to those objects that are mentioned in the narrative. This technique allows researchers to make inferences about on-line speech perception (see Tanenhaus and Spivey-Knowlton, 1996).

PHYSIOLOGICAL MEASURES

Since the 1980s, a number of physiological measures in addition to eye movements have been developed to study cognitive processes. These measures range from simply recording heart rate to recording more complex physiological activity, such as measuring changes in the magnetic activity of atoms within the brain. It is hoped that by using such measures, scientists will be able to accomplish two major goals: (1) to locate language comprehension regions (or pathways) in the brain, and (2) to more closely examine the time course of cognitive activity within the brain. Although there are a large number of physiological measures, in this section we will focus only on those measures which involve examining activity in the brain (see Gazzaniga, 2000 for a more complete review of physiological measures).

ERP

Among the most common physiological measures used today is event-related potentials (ERPs), which involves placing electrodes on the scalp. By averaging electrical potentials on the scalp over a number of trials, researchers hope to time-lock brain activity to a particular sensory event (e.g. the presentation of a word stimulus). The voltages associated with brain activity vary in both polarity and magnitude over time, resulting in a series of electrical 'peaks and valleys'. For example, when subjects are presented with a semantic incongruity, a relative large negative potential (i.e. a valley) occurs about 400 ms after the presentation of the stimulus (this is termed an N400 wave).

One advantage of using ERPs over other methodologies is that they may allow experimenters to more directly examine the time course of language comprehension processes within the brain itself. On the other hand, there is no guarantee that the ERP activity being measured is the direct result of a particular cognitive process, as opposed to being the result of later (e.g. memory) processing.

PET

Positron-emission tomography (PET) scans are based on a somewhat different framework than ERPs. This method involves the ingestion of a small amount of radioactive material which may be traced and used to measure blood flow in the brain; cognitive activity is represented by changes in blood flow to specific parts of the brain. Although the results of PET scans often involve complicated patterns of metabolic activity, studies using them have found that many different parts of the brain are involved in language comprehension (including

parts of the left temporal, parietal, and frontal cortex).

This complexity is perhaps the greatest disadvantage to the PET methodology. It is perhaps not surprising that language comprehension involves the coordination of a number of brain systems, but the metabolic activity measured by PET scans may also reflect additional processing not directly related to language. For example, researchers have found increased metabolic activity in brain systems which are not specific to language processing *per se*. Specifically, studies examining reading processes have found increased metabolic activity in the anterior cingulate cortex, which is normally associated with sustained attentional processing, as well as in the contralateral cerebellum, which is thought to be involved in the rapid shifting of attention.

MRI/*f*MRI

Magnetic resonance imaging (MRI) and its newest counterpart, functional magnetic resonance imaging (*f*MRI), are based on a framework similar to that of a PET scan – namely, that sensory, motor, and cognitive tasks produce a localized increase in neural activity which gives rise to subsequent increases in blood flow. MRI is very generally based upon the detection of electromagnetic signals which emanate from such increases in blood flow. Researchers utilizing MRI technology to examine language processes are typically interested in localizing language comprehension functions in the brain. For example, in a baseline condition an experimenter may present subjects with a word and simply require the subject to look at the word. In another condition, subjects may be asked to decide whether the word represents a living thing. Differences in neural activity between the two conditions can then be used to determine the region in the brain used in processing aspects of word meaning.

One advantage of the MRI/*f*MRI paradigm is that it is relatively non-invasive and represents little health risk to subjects (as opposed to PET scans which involve the ingestion of potentially harmful radioactive materials). In addition, they permit the experimenter to collect hundreds (or even thousands) of images from a single subject, with highly accurate spatial resolution. MRI technology is also becoming increasingly available to cognitive scientists, as many hospitals have MRI facilities.

The MRI/*f*MRI paradigm also suffers from several disadvantages. The most significant limitation is that temporal resolution is relatively poor (e.g. although it may only take about 250 ms to recognize a word, an *f*MRI can only acquire data in about two to three seconds), thus disallowing any clear examination of the time course of language processing. However, some scientists have also begun to combine the temporal resolution of ERPs with the spatial resolution of *f*MRIs. In addition, as mentioned earlier in reference to PET scans, a great deal of activity in the brain occurs which is only indirectly related to language functions, resulting in some degree of difficulty in localizing areas in the brain specific to language comprehension.

Finally, in addition to the recent *f*MRI methodology, cognitive scientists have begun to explore the potential of a relatively new physiological measure. The magnetoencephalogram (MEG) measures the magnetic fields which result from the electrical currents inherent in neurons. The advantage to MEG is that the sources of magnetic currents are more easily localized than are the sources of electrical currents (as measured by a more simple electroencephalogram), and the hope is that MEG measures will allow a more accurate topographic mapping of brain function.

CONCLUDING REMARKS

Given the rapid, complex, and sometimes unconscious nature of human mental processes, cognitive scientists have been forced to develop a growing number of empirical methods in order to study the activity of the mind. Analogous to the telescope of the astronomer or the electron microscope of the chemist, the tools and methods of cognitive science serve to enhance our limited physical senses, and they allow us to observe cognitive processes which were previously beyond our grasp.

Language Comprehension

Introductory article

Morton Ann Gernsbacher, University of Wisconsin, Madison, Wisconsin, USA
Michael P Kaschak, University of Wisconsin, Madison, Wisconsin, USA

CONTENTS

Language comprehension is the process whereby linguistic input (spoken or written) is transformed into meaning.

INTRODUCTION

Language comprehension is the process whereby information is extracted from speech or written text, resulting in the apprehension of the meaning of the language. Most research on this topic has focused on the comprehension of written text, rather than conversations. Despite the complexity of the processing involved, most humans are able to comprehend language quickly and efficiently. This efficiency is, in part, due to two types of knowledge that can be brought to bear on the task of determining the meaning of an utterance. The first is linguistic knowledge: knowledge of the syntax and lexical items of the language. Syntax provides the comprehender with cues as to which words go together, and as to who is doing what to whom in the sentence. The lexical items refer to the specific objects, actions, states, or relations between things that are being discussed in the sentence. The second source of information is what has been called 'world knowledge', or knowledge about how the world works. This knowledge is useful in filling in details of events and situations that are underspecified in the linguistic input. (*See* **Syntax**; **Lexicon**)

INTEGRATING MEANING AND GRAMMATICAL INFORMATION

The process of comprehending language might be described as follows. First, words must be recognized from the perceptual input (spoken or written) to the comprehender. Then, the comprehender must determine how these words are arranged into sentences. One step in this process is to try to analyze the string of words into a series of chunks, called phrases. This analysis is performed according to the comprehender's knowledge of the syntax of his or her language. (*See* **Parsing**)

Syntax is a set of rules that constrains the ways in which the words in a language can be fitted together to form a sentence. For example, the syntax of English provides the following rough stipulations about how words can be combined:

- Noun phrases (NP) are phrases in which a noun may be preceded by a determiner (*a*, *an*, *the*) or adjective (e.g., *the big red truck*, *the truck*, *red trucks*).
- Verb phrases (VP) are phrases in which a verb may be followed by a noun phrase or prepositional phrase (e.g., *kicked the ball*, *threw the ball over the fence*).
- Sentences contain noun phrases and verb phrases, and typically take the form NP–VP (e.g., *the big red truck bumped into the small white car*).

On the basis of one's knowledge of syntax and one's knowledge about the words in the sentence, a sentence like *the big red truck bumped into the small white car* can be broken down into the phrases *the big red truck* and *bumped into the small white car*. This is an important step in language comprehension, because this grouping of the input into phrases ('parsing') tells the comprehender who is doing what to whom in the sentence. In this example, the syntax of the sentence specifies that the truck bumped into the car. If the phrases are changed around (*the small white car bumped into the big red truck*), the relationship of the objects mentioned in the sentence changes. The parsing of a sentence can sometimes be difficult, but once the comprehender has determined how the linguistic input can be broken down into phrases, he or she can apply knowledge of the syntax of the language to get an initial sense of the action described in the sentence.

CHOOSING THE CORRECT SENSE OF A WORD

Parsing is but one component of the initial processing of speech or written language. Indeed, the comprehender cannot group a string of words into phrases until he or she knows what the words are, whether the words are nouns, verbs, adjectives, and so on. Beyond knowing what part of speech each word is, the comprehender also needs to retrieve information about what the word means. Determining what a word means can be difficult in some cases. Some words, such as *bug*, have many meanings ('insect', 'surveillance device', 'bother'). Given a sentence that begins *there was a bug …*, which meaning of *bug* should be chosen?

Research has shown that multiple meanings of *bug* are often initially activated by the language comprehension system. Then, within milliseconds, the appropriate meaning is selected, and the other meanings are discarded. The inappropriate meanings are deactivated through a process known as *suppression*. When information is suppressed, it is inhibited from being accessed. By dampening the activation of the inappropriate meanings, the language comprehension system ensures that the correct meaning will be available for generating the meaning of the sentence.

Sometimes, information is chosen through the opposite process, known as *enhancement*. Information that is enhanced is given a boost in activation relative to other available information. For instance, a story might be written that includes several characters interacting: Joan, Mary, Simon, and Jane. If the story repeatedly mentions Mary and the things that Mary is doing, her representation will be enhanced relative to those of Joan, Simon, and Jane. At some point in the story, the pronoun *she* might appear. To whom does *she* refer: Joan, Mary, or Jane? Because Mary's representation is enhanced relative to those of Joan or Jane, the comprehender will assume that *she* refers to Mary.

Thus, by selectively suppressing and enhancing information, comprehenders can select the appropriate meanings of the words they encounter. These word meanings, in conjunction with the comprehender's syntactic analysis, can be used to build the meaning of the sentence in which they appear.

BRIDGING INFERENCES

The language that we process is typically not in the form of isolated sentences like *the big red truck bumped into the small white car*. Rather, we encounter language within a rich context, such as a story, a conversation, a description, or a teaching session. We have considered some ways in which a single sentence could be understood; but how is a series of sentences understood as a whole? (*See* **Discourse Processing**)

Consider the following pair of sentences: *It was a cold winter morning. As Harriet made her way down the front steps, she fell and broke her leg*. These sentences are syntactically independent (it was cold outside; a person named Harriet broke her leg); however, most comprehenders will assume that they relate to the same situation. In fact, most readers will interpret the two sentences as implying that there may have been ice or snow on the front steps, which caused Harriet to fall. This information is nowhere to be found in the two sentences; so readers must use their background knowledge of winter weather to infer it from the information that is explicitly stated. This inference is called a *bridging inference*. It is generated in order to connect the information presented in different sentences.

Bridging inferences arise when readers make use of their world knowledge in interpreting language. World knowledge refers to a general store of information that humans possess about the way the world operates. For example, we know that birds fly to get from one place to another, but dogs walk or run. We know that people ordinarily make their way down front steps easily, but may slip and fall if the steps are icy. When readers encounter language about a particular situation, such as walking down steps on a cold winter morning, they are able to use their knowledge about such situations to go beyond the information literally presented in the sentences in order to build an understanding of what the language is communicating.

AUTOMATICITY OF INFERENCE GENERATION

We know that inferences are generated during the reading process, but there is some debate as to when inferences are generated automatically and when they are generated through some effort. In the example above, one can ask if the inference that the front steps were icy is automatically generated by readers, or if it is generated only in certain conditions, such as when the reader is being particularly attentive to the details of a story.

There are two basic positions in this debate. According to the 'minimalist' position, a comprehender draws an inference only when either the information leading to that inference is highly available, or the inference is necessary to maintain

the coherence of the text. According to the 'constructivist' position, a wide range of inferences are generated as a matter of course during reading, not just the minimum set of inferences needed for understanding. It is likely that the correct resolution of this debate is an intermediate position. Readers will make the inferences necessary to meet their goals in processing the text. Thus, if they are only skimming the text to get the gist of what happened, they will make few inferences. If they are reading the text in detail, they will make a more elaborate set of inferences.

BUILDING DISCOURSE REPRESENTATIONS

As a series of sentences is processed, the language comprehension system accumulates the information presented across the sentences into a discourse representation. This representation, often called a 'mental model', is a cumulative record of the information and events presented in the text. Mental models are representations of what the language is about, rather than representations of the structure (e.g. syntax) and lexical information in the linguistic input. (*See* **Mental Models**)

Mental models are built by creating a representation in memory into which information from the present situation can be inserted. This representation may be described metaphorically as a mental 'stage'. At the beginning of a story, a new mental stage is created. As characters are introduced in the story, they are placed on the mental stage. The actions of the characters are performed on the stage. By updating the mental stage with information from successive sentences in the story, the reader can keep track of who has done what to whom and where the characters are at the present time. In this way, the reader is prepared to receive information about what happens next. The same general processes operate in building mental models of texts that are not stories.

Mental models appear to be particularly sensitive to spatial and temporal information. Thus, in keeping a record of what happens on the mental stage, readers can keep track of which things (or people) are close to each other, and which are not. They can also keep track of which events belong to a single temporal unit (e.g. what happened when two characters went to the movies), and which events belong to different units (e.g. what happened on Thursday and what happened on Sunday). The selection of what information is tracked and what is not appears to be influenced by the goals of the reader.

INDIVIDUAL DIFFERENCES IN COMPREHENSION

Most humans learn to process language quickly and efficiently. But there are noticeable differences in how quickly and efficiently different people comprehend language. There are two basic explanations of this.

According to the 'capacity' account, people differ in the capacity of their working memory. Working memory is important in language comprehension because words and syntactic structures need to be held in memory until a given sentence has been processed fully. In addition, working memory is needed to manipulate information in mental models. Readers who have a large working memory capacity will be able to handle a lot of information when processing sentences or building mental models, and will thus be good at language comprehension. Readers with smaller capacity will lose some information from working memory during comprehension, and will consequently be less efficient in language processing. (*See* **Language Comprehension and Verbal Working Memory**)

According to the 'skill' account, better readers are those who have more experience reading, and thus have more skill in performing the mental computations necessary for comprehension. Although these views are often presented as opposing theories, it is likely that they are both correct in some sense. Language comprehension undoubtedly relies on keeping information in working memory, and so readers with better or bigger working memories will be better comprehenders. At the same time, it is likely that the reason why some readers can store more information is that they are more skilled at manipulating the information that is maintained in working memory.

Language Disorders

Intermediate article

Yosef Grodzinsky, Tel Aviv University, Tel Aviv, Israel; McGill University, Montréal, Canada

CONTENTS

Language disorders (as distinct from communicative deficits) provide an important tool for research on brain–language relations.

INTRODUCTION

The neurosciences seek to understand how the healthy brain works. What, then, is the reason to study it in disease? Language as a cognitive capacity is investigated intensively; yet under what guise do disturbances to language and speech become a topic for scientific inquiry? One undisputed goal is remedial: we study pathologies in order to cure them. Yet there is another, less obvious goal: We would like to study language diseases as a vehicle for biologically-based componential analyses of the human language faculty. Deficit analyses have been an extremely valuable research tool for over a century, providing a critical testing ground for theories of brain–language relations.

This article begins with an attempt to situate the language faculty within the human communicative system. This allows us to distinguish between linguistic disorders and other communicative pathologies. A selective review of exemplary pathological phenomena follows. We conclude with a discussion of the relevance of these phenomena to neurobiological and (psycho)linguistic approaches to natural language.

COMPONENTS OF COMMUNICATION

Communication involves interlocutors, communicative means, and media. For a successful communicative act, at least two interlocutors, a common code, a medium in which signals in this code can travel, and a common universe of discourse, are prerequisite. In humans, the language faculty constitutes a part of this scheme. Communication is fragile, as each part of the systems is liable to problems: a deaf ear, a broken wire in a telephone conversation, or a gap in the knowledge that the interlocutors share, are among the many possible disruptions that might bring about communicative breakdown. Note that communicative disorders need not be consequences of deficits in the language faculty. While most public aspects of our mental life are conveyed through language, a linguistically manifested disorder is not necessarily a language disorder. It is important, therefore, to be explicit about what language is, so that a delineation of its disorders would follow. We begin with a brief sketch of the language faculty as conceived by some major theoretical frameworks.

The Structure of Linguistically Represented Knowledge

The human language faculty consists of a system of knowledge, and neural mechanisms that implement it using dedicated algorithms. Briefly, the knowledge consists of a finite set of elements (symbols), and a finite set of combinatorial rules, which concatenate the elements into strings (phonetic units into phonemes, morphemes, words, phrases, sentences, and so on up to meaningful expressions and stories). This knowledge is multifaceted: it is divided into distinct levels in which formal rule systems operate over structured inventories of elements – phonetics, phonology, morphology, syntax, and semantics. Thus a speaker possesses a universal phonetics, a system of phonological elements from which sound sequences in his or her language can be created (and analyzed), a system of morphological elements and rules for words, a syntax, and a system for interpretation. This knowledge is formal, specific to the language capacity (as distinct from other cognitive capacities), and

cerebrally represented. It constitutes a biological module, putatively distinct from other knowledge bases and mental processes. This is the 'mental organ for language', for which Chomsky has argued so vigorously (e.g. Chomsky, 1995). (*See* **Government–Binding Theory**; **Morphology**; **Syntax**; **Phonology**; **Learnability Theory**; **Phonetics**)

During linguistic communication, the speaker puts to use mechanisms that regulate the production of utterances, and mechanisms involved in their reception. Yet these do not operate in isolation: a communicative act cannot be successful unless a host of nonlinguistic communicative skills are also invoked. Although the main vehicle for communication is language, other abilities are required: the abilities to integrate a sequence of sentences into a story, to make eye contact and take turns in conversation, to make inferences, to gesture, and to grasp irony, are all highly relevant to an individual's communicative functioning; and, while they interact with linguistic principles, they are neither governed by them nor mediated by linguistic processes in the head. Knowledge of the world is also linguistically communicated, but is not part of language.

This distinction is critical for a proper understanding of the nature of communication. In the present context, the specificity of the language domain demonstrates the communicative, rather than linguistic, nature of a number of linguistically manifested disorders. The deep involvement of language in cognition sometimes blurs the distinction between the two types, but we have ample scientific as well as clinical reasons to make it. Before we focus on true language disorders, we will provide a short survey of communicative disorders that are not linguistic.

LINGUISTICALLY MANIFESTED DISORDERS THAT ARE NOT LANGUAGE DISORDERS

Among the disorders that affect linguistic communication there are several pathologies for which a true language disorder can be ruled out with relative confidence. In some cases, direct language testing has determined the intactness of the language faculty; in others, indirect test results, or clinical descriptions, lead to a similar conclusion.

Autosomal Dominant Speech Disorder

Linguistic geneticists believe that they found a 'language gene'. This is mostly due to the discovery of the KE family in Scotland, whose members' phenotypes manifest a severe disturbance of speech and language. The disorder seems to follow from an autosomal dominant trait: half the family members in three generations (15 out of a total of 31 individuals, of both sexes) are affected; the offspring of an unaffected member are unaffected; and half the offspring of an affected member are affected. A series of sophisticated molecular and bioinformatic techniques were used to locate the disorder in a region on chromosome 7. Researchers have administered a variety of speech, language, and other cognitive tests in an attempt to distinguish impaired from healthy members. Yet among the many tests (e.g. of memory, lexical decision, naming, grammar, and meaning), only three established a 'characterizing phenotype', i.e. a deficit shown by every affected member but not by any who are unaffected. These deficits related to: word repetition; non-word repetition; and simultaneous and sequential orofacial movement to command (Lai *et al*., 2001; Vargha-Khadem *et al*., 1998). None of these tests pertains to an essentially linguistic rule system, or to components thereof. For all we know, then, this genetic disorder is not linguistic, although it is has a very adverse effect on linguistic communication.

Williams Syndrome

Chromosome 7 appears to be a locus related to communication. Williams syndrome also results from mutations in it, in this case spontaneous deletions. This syndrome is often mentioned in the context of language disorders. But it may instead be an extreme case of linguistic modularity: that is, outstanding linguistic ability accompanies moderate mental retardation. Consider these utterances, recorded from Williams syndrome patients by Ursula Bellugi and her team (Bellugi *et al*., 1998, p. 183):

> 'When I got up the next morning, I talked but I couldn't say anything so my mom had to rush me to the hospital.'

> 'There is a huge magnetic machine. It took a picture inside the brain. You could talk but not move your head because that would ruin the whole thing and they would have to start all over again. After it's all done they show you your brain on a computer and they see how large it is. And the machine on the other side of the room takes pictures from the computer. They can take pictures instantly. Oh, and it was very exciting!'

An impaired language faculty could hardly produce sentences like these (note that they are

phonetically well formed – the speech of Williams syndrome children is not garbled). Upon formal testing of their receptive and productive abilities, these patients show a linguistic ability on a par with normal children of their mental age, suggesting that their impairment is not linguistic (Zukowski, 2000). (*See* **Williams Syndrome**)

Autism

Autistic children are usually diagnosed on the basis of impaired development in communication, social interaction, and action. Given this broad range of problems, is language a primary source of their deficit? The available evidence suggests that the problem manifests, at least in part, as an inability to attribute beliefs to others, or to see things from a perspective other than one's own. This is the well-known 'theory of mind' disorder. The evidence concerning language appears contradictory. In at least one major study, autistic children were indistinguishable from controls in their language; another major study, however, documented many differences in language skills: children (who were normal in the domain of articulation) varied greatly in their ability in the various grammatical domains (Kjelgaard and Tager-Flusberg, 2000). The conflict among these studies, and the degree of variation, suggest that language is sometimes affected in autism and sometimes not. Even when it is, the nature and degree of the impairment are not clear. It is difficult to reach a definite conclusion on the basis of such evidence (which is a result of sound research on large numbers of cases). It may be that the linguistic disturbance is a consequence of a more general cognitive impairment that is projected onto communicative skills and hampers aspects of language use. To classify autism as a language disorder would thus be misleading.

Schizophrenia

Standard descriptions of schizophrenia explicitly mention a language disorder as part of the symptom complex. For example, Andreasen (2000, p. 107) states:

> Schizophrenia is characterized by symptoms that reflect multiple mental processes: hallucinations, or abnormalities in perception; delusions, or abnormalities in inferential thinking; disorganized speech, or abnormalities in language; disorganized behavior, or abnormalities in behavioral monitoring and control.

Upon closer examination, the relevant aspect of the disturbance looks different: while productive abilities of schizophrenic patients appear impoverished, they do not appear to be linguistically ill-formed (either grammatically or semantically). On the view of language described above, the cognitive disorder from which these patients suffer is not linguistic. They may use fewer words than normal, but no phonological or morphological errors are reported; their sentences may be short and low on content, but incorrect syntax or incoherent meaning are not central features of the disease. Some descriptions refer to an inability to make proper inferences, a 'negative thought disorder', failures to integrate texts, and 'discourse coherence' disturbances (somewhat reminiscent of right-hemisphere-damaged patients), but there is nothing in their communicative problem that suggests a disturbance to language mechanisms (Barsch and Berenbaum, 1997).

CONGENITAL AND DEVELOPMENTAL PATHOLOGIES THAT ARE LINGUISTIC

Dyslexia and Developmental Reading Disorder

Some reading disorders have been explained in terms of deficits in phonological awareness. The argument is that because alphabetic writing systems require that the reader and writer have awareness that words are made up of individual speech sounds (i.e. phonemes), insufficient awareness of the speech segments in spoken words would impede learning to read and write. Young children and poor readers have been shown to be lacking in awareness of the sound structure of words, as demonstrated by failures on metaphonological tasks. It is now known that very young children lack phonological awareness; that they acquire it over several years; and that many children when they begin school are deficient in phoneme awareness and find the writing system difficult to acquire. This problem has been related to observed deficiencies in auditory processing, which have been increasingly documented in reading-disabled children.

It is not clear what the causes of this failure are. One influential approach has attributed developmental reading (and some writing) disorders to a processing limitation. On this view, there is an informational 'bottleneck' in the course of processing from form to meaning. This bottleneck can manifest in phonological disorder in spoken language comprehension, or in a reading disorder when an orthographic code is involved. Poor readers have been found to fail in tasks that require auditory comprehension of syntactically complex

sentences (e.g. relative clauses such as *point to the butterfly that the kangaroo is flying over*). More generally, it is claimed that limited processing resources (a bottleneck) may affect all levels of linguistic analysis, reading being a special, more tangible case (Shankweiler and Crain, 1986).

The Neurobiology of Developmental Dyslexia

The co-occurrence of reading disorder, possible auditory processing deficiencies, reduced right–left asymmetries in a cerebral region (planum temporale), and cortical malformations at the cytoarchitectonic level (microgyria), has inspired research into the neural basis of dyslexia. A group of researchers led by Norman Geschwind and Albert Galaburda have developed methods to model such neural defects in laboratory animals (although obviously the animals cannot read). The modeling focuses on certain properties of brain cells in animals and humans, similar in health and disease, in ways that may lead to a deeper understanding of the neural mechanisms that underlie congenital dyslexia. These models currently point to a neural antecedent of an auditory processing deficit that presumably causes dyslexia in humans (Rosen *et al*., 2001). This line of research is promising, and has attracted a lot of interest. It remains to be shown how this defect is projected further up the language processing system, to cause problems located at higher levels of language processing, most notably problems of sentence comprehension. An explanation of this would represent a major advance towards a truely biological model of language processing.

Specific Language Impairment

There is a fairly large group of children whose language abilities in all modalities remain immature while their peers master language fully. This is called 'specific language impairment' (SLI) or child dysphasia. SLI children are generally a rather heterogeneous group, but certain interesting subgroups have been identified, and investigated extensively. One such subgroup tends to omit, or substitute, certain grammatical morphemes, despite having normal intelligence and relatively few deficits in the phonological or semantic domains. This is observed in many languages, in forms that, by and large, fall under a small set of generalizations. The fact that many of these children are otherwise normal, and suffer from a highly specific, grammatical deficit, implies that this is a true language disorder. Moreover, there is evidence that certain aspects of the disturbance are in fact delays in normal grammatical (as opposed to cognitive) development. (*See* **Developmental Disorders of Language**)

Three questions remain: (a) what is the reason for this disorder, (b) what is its correct characterization, and (c) how can it be fixed. Regarding (a), while no biological element (brain area, or a gene) has been tied to SLI directly, there are some reasons to believe that there is a genetic component in SLI. As for (b), one influential approach has proposed that SLI children are delayed in that a stage that is fairly short for non-SLI children – a stage in which certain grammatical rules are optional – is extended in SLI for a long period of time. This has led to (c) attempts to help these children overcome the difficulty by helping them, through remedial teaching, to get beyond optionality (Leonard, 1998).

ACQUIRED LINGUISTIC PATHOLOGIES

Aphasia

Acquired aphasia is a collection of linguistic impairments, mostly subsequent to organic brain disease. Central to this extensively studied group of disorders are impairments due to focal brain lesion. Focal lesions (common etiologies of which are stroke, intracranial hemorrhage, protrusion wound, and brain tumor) are contrasted with diffuse lesions, due to neurodegenerative disease (e.g. Alzheimer's disease), anoxia, and other circumstances that affect brain tissue in a nonfocal fashion. Scientifically, the most important aspect of the aphasias is their selectivity: a well-delineated brain region is affected, bringing about a selective functional impairment. Localization, accompanied by a precise characterization of the functional damage, might improve our understanding of the brain mechanisms of language, as well as our ability to restore them.

Injury to several different cerebral locations brings about language problems of different kinds. Here we will focus on limited aspects of a narrow range of pathologies, mostly those interpretable within current theories of linguistic representation and processing: namely, the Broca's and Wernicke's aphasias, which are subsequent to lesions in the frontal and temporal lobes, respectively, of the left cerebral hemisphere, and are traditionally characterized as problems of language production and reception, respectively.

The language 'centers' were initially thought of as governing receptive or expressive modalities.

But as research progressed it became clear that the emphasis should be placed on grammatical rule systems. It was shown that despite the importance of the channels through which language is practiced, the correct (and most telling) unit of analysis for the interpretation of lesion data is the rule type. This applies to phonology, syntax, and semantics. Activities and tasks no doubt play a mediating role in linguistic communication, yet the defining characteristic of the language faculty is the rule systems it possesses. How these rule systems are instantiated in neural tissue then became the central question in neurolinguistics. (*See* **Aphasia**)

In the domain of language production, the brain makes fine distinctions among rule types: Broca's aphasics are deficient in producing tense inflection, but intact in agreement inflection. This has been demonstrated for a wide variety of languages (Friedmann and Grodzinsky, 2000). Cross-linguistic studies further indicate that not only the inflection type of a verb, but also its position in the sentence, determines whether it is produced subsequent to a lesion in Broca's region. (*See* **Tense and Aspect**; **Agreement**)

In receptive language, the distinction between transformational and nontransformational sentences yields a big performance contrast: aphasics with lesions in Broca's region understand active sentences, subject relatives, subject questions, and the like, normally, yet fail on their transformational counterparts: passives, object relatives and questions, and so on (Zurif, 1995). This has led some to the more general hypothesis that in receptive language, Broca's aphasics are unable to compute transformational relations. According to this hypothesis (known as the trace-deletion hypothesis (Grodzinsky, 1986, 2000)), critical components of the mechanisms that underlie transformational analysis are localized in Broca's region. Furthermore, the highly selective character of this deficit has major implications for linguistic theory and the theory of sentence processing. (*See* **Constraints on Movement**)

A particularly compelling argument that supports the localization of transformations in Broca's region comes from cross-linguistic comparisons: Chinese, Japanese, German, Dutch, Spanish and Hebrew have different properties, and the performance of Broca's aphasics is determined by the trace-deletion hypothesis according to the particular grammar of the language. In English, aphasics comprehend active sentence correctly. Yet the finding are different in Japanese, which has two types of actives: *Taro-ga Hanako-o nagutta* ('Taro hit Hanako' – subject, object, verb), and *Hanako-o Taro-ga nagutta* (object, subject, verb). These constructions are simple; they mean the same thing and are identical except that the latter is derived transformationally, with the object moved to the left edge of the sentence. Broca's aphasics handle the subject–object–verb type correctly, but are at chance level on the object–subject–verb type. (*See* **Local Dependencies and Word-order Variation**)

Chinese is generally a subject–verb–object language like English, but heads of relative clauses follow the relative, unlike English in which they precede it. This correlates perfectly with the cross-linguistic results in aphasia: subject relatives are comprehended at chance level in Chinese (sentence 1a) and above chance level in English (sentence 1b), whereas object relatives yield the opposite pattern (sentences 2a and 2b).

a. [_zhuei gou] de **mau** hen da — ***chance***
   chase dog that cat very big
b. **The cat** that [_chased the — ***above chance***
   dog] was very big (1)

a. [mau zhuei_] de **gou** hen xiao — ***above chance***
   cat chased that dog very small
b. **The dog** that [the cat chased_] — ***chance***
   was very small (2)

English and Chinese relative clauses thus give rise to a fascinating mirror-image result pattern, which correlates with a similar syntactic contrast between the two languages. Other interesting cross-linguistic contrasts have also been documented, providing further evidence that Broca's region is critically involved in transformational analysis. Moreover, reflections of the same disruption are also found in the domain of real-time processing (Zurif, 1995). There are further results regarding grammatical aspects of the mental lexicon (Shapiro *et al*., 1993), which are also localizable, as they appear to be retained in Broca's aphasia but severely disrupted after a lesion in Wernicke's area (Grodzinsky, 2000).

While Broca's region appears to govern syntactic knowledge and algorithms that implement it in use, Wernicke's region governs some combinatorial semantic operations. This has been demonstrated by tests of semantic composition that have been administered to both Broca's and Wernicke's aphasic patients. Phonological impairments subsequent to focal brain damage also exist. Thus, parts of the left hemisphere are now believed to govern aspects of combinatorial linguistic knowledge at all levels.

Other Acquired Disorders

Brain disease – whether focal or diffuse – has many possible causes, manifestations and locations. It can produce a multitude of cognitive and affective disorders, many of which have linguistic manifestations. These include the alexias and agraphias, and a variety of pragmatic disorders due to damage to the right hemisphere of the human brain. There are also diseases that bring about diffuse lesions, such as the various dementias. Because these affect multiple cognitive functions, our ability to discern linguistic from other impairments in this class of diseases is severely limited. (*See* **Language and Brain**)

RELATING BRAIN AND LANGUAGE

We have discussed language disorders, but said little about ways to study them. A central and traditional method of investigation is based on error analysis. Most of the results discussed in this article are of this type. The idea is to compare error rates on a given task for deficient and normal speakers, and then try to infer the site of the functional damage.

There are other methods: differences in reaction time, in electroencephalographic (EEG, MEG) and electromagnetic (fMRI) measurements, in measures that involve neuroradiation (PET), and in other kinds of precise measures of brain activity, are used in the effort to understand the brain mechanisms for language and communication. Studies of disordered speakers are conducted in parallel with investigations of intact language users, in the hope of providing not only remedy to the former, but also a comprehensive theory about the latter.

Such a theory is not easy to reach. Any theoretical consideration of brain–behavior relations begins with a complex equation: on one side there are properties of neural tissue, and on the other side, behavior. The relationship between the two sides is highly complex, and understanding it requires, as a first step, a clear set of ideas regarding the proper description of each side. Thus, in the case of language, a comprehensive and coherent picture of what language is – i.e. a general linguistic theory – is a prerequisite.

In this context, the disorders discussed in this article have a dual role. Firstly, they point to natural biological classes among linguistic types. Thus, if brain damage undermines linguistic performance in a particular way (say, it impairs the ability to process inflections), then the line separating the impaired from the preserved must feature in any biologically feasible account of language. Secondly, the patterns of impairment and sparing observed in the various disorders support the claim that a precise neurological account of the language regions in the brain must be based on linguistic concepts. A theory of brain–language relations, then, must be both linguistically and neurologically adequate. This makes the investigation difficult, but interesting and rewarding.

CONTENTS

Incrementality concerns the processing stages of linguistic output: conceptual structure, lexical selection, and generation of grammatical and phonological structure, and suggests that these processes can to an extent run in parallel to aid the speed and fluency of speech production.

INTRODUCTION

In order to express ourselves in speech we must translate some nonlinguistic idea into a fluently articulated utterance. All models of speech production postulate that this translation process occurs in a number of successive steps. The starting point is a conceptual structure for an utterance that details the information or message to be conveyed. Based on this information, the appropriate lexical items are selected and a grammatical structure is generated that places these lexical items in the correct relation to each other. Finally, the phonological structure of the utterance must be generated before articulation can commence.

The question to be addressed in this article concerns the way in which processing at each level proceeds over time and, in particular, how processes at different levels are coordinated with each other. The speed and fluency with which we can articulate complex sentences makes it unlikely that processing at each level is completed before processing at the next begins. Following Kempen and Hoenkamp (1987), Levelt (1989, 1992) proposed that processing at all levels occurs in an incremental fashion with a processor being triggered by any piece of characteristic input from the processors that feed into it. This means that some processing must have occurred at a particular level before processing at the next level can begin, but that processing at all levels can run in parallel on different pieces of the utterance to be produced.

An incremental production system is attractive for a number of reasons. It can explain the fluency of speech because it allows the fast release of formulated chunks of the utterance for phonological processing and articulation. This in turn removes the need for temporary storage of completed chunks of the utterance, thereby reducing processing costs. Finally, incremental processing spreads the costs of production evenly across the period of time in which a sentence is articulated, thus reducing the likelihood of dysfluencies that can result from excessive processing loads. In order to work efficiently, an incremental system requires that processing can occur from left to right in an utterance with minimal look ahead. Thus problems for an incremental system would be caused by evidence of large scope dependencies where processing of a particular fragment of an utterance is dependent on information available in much later fragments. A detailed incremental model of language production must clearly specify for each component process the minimal chunk of information it processes and delivers as output. The sections below discuss the relevant data for the processes involved in lexical access and the generation of grammatical and phonological structure.

ACCESSING LEXICAL INFORMATION

The mental lexicon is a store of words that can be retrieved independently of each other and in any order. The minimal input unit for lexical access is a lexical concept (or, in some theories, a set of semantic features) that maps onto one lexical entry. Such one-to-one mapping occurs, for instance, when a speaker names a single object in one word.

All models of lexical access assume that lexical access is essentially the same for words spoken in isolation and in context. When speakers produce

sentences, they simply retrieve many words. Theories widely agree that lexical selection is a sequential process. Thus, while several lemmas or several word forms may simultaneously receive some activation, their selection as part of the grammatical or phonological representation is a sequential process (e.g. Levelt *et al*., 1999).

In a recent series of experiments testing the sequentiality assumption, the speakers' eye movements were registered while they named picture pairs in noun phrases such as 'the dog and the bike' (see Levelt and Meyer, 2000, for a review). On most trials, the speakers fixated upon each of the objects in the order of mention. Importantly, the viewing time for an object depended on the time required for lexical access to its name. For instance, objects with frequent or short names were looked at for shorter periods than objects with less frequent or longer names. In addition, phonological priming reduced the viewing times. In one study speakers referred to objects in two- or four-word phrases (e.g. 'the dog' versus 'the little brown dog'). Measurements of the coordination of speech and eye movements showed that for both types of phrases the shift of gaze from the first to the second object usually occurred just before the onset of the last word of the phrase referring to the first object ('dog', in the example).

These results support one aspect of the incrementality assumption, namely that speech planning and speaking co-occur in time. However, they do not support another aspect of the assumption, which is that speakers plan different fragments simultaneously. Instead the speakers first focused on one object until they had planned the corresponding utterance fragment down to the level of phonological form, and then turned to the next object.

One may argue that the two-objects naming paradigm is particularly conducive to the use of a sequential planning strategy, and that speakers may often be forced to plan several utterance fragments in parallel. There are, for instance, idioms, such as 'to fall into disuse' versus 'to sink into oblivion', in which the choice of verb and noun seem to be interdependent. However, idioms must be stored in the mental lexicon. Sprenger *et al*. (1999) have proposed to represent them as complex structures including a super-lemma representing the idiom as a whole plus subordinate lemmas representing the individual words. A speaker first selects a super-lemma corresponding to the idiom and then sequentially selects the subordinate lemmas. Thus, idioms do not require simultaneous selection of several lemmas.

Obviously, speakers must often engage in considerable advance planning to decide what they wish to say. For example, when they describe an event, they must first seek to understand who does what to whom. However, these processes are conceptual planning processes. As soon as a coherent message has been generated, it can be used to select lexical items in a strict sequential fashion.

GENERATING GRAMMATICAL STRUCTURE

In an influential theory of speech production, Garrett (1982) suggested that grammatical processes such as lemma access and grammatical role assignment are not incremental but employ a more holistic, clausal scope. Recent empirical work, however, suggests otherwise. In a study by Schriefers *et al*. (1998) participants were presented with incomplete German sentences and required to complete them. As participants completed the sentences they heard distractor words which were either semantically related to the words they were producing, or unrelated. When the distractor word was similar semantically to the first word of the clause produced by the participant, speech onset was delayed relative to the unrelated word, indicating that the first word of the clause had been accessed prior to speech onset. In contrast, when the distractor word was related to the final word of the clause, no delay was found, indicating that the final word had not been accessed prior to speech onset. Similarly, Smith and Wheeldon (1999) found that speech onset latencies were longer to sentences featuring an initial coordinate noun phrase (as in 1) than to sentences featuring a final coordinate noun phrase (as in 2):

The dog and the boot move above the car. (1)

The car moves above the dog and the boot. (2)

Clearly, if participants had planned the entire sentence prior to speech onset we should expect latencies to (1) and (2) to be similar since they feature equivalent numbers of words. In contrast, we should expect longer latencies to (1) than (2) if only the lemmas within the first phrase of the sentence had been accessed prior to speech onset, since the first phrase of (1) contains more lemmas than that of (2).

Crucially, such evidence is supported by observations of naturally occurring language. Using a corpus of English utterances, Clark and Wasow (1998) investigated the frequency of word repetitions such as:

I uh I wouldn't be surprised at that. (3)

Such repetitions were more frequent for the leftmost phrases in a clause than for the rightmost phrases and more frequent for words at the left edge of a phrase than at the right edge. On the assumption that dysfluency frequency is an index of planning load, Clark and Wasow concluded that speakers employ both a clausal and a phrasal planning scope during speech. The phrasal scope fits with experimental evidence of incremental grammatical encoding (Schriefers *et al*., 1998; Smith and Wheeldon, 1999), whilst the clausal scope fits with experimental evidence of holistic conceptual planning (Ford and Holmes, 1978; Smith and Wheeldon, 1999). Despite such evidence of incremental grammatical encoding, there remains debate over whether incremental processing is parallel, with grammatical and phonological planning stages simultaneously processing distinct chunks (De Smedt, 1996), or whether it is serial so that only a single chunk is processed at a time (Ward, 1992).

Finally, there is the question of the minimum size of the chunks employed in grammatical encoding (Schriefers *et al*., 1999). There must be such a lower limit since, in many languages, there is grammatical agreement between elements. Moreover, this lower limit will differ depending on the scope of the dependencies in a given language, for example a noun and a determiner (German) or a verb and a direct object (Swahili). Models of grammatical encoding often assume that the controlling lemma (e.g. the noun in German determiner–noun phrases) transmits features to the controlled lemma, thereby specifying the morphological and phonological form of the controlled element. Since the controlling element can follow the controlled one in the surface structure of the utterance, the controlled element cannot be phonologically encoded or articulated before the controlling lemma has been accessed.

GENERATING PHONOLOGICAL STRUCTURE

Producing the sound form of the selected words in a sentence is a generative process. We do not simply retrieve and concatenate the stored phonological representation for each word. This is because the exact sound structure of a word is dependent on the context in which it is produced.

Levelt (1989, 1992) argued that the unit of phonological encoding is the phonological word – a prosodic unit comprising minimally a stressed foot and maximally a single lexical word combined with any associated unstressed function words (see Wheeldon, 2000, for a review). Levelt claims that the phonological representations of the selected words are combined to form phonological word frames. The phonological segments for each word are made available separately and then associated to the newly constructed phonological word frames in a left-to-right manner. For example, in the utterance, 'I gave it to him', the five lexical items resyllabify to form one phonological word $[aɪ\text{-}geɪ\text{-}vɪ\text{-}tɪm]_ω$ with one main stress. As the segments for each syllable are associated to their prosodic frame they are used to retrieve stored, syllable-sized, articulatory routines (Levelt *et al*., 1999; Levelt and Wheeldon, 1994). When the articulatory routines for the entire phonological word have been retrieved, the phonetic plan can be articulated. Thus, during the production of connected speech, a whole phonological word is constructed before articulation commences.

A number of experimental results provide support for this hypothesis. Using a picture–word interference task, Meyer and Schriefers (1991) found significant priming effects from spoken distractors that overlapped with either the first or the second syllable of the target picture name (e.g. picture: ha-mer, 'hammer'; distractors: *ha-vik*, 'hawk' or *zo-mer*, 'summer'). Moreover, latency to produce a spoken word has been shown to increase with its number of syllables (see Wheeldon, 2000, for a review). These findings suggest that all the syllables of a word are encoded prior to the onset of articulation.

However, these experiments do not distinguish between phonological and lexical words as the minimal unit of phonological encoding. Wheeldon and Lahiri (1997) tested the production of phonological words comprising a lexical word plus unstressed function words. They demonstrated that sentence production latencies are a function of the size of the initial phonological word in the utterance. Latencies for the sentence $[\text{Ik zoek het}]_ω$ $[\text{water}]_ω$ 'I seek the water' were longer than latencies for sentences like $[\text{Ik zoek}]_ω$ $[\text{vers}]_ω$ $[\text{water}]_ω$ 'I seek fresh water'.

However, the syllable latency effect has proved difficult to replicate. Moreover, Schriefers and Teruel (1999) have demonstrated that priming may be limited to the initial syllable of disyllabic words in some two-word utterances. It is possible therefore that while the phonological word may be the preferred unit of phonological encoding it may not constitute the *minimal* unit of phonological

encoding. Indeed it is possible that the unit chosen may differ for different utterances (e.g. single word or sentences) and in different speaking contexts. Finally, there remains the issue of cross-linguistic differences in the scope across which dependencies may operate during the generation of prosodic structure. Lahiri (2000) discusses several tonal and intonation processes in languages that require a processing scope greater than a phonological word.

CONCLUSION

All current models of speech production incorporate some form of incrementality of processing in order to explain both the speed and fluency of speech production. Nevertheless, it is clear that the minimal size of the units that can be processed at each level is constrained by the scope of the linguistic dependencies operating in a given language – and perhaps by differences in the demand for speed in different speaking situations.

Language, Connectionist and Symbolic Representations of

Advanced article

Mark Steedman, University of Edinburgh, Edinburgh, UK

CONTENTS

Connectionist or neurocomputational representations are based on sets of similar, multiple connected neuron-like parallel processing units, the connections bearing modifiable weights adjusted on the basis of locally available information using a learning algorithm. Symbolic representations, by contrast, are defined in terms of rules relating expressions in a formal language. Among the claims that have been made for connectionist models is the 'emergence' of generalizations that had been thought to require the mediation of rule-based grammars and modular symbolic processing architectures. A more convincing linguistic role for such networks lies in their potential for inducing grounded conceptual structure and statistical models as infrastructure for acquisition and processing of standard symbolist representations of lexicalized syntax and semantics.

INTRODUCTION

Connectionist theories of the parallel distributed processing (PDP) variety (Rumelhart *et al*., 1986) begin from the reasonable belief that phenomena of mind are the result of computation in richly interconnected networks of neurons or neuron-like units. They embody the hypothesis that the nature of this computational device critically determines the nature of the computation itself. Symbolic theories begin from the equally reasonable belief that such phenomena of mind as language use, understanding, and reasoning are symbolic in nature, in much the same sense as mathematical and logical inference are, and that the computation involved can therefore be characterized independently of the specific device, whether parallel-distributed or not, that implements it. The connectionist approach is by nature reductionist (in the best sense of a much-abused term): it attempts to generalize from low-level mechanisms to higher-order phenomena. The symbolic approach is phenomenological (again in a positive sense): it tries to work in the opposite direction, from a high-level description to the implicit underlying mechanism. These approaches are clearly compatible, and can coexist. Both are necessary: the interesting question to ask is to which particular problems each is best suited, and under what circumstances they can be unified.

In our present state of knowledge in this rapidly evolving field, the answers to these questions are far from clear. Neurocomputational mechanisms have proved their worth in the field of pattern recognition and classification, where they can extract structure latent in inputs such as images of faces, handwritten letters, and speech, and embody that structure in recognizers that would be impossible to specify by hand, or that are orders of magnitude more efficient than rule-based mechanisms, even when these are statistically optimized. On the other hand, except where they have been used to explicitly simulate the structure of a symbolic parser and associated devices such as the push-down automaton, these mechanisms have been much less successful in demonstrating the kind of recursive productivity that rule-based symbolic systems are good at, or in supporting semantic interpretation and inference.

In contrast, rule-based discrete symbolic systems express productivity or systematicity, semantic interpretation, and processes of inference immediately. However, it has proven very difficult to build rule-based linguistic or computational-linguistic systems with coverage on the scale characteristic of human linguistic and reasoning abilities, and in recent years such systems have increasingly relied upon machine learning and statistical optimization techniques, of a kind closely related in mathematical terms to neurocomputational techniques. It seems likely that there is much to be gained from combining these approaches.

In order to compare the approaches, it is helpful to recall that symbolist theories distinguish a number of distinct components of language processors. One fairly generally applicable architecture distinguishes: (1) a *grammar*, characterized by syntactic and semantic rules of certain classes and a related characteristic automaton; (2) a nondeterministic *algorithm*, characterized by properties such as the order in which rules are applied to strings, whether bottom-up or top-down, the order in which the words of a string are examined, whether first-to-last or otherwise, and certain memory resources, such as those used in building structure and the charts or tables used in parsers based on dynamic programming; and (3) an oracle, or decision criterion for rendering the algorithm deterministic and deciding which rule to apply in cases where there is more than one possibility.

In any given theoretical presentation or implementation, these modules may be combined, but in rule-based theories they can usually be distinguished in functional terms. The fact that they are in that sense distinct modules does not of course imply that the corresponding computations must be carried out in series, in chronologically separate phases: for example, it is quite possible to construct systems in which the oracle can call on the results of semantic interpretation and contextual reference in mid-sentence, while syntactic analysis is still under way.

It is important to be clear on this last point, because the fact that phenomena like 'garden path' effects in parsing can be affected by semantics and even by extrasentential context is often adduced as evidence in specific support of PDP models and against symbolic ones. However, parallel constraint satisfaction drawing on multiple knowledge sources is commonplace among rule-based models of sentence processing, and is acknowledged by Fodor (1983, p. 78, pp 134–135) to be entirely modular.

It follows by the same token that connectionism is not intrinsically less modular than any other approach. Nevertheless, there has been a considerable emphasis in the connectionist literature on the idea that the appearance of rule-like behavior is 'emergent' in such systems, and that language processing and language acquisition can be modeled in monolithic nonmodular PDP machines or algorithms without the explicit involvement of grammars.

In assessing the connectionist claims it is important to ask what it is that neurocomputational machinery actually learns, and whether it can in principle do the jobs that language does for us. In particular, we must ask whether it will deliver meaning in a form that will in turn support logical inference. In practice, inference systems of any generality have generally depended on explicit representations of structure of some kind.

In investigating these questions, two claims are of particular interest. The first is the claim that grammars, in the sense used by symbolists, are an emergent phenomenon of the learning of sequential dependencies by recurrent neural networks with 'contextual' units. The second is the claim, and originating with Niklasson and van Gelder (1994), that structure can be represented in distributed memory and manipulated systematically (in the sense of that term that Fodor and Pylyshyn (1988) claimed to intrinsically require symbolic representation), without explicitly representing the pointer structure of the symbolic representation. Clearly if both of these claims are correct then the neurocomputational account has gone a long way towards delivering a distinctively nonsymbolic account of language.

NETWORKS AND GRAMMARS

Simple Recurrent Networks

The 'simple recurrent network' (SRN) (Elman, 1990) approximates the more costly but exact 'back propagation through time' algorithm of Rumelhart *et al*. (1986) for learning sequential dependencies. It does so by using a single set of context units which store the activations of the hidden units at time $t-1$ as an input to the hidden units at time t, along with the activations of the normal input units corresponding to the current item, item_t, as in Figure 1. Since the activations of the hidden units at time $t-1$ were themselves partly determined by the activations on the hidden units at time $t-2$, which were in turn determined by those at time $t-3$, and so on, the context units

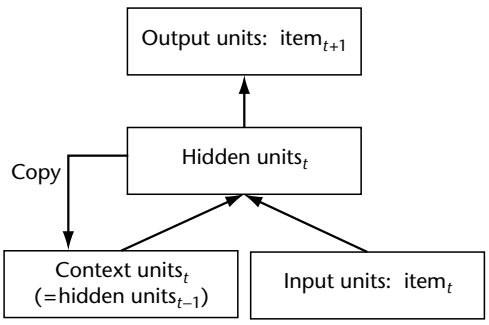

Figure 1. The simple recurrent network.

carry ever-diminishing echoes of ever more distant items in the preceding sequence.

Because there is no clear bound to the extent of the preceding sequence about which information can be captured in the context units, it is not clear precisely what is the automata-theoretic power of such 'graded-state machines' (Cleeremans *et al*., 1995). However, the signal-to-noise ratio for information concerning distant items falls off very rapidly with this mechanism, and it is fairly clear that in practice SRNs of the kind that can actually be built and trained approximate the class of finite-state Markov machines that can be learned using the exact technique to a degree of accuracy that depends on the maximum number of timesteps required.

Finite-state machines are interesting devices, and it is often surprising to see the extent to which they can approximate the output of devices that are intrinsically higher in the automata-theoretic hierarchy. It is interesting to ask whether similar mechanisms can play any part in natural-language processing.

This is possible, because some neural-network algorithms are capable of inducing extremely efficient – and correspondingly opaque – representations, when compared with standard hidden Markov models. However, as SRNs are actually used by psychologists and linguists they appear to approximate something much closer to a familiar standard symbolist finite-state device, namely the *n*-gram part-of-speech (POS) tagger. (This also seems to be their role in 'hybrid architecture' connectionist parsers, which use networks to implement a push-down stack, and structure-building modules in a more standard parser architecture.)

Finite-state Part-of-speech Tagging

n-gram POS tagging – that is, the determination of the form-class of ambiguous lexical items like *bear* on the basis of sequential probabilities at the word level – can be remarkably successful in reducing the degree of nondeterminism that practical parsing algorithms must cope with (accuracies over 97% are standard). Moreover, there is growing evidence that if the standard Brown-corpus POS categories like VB are replaced with the more informative lexical categories that are used in lexicalized grammars – such as lexical functional grammar, tree adjoining grammar, head-driven phrase structure grammar, and the various forms of categorial grammar – and if different senses of the same syntactic type are also distinguished as different lexical items, lexical disambiguation may do a great deal of the work of parsing itself, leaving only structural or 'attachment' ambiguities to be resolved by parsing proper.

Why do SRNs and Part-of-speech Taggers Work?

Finite-state POS taggers, and by assumption SRNs, work reasonably well on tasks like category and sense disambiguation and prediction of succeeding category, because the implicit Markov processes encode a lot of the redundancy (in the information-theoretic sense of the term) that is implicit in grammar, interpretation, and world knowledge. This means that, like standard Markov processes, SRNs can be made the basis of good predictors of processing difficulty. For example, the SVO word order of English and our knowledge of the world between them determine the fact that the transitive category for the word *arrested* is more likely to follow the noun *cop* than the past participial category, while these preferences are reversed following the word *crook*:

The cop arrested by the detective was left. (1)

The crook arrested by the detective was left. (2)

These likelihoods are reflected in increased reading times for human subjects at the word *by* in sentence 1 as compared with sentence 2, for example.

Are Grammars Emergent from SRNs?

While claims exist in the literature to the effect that recognizers for string sets of kinds that in general require grammars of higher than finite-state power have been acquired by SRNs (Christiansen and Chater, 1994), none of these results suggests that the grammars in question are therefore 'emergent' properties of mechanisms like SRN, any more than they are of *n*-gram POS taggers. Although the context defined by the context units is in a limited sense unbounded, and SRNs can in theory be used to model long-distance agreement dependencies, because of already-noted properties of the context unit representation, reliability falls off with distance, and these dependencies cannot be regarded as unbounded in the technical grammatical sense. They should instead be regarded as a finite-state cover of the higher-power grammar to some limited maximum string length. This means that claims to model human language acquisition using SRNs must be treated with some caution, although such models raise developmentally

interesting questions. (Interestingly, there are conflicting claims by Elman *et al*. (1996) and by Rohde and Plaut (1999) as to whether SRN learning depends on 'starting small', ordering presentation of simple examples before complex ones, or is rather inherently biased towards acquisition of local dependencies before long-range dependencies, and therefore independent of the order in which training examples are presented.)

Even within these limits, error-free sequences of grammatical categories fall short of semantic interpretability, as can be seen from the fact that the following word sequence has two interpretations based on identical Brown-corpus categories:

Put the block in the box on the table. (3)

Although SRNs can be regarded as disambiguating lexical items, this other kind of ambiguity – structural or attachment ambiguity – remains, as in the case of POS taggers.

For the same reason, it does not seem legitimate to regard 'trajectories' through the high-dimensional space defined by the hidden units as the equivalent of parses or interpretation (Tabor *et al*., 1997). Many other defining properties of interpretations – such as the ability to support the kind of structure-dependent transformations characteristic of inference – seem to be lacking in trajectories or category sequences of this kind. To find such properties in neurocomputational representations, we need to look to devices other than SRN.

INTERPRETABLE STRUCTURE AND ASSOCIATIVE MEMORY

Much neurocomputational work has explicitly or implicitly taken on board the need for the equivalent of trees or pointer structures to represent syntactic or semantic analyses (Hinton, 1990a) using associative memories of various kinds.

Such devices are of interest for (at least) two reasons. Firstly, they inherit some psychologically desirable properties of distributed representations, such as content-addressability and smooth degradation under noise and damage. Secondly, they offer a way to think about the interface between neurally embedded map-like sensorimotor inputs and outputs, and symbolic knowledge representation.

Recursive Auto-associative Memory

Recursive auto-associative memory (RAAM) (Pollack, 1990) is a device that uses hidden unit activation patterns to store associations between input and output patterns. It is called 'auto-associative' because it uses the same patterns as input and output.

An *n*-ary recursive structure can be stored bottom-up in the RAAM starting with the leaf elements by recursively auto-associating vectors comprising up to *n* hidden-unit activation patterns corresponding to either leaves or previously encoded structures. The activation pattern that results from each auto-association of the children can then be treated as the address of the parent (see Figure 2).

Since by including finitely many further units on the input and output layers we can associate node-label or content information with the nodes, a modification sometimes referred to as 'labeled RAAM', this device can store recursive parse structures, thematic representations, or other varieties of logical form of sentences.

The device should not be confused with a parser: it is trained with fully articulated structures which it merely stores efficiently. The hidden units can be regarded as encoding to some approximation the context-free productions that defined those structures, in a fashion similar to the way Hinton (1990b) encoded part–whole relations, enabling recognition of pattern instances that have not been encountered before. In that sense the device has been claimed to be capable of inducing the corresponding grammar from the trees (Pollack, 1990), contrary to the claims of Fodor and Pylyshyn (1988) concerning the systematicity or generalizing capacities of neural networks.

This claim was challenged by Hadley (1994a), who extended Fodor and Pylyshyn's critique to distinguish a number of levels of systematicity in the induced classifier, contingent on the relation of the test examples to the training set. The system of levels of systematicity was further refined by Niklasson and van Gelder (1994) who among other levels distinguished: level 3, generalization to all and only legal seen structures with novel constant–position pairings; level 4, generalization

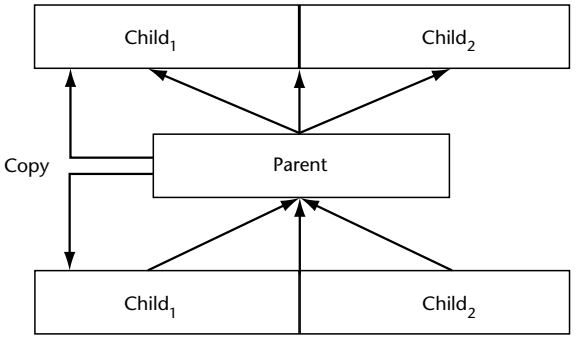

Figure 2. Recursive auto-associative memory.

to all and only legal novel embeddings of seen structures with seen constant–position pairings; and level 5, generalization to all and only legal novel embeddings of seen structures with novel constant–position pairings – where 'legal' means permitted by the corresponding rule-based system.

Scope and Limits of Systematicity

Niklasson and van Gelder's (1994) experiment had the novel feature of representing both formula-like structures and (via a separate network) operations over those representations resembling logical equivalence transformations, such as the rule that replaces formulae of the form $P \rightarrow Q$ with corresponding formulae $\neg P \vee Q$, or syntactic transformations, such as the passive rule that relates psuedo-English sentences of the form *cat chase dog* to those of the form *dog chased by cat*. Niklasson and van Gelder were able to demonstrate level-3 systematicity on this task (although Hadley (1994b) expresses some reservations about statistical reliability). Remarkably, these operations worked without explicitly unpicking the representation, via pointer dereferencing of the kind standard in symbolic representations of logical formulae and their transformation using list-processing computer programming languages like LISP and PROLOG.

This is probably a more appropriate use for RAAM than building parse trees, since RAAM is slow to train, and inherits poor scaling properties from its use of back propagation. Devices such as the 'holographic reduced representations' (HRR) proposed by Plate (1994) are an interesting alternative. Their properties for the storage and holistic transformation of such structures have been investigated by Neumann (2001), who reports replication of Niklasson and van Gelder (1994) using RAAM and an extension to their level-5 systematicity (generalization to novel embeddings of seen structures with novel constant–position pairings) for a related system using HRR.

Neumann shows that these networks can learn superimposed collections of linear-transformational rules that depend on the relation of isotopy which holds between the distribution of their inputs and that of their outputs in the hyperspace defined by the weights. (This space can be examined using principal components analysis and other clustering techniques. This representation of whole disambiguated structures as points in a high-dimensional space is unrelated to the SRN representation of sequences as trajectories in such a space.) Among the rules that Neumann shows can be learned in this way is one mapping $P \wedge (P \rightarrow Q)$ to Q. This rule is related to the rule of modus ponens, a fundamental rule of inference. It therefore seems possible in principle that structures represented in this way could support inference.

However, some caution is needed in interpreting these results, as Neumann points out. To build a practical inference engine to exploit this property requires a number of further steps, including the identification of suitable pairs of formulae of the form P and $P \rightarrow Q$ from a larger set to form the input to the rule, and a process of search for proofs through a potentially exponentially growing space of sequences of inference steps. It is unclear whether such processes can be helpfully thought of in distinctly neurocomputational terms, or whether this is the level at which at least part of cognition becomes distinctively symbolic.

USING CLASSIFIERS TO LEARN GROUNDED CONCEPTUAL CATEGORIES

One promising use of associative memory models like RAAM and HRR might be to learn the bounded syntactic–semantic structures that are associated with lexical items, particularly verbs, which provide the input to lexicalized grammars and parsers of the kinds referred to earlier.

We might assume that a subset of such structures is available prelinguistically, resulting relatively directly from the evolved or learned structure of connections to the sensorium, short-term memory, and the like. At higher levels, such structures may arise from nonlinguistic network concept learning along lines set out by Hinton (1990b), without mediating symbolic forms.

Part of the interest of this proposal lies in the possibility that the interaction of such structured sensorimotor manifolds and this novel form of concept learning might give rise to 'grounded' conceptual categories within a standard symbolist approach. Grammar acquisition would then mainly reduce to the association of lexical items to concepts, and decisions such as whether the syntactic type corresponding to the concept of walking looks forwards, backwards, or either way, for its subject in the particular language that the child is faced with, and how the multiple arguments of transitives, ditransitives, and the like map to the underlying universal logical form, as reflected for example in the possibilities for reflexivization. Since directionality can be represented as a value on an input unit, and since an individual category can be defined as a finite-state machine, and its

mapping to universal logical form can be captured as a finite-state transduction, such categories are good candidates for learning with neurocomputational devices.

A similar tendency towards lexical involvement is evident in current statistical computational linguistic research. Much work in probabilistic parsing moves away from autonomous Markovian POS tagging and prefiltering, and towards a greater integration of probabilities with grammar – see Manning and Schütze (1999) for a review.

Part of the interest of this proposal lies in the possibility that such learning might capture word-order generalizations over the lexical categories. Certain constraints that have been discussed within optimality theory (Prince and Smolensky, 1997), such as the tendency for semantically related categories (such as tensed transitive verbs) to have the same directionality (such as SVO order) are 'soft,' in the sense that they can have exceptions (such as English auxiliary verbs). It seems likely that the lexical acquisition device based on associative memory, sketched above, might also be suited to acquiring such lexicons based on soft constraints. If so, then the claim that the form of possible human lexicons is 'emergent' from the neural mechanism would have real force.

In this connection it is interesting to note that monolithic PDP-based connectionist models have been successful in modeling the acquisition and processing of systems of morphologically inflected lexical items that mix regular and irregular forms, such as the English past-tense system (first approached by Rumelhart and McClelland (1986)), competing successfully if not conclusively with models based on rules and exceptions (Pinker, 1999) in accounting for the course of acquisition in children, including the 'U-shaped curve' in frequency of correct versus incorrect use of irregulars, whereby children initially use forms like 'ran', then drop them in favor of over-regulations like 'runned', before returning to using 'ran'.

IMPLICATIONS FOR NATIVIST THEORIES OF THE LANGUAGE FACULTY

Given the origins of the term 'connectionism' in the behaviorist theories of Thorndike and others as modified by Hebb, it is perhaps not surprising that its advocates see themselves as in conflict with the nativist position associated with Noam Chomsky, the opponent of behaviorist theories of language and founder of modern symbolic approaches to language.

The conflict, which has been most eloquently pursued by Elman *et al*. (1996) and in the response by Marcus (2001), is more apparent than real. Chomsky's point has always been that attempts to explain the universal form of language and the course of language acquisition in terms of more general-purpose cognitive faculties or psychological laws have in practice not been notably effective. While constantly deriding the inability of currently available theories of learning, cognitive development, or semantics to make any significant contribution to linguistic explanation, he has consistently advocated the study of innate universal principles of language in isolation from other aspects of cognition as a matter of methodological expediency. The fact remains that the only plausible source for the innate component lies in the conceptual structure with which the child comes to language learning, and which either evolved or was learned for more general cognitive purposes. This observation is implicit at least as early as Chomsky (1965, section 1.5) and is explicit in Pinker's early work on modeling acquisition.

Elman *et al*. (1996) do a good job of demolishing certain dubious claims for evidence of specifically linguistic genetic components. (In particular, their review of the widespread exaggeration of the significance of the heritable disorder of the KE family is telling.) However, the contribution of neurocomputational theories to our understanding of language seems unlikely to be to demonstrate the emergence of grammar from monolithic neural computation. Machines that are emergent in this sense are intrinsically implausible as psychological models, because they offer the same kind of obstacles to further evolutionary development that unstructured programs offer to software developers, as Holland (1998) points out in different terms. The distinctive contribution of neurocomputational models is more likely to lie in explaining how the structure implicit in the sensory manifold and our interactions with the world can be extracted by classifiers based on algorithms like back propagation and the restricted Boltzmann machine learning algorithm, to provide the grounded conceptual structure upon which both reasoning about the world and the development of language depend. The question of how much of this conceptual structure is actively learned by the individual prelinguistic child, and how much of it has been compiled into heritable 'hard-wired' components during the process of evolution of humans and their animal ancestors, and the question of what further apparatus is needed for the development of language and whether its origins can also be

traced to more generally useful cognitive abilities, remain open. (One promising but in formal terms under-investigated source for the latter apparatus that is suggested by both developmental and neuroanatomical evidence lies in the system for planning action in the world.) These will be questions of considerable empirical interest to both symbolic and neurocomputational theorists.

Learnability Theory

Advanced article

Ken Wexler, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA

CONTENTS

The issue of learnability has dominated the study of generative grammar for most of its history. The problem of learnability is how to account for the fact that any normal child can learn any natural language.

INTRODUCTION

There is a theoretical tension between the fact that natural language is learnable and the fact that there exists (so it appears) more than one natural language. If there were exactly one natural language that all humans shared, then it would be possible (though not necessary) that every feature of this language was encoded by the genome. The fact that there is some variability in natural languages means that there is at least some learnability problem.

Empirical and theoretical discoveries in linguistic theory have led to the conclusion that most of the problem of learnability can be solved via the assumption that variability in the bases of natural languages is severely restricted. Let us use the term 'grammar' as it is used in linguistic theory: to mean the underlying computational system of the language (e.g. Chomsky, 1965, 1995), the part that is encoded in the human genome. Then the fundamental axiom of linguistic theory is that there is exactly one grammar. This grammar is called 'universal grammar' (UG). We take UG to mean this one computational system of language that is encoded in the human genome.

This assumption (to the extent that it is true) solves the problem of learnability. However, it is an idealization, as there is at least some variation in human grammar. The grammar of French is different from the grammar of English, which is different from the grammar of Chinese, and so on. However, the results of linguistic theory imply that the differences between these grammars are minor, compared to the fundamental similarities.

We will concentrate on syntax (though similar arguments might apply to phonology, morphology, and semantics).

The fundamental framework of linguistic theory is the 'principles-and-parameters' framework. Principles are the universal parts of grammar, the properties that govern the computational system of language in all languages. Parameters represent those parts of syntax that vary from language to language. Thus, French sets a particular parameter one way, while English sets it another way. Parameters account for the differences in syntactic properties between languages.

PARAMETER SETTING

There are two possibilities for how parameters are determined. The first possibility is that parametric variation is encoded in the genome: for example, a particular individual has a particular value of a parameter as a function of her genetic inheritance. If, say, she comes from a long line of Italian speakers, then a parameter setting for Italian is encoded in her genome.

There is no evidence that there is any genetic variation that predisposes individuals to have particular parameter settings. That is, normal experience (as well as research in language acquisition) shows that any normal child, of whatever genetic background, can learn any natural language. (We ignore questions of language impairment here.)

Thus, we must assume the second possibility, that children set their parameters via experience, as a process of learning.

Of course, the process of learning that allows children to set their parameters interacts with children's UG, the genetically inherited principles that account for the basic properties of language. But the differences between languages result from the child's being exposed to a particular language and learning what the correct parameter-settings are for that language.

For example, many languages (like English and Chinese) have the basic constituents of their sentences in the order SVO (subject–verb–object), as in *Mary ate the cake*. On the other hand, many languages (probably a greater number, in fact) have the order SOV, as in *Mary the cake ate*. These languages include Korean and Japanese (and German, although the order in simple sentences in German is complicated by additional processes).

To account for these differences, one might postulate an 'object' parameter that has two values: V before O, and O before V. The basic idea of parameter setting is that children listen to sentences. If they hear sentences like *Mary ate the cake*, then they set the object parameter as VO; if they hear *Mary the cake ate*, then they set the parameter as OV.

Research indicates that most (perhaps all) parameters are binary: they can take one of two values, like VO and OV for the object parameter. It would thus seem to be a simple matter for a child to set parameters – in principle, experience should tell a child, who has the knowledge of UG from genetic inheritance including a genetically inherited list of parameters, what the value of each parameter is. This is the basic model of parameter setting that is the basis for the theory of variation and learning in syntactic theory.

A theory that has become especially popular in phonology is 'optimality theory'. Here, variation is treated somewhat differently, though in the same spirit. Namely, what distinguishes languages, and what the child has to learn from experience, is the ordering of a set of innately (genetically) specified constraints. There is at least as much need for an innate, genetically specified basis for language in optimality theory, in many respects even more minutely specified than in a principles-and-parameters framework.

EMPIRICAL FINDINGS

Before discussing how well such a theory explains parameter setting, we should ask what the basic empirical properties of parameter setting are. As we have already indicated, children learn the parameters of the language to which they are exposed. But how difficult is this learning? Is it fast and simple and relatively error-free, or is it subject to many errors?

Answering this question of how easily and well children learn parameters is important in order to contrast two types of theory. The first is the theory of language that comes from linguistic theory, whose framework we have just sketched. This theory says that there is a large genetic component to language, and fairly simple learning of a few variable parameters. It predicts that learning of language-particular properties should be simple, and that even very young children should learn their parameters correctly, since the parameters are simply stated given the biological basis for UG.

However, many theories emanating from empiricist psychology hold that the child has little or no knowledge of the computational system of language passed down through the genome, and that all learning, including language learning, starts with a 'blank slate'. If these theories are right, we would expect that language learning would be slow and tedious, that – given the enormous complexity of human language – there would be many errors in learning the properties of any particular language that a child was exposed to.

The empirical answer is quite clear. Extensive research on first-language acquisition has shown that many basic parameters of sentence structure are acquired at an early age. The principle of very early parameter setting (VEPS) (Wexler, 1998) states that basic parameters of clause structure are set correctly at the earliest observable age, that is, the beginning of the two-word stage of language production, at around 18 months of age.

VEPS has been demonstrated by extensive quantitative studies of children's production of utterances. For most syntactic parameters, in order to tell whether a production agrees with a parameter setting or not, at least two words must exist in the utterance (for example, we must observe a verb together with a grammatical object in order to determine whether the object precedes or follows the verb). Thus we cannot determine whether a parameter has been set correctly until a child begins to utter two-word sentences, and this typically happens at around 18 months of age. By this time, children's productions agree with the parameter setting of the ambient language – they vary, for example, according to whether the language is Japanese or English.

Before this age, the child may already have set the parameters correctly: we just cannot tell given the evidence currently available, though experimental studies on infants (e.g. using the 'selective looking paradigm') may eventually tell us that children set parameters before they are 18 months old. The important point is that for crucial parameters for which evidence is available, children apparently never go through a period in which a parameter is set incorrectly or uncertainly. This includes not only relatively straightforward parameters such as the 'verb–object' parameter, but more

subtle parameters such as the 'verb-second' parameter (which says that a finite verb in a simple clause moves to second position) or the 'verb-raising' parameter (which says that a finite verb is raised to a particular position).

Given this empirical result – one of many results from the study of linguistic development in the 1990s – it must be the case that parameters are set relatively easily. There is no trial-and-error period during which parameters are changed by correction or similar processes. Children listen to sentences and produce sentences in accordance with the correct parameter.

Therefore, children must use genetically endowed abilities to help them to set their parameters quickly and well. The drawn-out, error-filled process proposed by empiricist psychologists simply does not occur.

POSITIVE AND NEGATIVE EVIDENCE

Wexler and Hamburger (1973) introduced the term 'negative evidence' to indicate the kind of input that would tell the child that certain utterances were ungrammatical. They argued that empirical research by Brown and Hanlon (1970) meant that negative evidence did not systematically exist. Namely, many (probably most) children at the very young age when grammatical development was taking place were not corrected for speaking ungrammatically. However, Wexler and Hamburger proved that linguistic systems of the 1970s (the 'Standard Theory') could not be learned by any specifiable procedure if the only information available was positive evidence. They therefore argued that even more innate constraints had to be specified, or information had to be available from 'semantic' sources available to the child.

Since these early results, researchers in the field of language acquisition influenced by generative grammar have for the most part assumed that negative evidence does not exist. Both its proponents (e.g. Hoekstra and Schwartz, 1994) and its opponents (e.g. Tomasello, 2000) agree that the generative approach to the empirical study of language acquisition has become dominant. Thus the assumption that negative evidence does not exist has become dominant in the field of language acquisition.

Note that the VEPS result confirms that there is no necessity for negative evidence in order for a child to set their parameters correctly. This is because correct parameter setting has taken place before the child produces utterances that can even potentially be corrected, or misunderstood. The child does not produce any sentence that shows an incorrectly set parameter, so that no matter what an adult's intentions, the adult cannot provide negative evidence. In other words, parameters are set by the psychological process of 'perceptual learning' (Wexler, 2002). Of course, to make this learning possible, there has to be a large amount of genetically specified knowledge of the computational system of language.

THEORETICAL RESULTS

Wexler and Hamburger's learnability result was proved by mathematical methods. They showed that no specifiable learning device (in the accepted sense of 'specifiable device' in cognitive science, an effective system) could learn every natural language specified by linguistic theory. The mathematical framework for that result was the abstract framework of 'text-identifiability' devised by Gold (1967). No effective device could eventually converge on every natural language given sentences from that language. For an extensive mathematical study of learnability in the Gold framework (though one with very few linguistic applications to date), see Osherson *et al*. (1986).

DETAILED MECHANISMS OF PARAMETER SETTING

Since Wexler and Hamburger's result, there have been a large number of learnability results with direct relevance to linguistic theory and the problem of language acquisition, although these have had to diverge from the Gold framework. Thus, Wexler and Culicover (1980) were concerned with the problem of 'boundedness', in essence showing that all grammars specifiable by a theory could be learned from data of bounded complexity, in particular data of degree 2 (no more than an embedding of a sentence within a sentence within a sentence). Their work was motivated by the goal of demonstrating that learning procedures that were psychologically real (i.e. agreeing with a child's abilities) could learn the specified grammars. Wexler and Culicover's 'degree-2 theorem' showed that any grammar of the standard kind could be learned from input of degree no more than 2. To achieve this result (rather complex in its proof), many aspects of UG had to be assumed to be genetically specified. Thus, learnability theory agreed with the results of linguistic theory.

It still was possible in the degree-2 theory for the learner to make a very large number of mistakes, to not be quickly led to the correct learning. The

principles-and-parameters framework was introduced into linguistic theory in an attempt to understand how children can learn language quickly and well, without a large number of errant paths. Theories of learnability are now carried out in this framework. The problem is to find a theory of learning that shows how parameters can be set correctly given bounded evidence (in the sense of Wexler and Culicover (1980)).

This problem has stimulated a number of studies, none of which has been wholly successful in explaining how parameters can be set easily and well. Thus, Gibson and Wexler (1994) showed that even in a very simple system of three linguistically plausible parameters, the learner could end up in incorrect states and not be able to recover. The assumptions that went into this theory were the traditional ones of learnability theory – that learning (parameter setting) took place by the learner's noting that the sentence he or she produced was the wrong sentence, and that the learner had a large amount of grammatical knowledge specified genetically, but only limited processing and memory capacities. With greatly expanded processing and memory capacities, at least in principle, correct learning might result. However, the most natural and plausible theory is probably one in which the child has limited memory capacities while setting parameters, so that most of the work should be done by the genetically specified UG. Remember that the VEPS result indicates that parameters are set before 18 months of age. The learner cannot be assumed to have memory or processing capacities that go beyond those of an 18-month-old child.

Some researchers (e.g. Dresher and Kaye, 1990) attempt to solve the learnability problem by assuming that the child's genetically inherited knowledge of UG is supplemented by a genetically inherited set of 'cues': patterns of input that would be used to set a parameter a particular way. Thus learning does not take place by the child's noting that he or she makes an error and has to correct it. Rather, the child has to note that a (possibly quite complex) pattern (possibly using large memory resources) exists in the input.

No such cue theory has been successful in showing that a range of linguistically natural parameters can be set correctly. The problem is that there is a great deal of interaction between parameters, so that if n parameters have to be set, 2^n cues may have to be built into the learner through inheritance, one for each combination of parameter values. This would seem very unlikely.

On the other hand, no theory of the 'learning on errors' type has been shown to be successful for a large set of parameters either. There may be missing concepts in the theory of learnability. Even given a large amount of innately specified linguistic knowledge, the detailed theory of parameter setting is not fully understood.

However, a great deal of empirical evidence on language acquisition, as well as linguistic theory, converges to show that the general thrust of the theory is correct. Language learning turns out to be continuous with other biological abilities, as suggested by Lenneberg (1967). There is a large core of genetically specified pieces of knowledge, together with a learning system that accounts for the effects of experience. Unification of the study of language and the study of biology is in principle possible.

Lexical Access

Intermediate article

Anne Cutler, Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands

CONTENTS

Lexical access occurs in speaking when the pronounceable word forms are found which encode the concepts the speaker wishes to communicate; and it occurs in listening when the meaning is found which is expressed in the word forms the listener has heard.

THE LEXICON

Communication of a message from a speaker to a hearer can take the form of word sequences which the speaker has never before produced and the listener never heard before. *This article tries to give a plain introduction to lexical access* – most people have probably not heard this sentence, but it is no problem for listeners presented with such a new utterance to understand it. This is because utterances, though they may be uniquely constructed, are built up of discrete units (such as *article*, *give*, *plain*, *access*) which speakers assume their listeners will already know. These discrete units we call 'words', and the stock of words which speakers of a given language use in speaking and listening constitutes the vocabulary. The mental lexicon is the mental representation of the vocabulary.

Entries in the mental lexicon may correspond to words such as *give* and so on, but they may also be other forms which speakers store as discrete units: fixed phrases such as *bon appetit*, manipulable idiomatic phrases such as *let the cat out of the bag*, productive derivational affixes such as *re-* or *un-* or *-ish*, inflections for pluralization, tense and so on, stems which occur in multiple words. That is, the forms in the mental lexicon are those which language users store as discrete entities, and they may or may not coincide with forms which are written as discrete words. (Nevertheless, in this text 'words' will serve as shorthand for lexical representations.)

Speakers begin with the intention to communicate a message, and to achieve this they must encode the message in words and articulate the resulting string of words. Listeners hear the string of words, which they must decompose into its word parts, and their first step in decoding the message is identification of the meaning associated with each word. Lexical access in speaking is the process of finding the lexical representations to express the desired meaning. Lexical access in understanding is the process of finding the lexical representations which correspond to the heard sounds. Both speaking and understanding thus require lexical access, but the two processes are the reverse of one another. It has been a matter of dispute whether there is a unitary mental lexicon that is drawn upon both in speaking and understanding.

LEXICAL ACCESS IN SPEAKING

The speaker begins with an intended message and must convert this into spoken sound patterns. Models of word production (Dell, 1986; Levelt *et al*., 1999) agree that the conversion process consists of multiple stages, and in particular that retrieval of meaning and retrieval of sound are separate processes.

Retrieval of Meaning

In the model proposed by Levelt *et al*. (1999) it is assumed that the speaker effectively translates the intended message into individual lexically represented concepts. Each such concept has a unique lexical representation (the lemma) associated with it, and activation of the concepts expressed in the message causes activation of the lemmas to which they are connected. The lemmas contain the syntactic constraints associated with the concepts.

For example, Figure 1 depicts a single part of the lexical network which could be involved in expressing the message that this article is trying to give – *a plain introduction*. The lemma for *plain* is assumed to be activated by a corresponding conceptual node selected to express an attribute; the

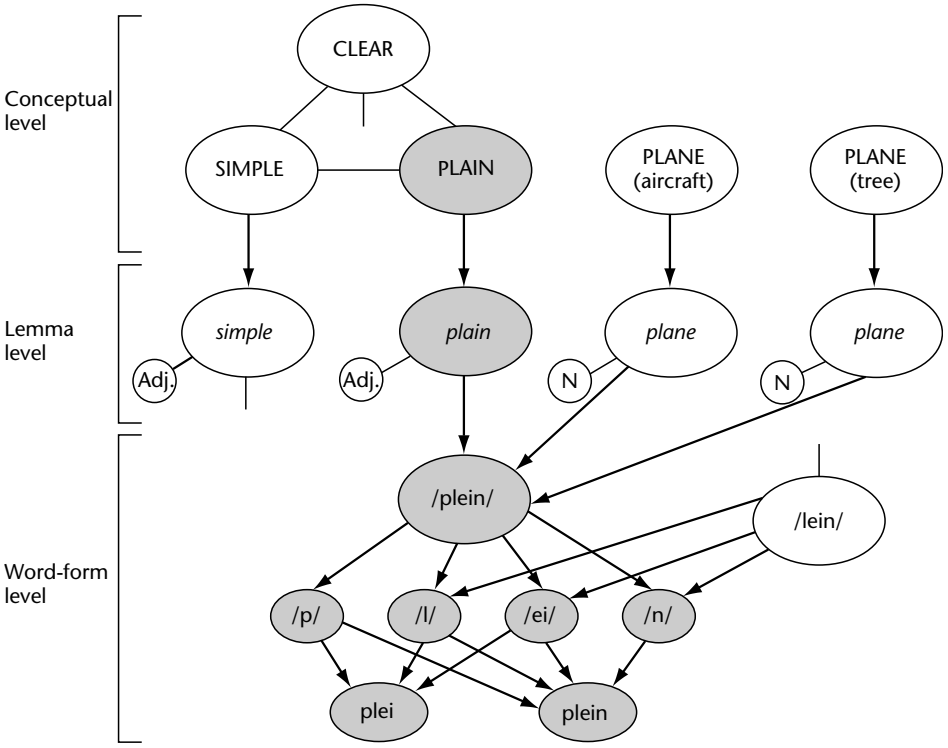

Figure 1. Fragment of a lexical network for word production.

lemma *plain* accordingly includes the syntactic attribute of being an adjective. Other syntactic information which can form part of a word's lemma representation includes the expression of, for instance, tense and number (in verb lemmas), case (in noun and adjective lemmas for languages which mark case), or grammatical gender (in noun lemmas for languages with gender).

Related conceptual nodes are connected to one another, but each conceptual node is connected to only one lemma. Lemmas are not connected to one another at all; they receive activation from concepts, and pass activation to the phonological forms (the word-forms) which express them as sound patterns, but they do not pass activation to other lemmas.

Activation from the conceptual node may spread to other conceptual nodes to which it is connected, and these nodes may in turn send activation to their associated lemmas. At the lemma level, however, a selection takes place; the most-activated lemma is chosen to pass activation on to the word-form level.

Retrieval of Sound

The lexicon includes separate representations of phonological form, the word-forms. Each lemma is connected to just one word- form. (An exception may perhaps occur in the special case of a single word for which a speaker knows two pronunciations; for example, some British speakers can pronounce the word *garage* to rhyme with either *marriage* or *mirage*.)

Word-forms, of course, may be connected to more than one lemma, because word-forms are very often homophonous – two words can sound the same. Thus the word-form to which the adjective lemma *plain* sends activation has many other connections – from the noun *plain* (a level tract of land), and from the various lemmas *plane* (an aircraft; a kind of tree; a surface; to make level; and so on). Figure 1 shows just two of these. None of these lemmas are connected to one another, nor to the adjective *plain*.

Evidence for the connection of word-forms to more than one lemma, and in general for separation of the lemma and word-form levels, appeared in some studies of frequency effects in production. Speakers can produce common words more rapidly than uncommon words; but if an uncommon word happens to be homophonous with a common one (e.g. *plane* the name of the tree and *plain* the adjective), then the uncommon word is produced as rapidly as the common one. Apparently it is the frequency of the word-form which matters.

The word-form representation contains information about how the word is pronounced, in the form of connections to the appropriate phonemic representations, together with instructions for the compilation of these phonemes into possible syllables. In actual utterances, syllable boundaries are determined by the string of words as a whole rather than only by the lexical representations of the individual words. A syllable-final phoneme may become syllable-initial if the word following it begins with a vowel (and, in English and similar languages, especially if that second word is a function word). In *plane that wood!*, the [n] is syllable-final, but in *plane it!*, the [n] may be syllable-initial, and the precise phonetic realization of the [p] can differ in the two positions. Therefore the phonemic representations activated at the word-form level are not fully compiled, because their final compilation depends on the rest of the utterance. In Figure 1, the word-form of *plain* is connected to four phoneme nodes (three of which, for example, it shares with the word-form of *lane*), and can activate two potential syllable nodes.

Slips of the Tongue

Errors can arise at all points in the process of producing an utterance. Slips of the tongue (see Fromkin, 1973) fall into two major classes: mis-selections and mis-orderings. Among the former are errors of lexical access, in which the wrong word is selected. These in turn are of three main kinds. Most common are mis-selections in which the meaning is similar but not identical – *next* instead of *last*. Mis-selections also occur in which the erroneously selected word is similar to the target word in sound though not in meaning – *single* instead of *signal*. And finally, blends of two words can occur – *bookstop* as a blend of *bookstore/bookshop*.

How do such errors arise? Semantic errors, understandably, arise in the process of accessing word meaning. They can be explained in terms of activation spreading among related conceptual nodes, leading to a lemma related in some way to the target being activated to the same or a greater extent than the target lemma. The nonintended lemma (*next*) is selected and from that point on word production proceeds just as if *next* had been the intended word.

Blends could also arise in the same way during the access of meaning representations. The difference between semantic errors and blends is that in the latter case the problem is carried beyond the lemma level: two equally activated lemmas could simultaneously pass activation to the word-form level, the two word-forms would then activate phonetic components at the articulatory level, and at this point the potential problem of competing candidates would perforce be resolved since the output would allow utterance of only one of the available syllable onsets, one of the available syllable nuclei, and so on.

Finally, form-based selection errors (malapropisms) could arise at the word-form level; activation spreading to the phonemic segments could be misassigned, leading to the syllabic packets appropriate for a similar form (*single*) being articulated, instead of those required by the target form (*signal*). The existence of both purely form-based and purely meaning-based slips lends further support to the two-stage model of lexical access in speaking. The 'tip-of-the-tongue' phenomenon also supports this division; a speaker who has a word on the tip of the tongue has accessed the word's meaning (and, in languages with grammatical gender, the speaker has also accessed the gender), but the pronunciation, i.e. the word-form representation, is for some reason temporarily inaccessible.

LEXICAL ACCESS IN UNDERSTANDING

The listener's task is to identify the words making up the speaker's message. Languages do not make life easy for listeners. The vocabulary of any language consists of tens or hundreds of thousands of words on average made up of only about 30 speech sounds, or phonemes (English has – depending on dialect – 40 or more phonemes, and is thus a relatively phoneme-rich language). Thus words inevitably resemble one another, and short words may fortuitously occur within longer ones; in consequence, in any spoken utterance the words uttered by the speaker are not the only words present in the speech signal. This would pose the listener little problem if words in speech were reliably demarcated with signals indicating where each word ends and the next begins. In many written texts (such as this one in English) such helpful signals are indeed available – white spaces between the words. That is not true of speech; spoken utterances reach the listener's ear as a continuous stream.

Segmentation

Figure 2 is a spectrogram of the phrase *A plain introduction to lexical access*, uttered by an American speaker. The gaps in the spectrogram correspond to

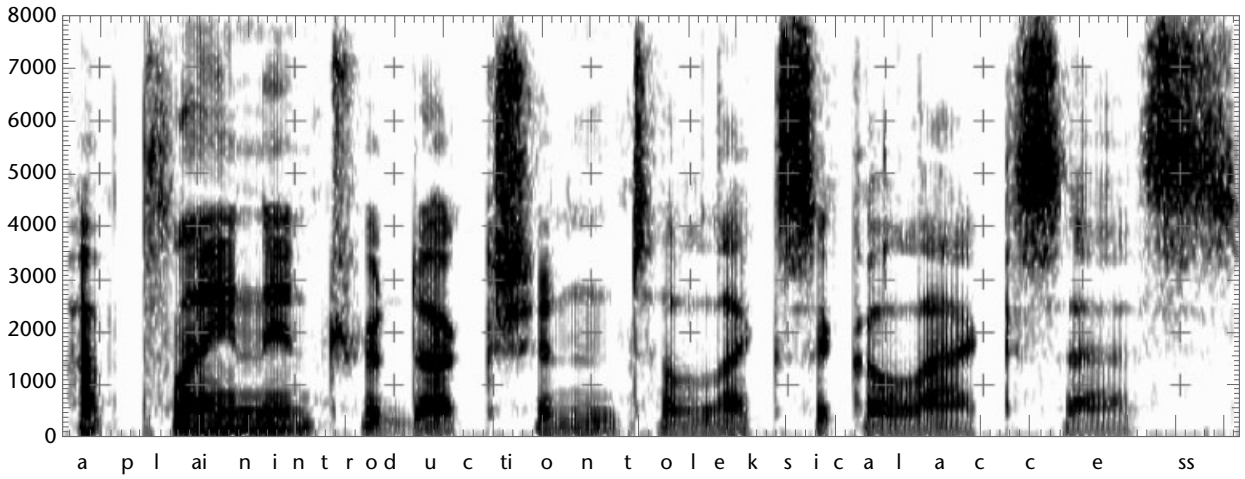

Figure 2. Spectrogram of the utterance 'A plain introduction to lexical access'. The display represents frequency on the vertical axis against time on the horizontal axis, with greater energy represented by darker shading. The transcription is aligned as closely as possible with the corresponding sounds on the spectrogram. There are clear breaks in the speech signal, but these do not correspond to breaks between words. The breaks occur whenever a speech gesture actually stops the flow of air through the speaker's vocal tract for a brief period – for instance the sounds 't' and 'd' in 'introduction'. In contrast, the individual words adjoin to one another continuously, without a break.

speech sounds, not to pauses between words. Certain speech sounds cause a momentary obstruction of the vocal tract, resulting in a brief period of silence – the consonants [p], [t], [k] and [d] are among such stop consonants and they occur in this utterance – [p] in *plain*, [k] in *introduction*, *lexical* and *access*, and so on. In contrast, there is no pause at word boundaries – *plain* runs continuously into *introduction*, *lexical* into *access*. The listener must find the words despite the absence of clear word boundary signals. This utterance in Figure 2 also shows how easy it is for shorter words to appear by accident within longer ones – thus *plain* contains *play*, *lay*, and *lane*; *introduction* contains *duck*; *access* contains *axe*. Words may even occur across word boundaries, because of the continuous flow of one word into another: thus across the boundary of *lexical* and *access* there is a string of sounds consistent with *lack* and *lax*.

Listeners can use knowledge about their language to help them segment continuous speech into its component words. For instance, certain phoneme sequences cannot occur within syllables (e.g. [nl] in English), or even within words (e.g. [mg] in English). Listeners can use this information to find words; the beginning of *lexical* would thus be clearer in the phrase *in lexical access* than it is in *to lexical access*. In English, words more often than not begin with a stressed syllable, and this information is also useful in segmentation; *plain*, *lexical* and *access* all begin with a primary stressed syllable, and *introduction* has secondary stress on its initial syllable. Only the function words *a* and *to* are unstressed; this also is typical of English, and also used by listeners to assign grammatical category. Of course, all these types of information differ across languages, so that the way they are exploited in listening will also be language-specific.

Activation and Competition

Models of spoken-word recognition (e.g. Marslen-Wilson and Welsh, 1978; McClelland and Elman, 1986; Luce *et al*., 1990; Norris, 1994) agree that words which are present in the speech signal are automatically activated in the listener's mind. Even words which are accidentally present (e.g. *lane* in *plain*) can be activated.

Simultaneous activation of all candidate words which are supported by information in the input means that a unique selection within the lexicon is not immediately possible; selection is achieved by allowing the activated words to compete with one another until one or more winners emerge. This process of competition provides a solution to the problems arising from the similarities between words and the embedding of words within other words; *plain* and *lane* compete for one portion of the input, *axe* and *access* for another, and so on.

Concurrent activation has been a feature of all models of spoken-word recognition since Marslen-Wilson and Welsh (1978). Competition was first

proposed in the TRACE model (McClelland and Elman, 1986), and in the same form – competition via lateral inhibition between competitors – it is the central mechanism of the Shortlist model (Norris, 1994). In other forms it is also found in the other main models currently available, such as the Neighborhood Activation Model (Luce *et al*., 1990) and the latest Cohort model (Gaskell and Marslen-Wilson, 1997).

There is substantial evidence of activation of words embedded within other words, and of simultaneous activation of partially overlapping words. This sort of evidence is gathered in laboratory studies in which listeners hear words or parts of words, and also perform another task such as deciding whether a visually presented letter string (e.g. GIVE or FLERK) is a real word or not. Hearing a word facilitates acceptance of a related word – it is easier to decide that GIVE is indeed a word after just hearing *take*, for instance. Activation of embedded words has been proposed because it has been observed that they too provide such facilitation – e.g. the recognition of GIVE could be facilitated by hearing *mistake*. And simultaneous activation of partially overlapping words has been supported by experiments which showed that hearing a fragment such as *lec-*, which could be the beginning of several words (e.g. *lexicon*, *lecture*) facilitated words related to all of them (such as DEFINITION, COLLEGE).

The activation process is continuous, and can effectively use early co-articulatory information, as is shown by experiments in which words are cross-spliced with other words and with nonwords. It is hard to decide that *shrud* is indeed a nonword if its spoken form includes a 'shru-' taken from an utterance of *shrub* or *shrug*. Thus even nonwords which resemble words will activate lexical information, and the more similar the nonword is to a real word, the more effective it will be in activating word candidates. Activation of a lexical representation thus does not obligatorily require full presentation of the corresponding word form; partial information (in partial words, for instance, or in nonwords which in part overlap with real words) suffices to produce partial activation.

Simultaneous multiple activation of words does not, of course, necessarily entail competition between those words. Models such as TRACE and Shortlist predict that simultaneously activated words will compete by passing inhibition to one another. This too has been demonstrated in the laboratory. One way to show such effects is in experiments in which listeners hear nonsense strings, some of which have a real word in them; the task is to find any such real word. In the strings *obzel crivlish lakfid*, for example, only the last string contains a real word – *lack*. When such nonsense strings activate competing words, listeners find it harder to find the embedded words. Thus, *mess* is harder to find in *domess* (which could partially activate *domestic*) than in *nemess* (which activates no competitor). The more competing words may be activated, the more the recognition of embedded words will be inhibited. This kind of finding is direct evidence for competition between words.

Figure 3 shows simulations of the input *lexical access* in the Shortlist model (Norris, 1994). The input activates temporarily words such as *lecture* and *excema* which are eventually defeated by competition from *lexical*; *collapse* and *lax*, which straddle the word boundary, are also briefly active, but joint competition from *lexical* and *axe* defeats them in turn; initially, *axe* enjoys stronger activation than *access*, but by the end of the input the two most activated words are, as intended, *lexical* and *access*. Competition between candidate words which are not aligned in the signal helps to achieve segmentation of the speech stream into individual words. Thus although the recognition of *lexical access* involves competition from other words, this is eventually overcome by joint inhibition from the actually spoken words. The competition process, and its concomitant constraints, can so efficiently result in victory for words which are fully present in the signal that concurrent activation of partially present words, or of words embedded within other words, is simply a low-cost by-product of the efficiency with which the earliest hints of a word's presence can be translated into activation.

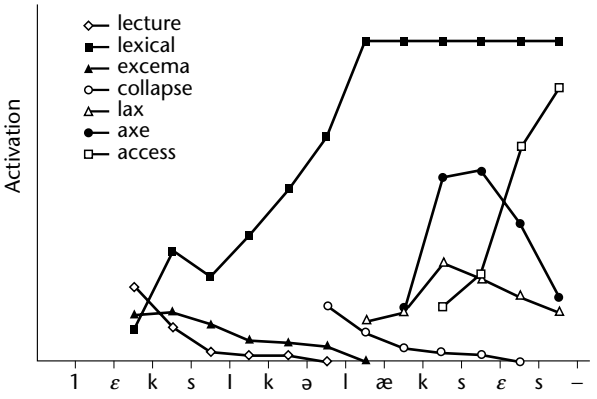

Figure 3. Shortlist simulations of word activations given the input 'lexical access'.

An activated word form passes activation on to the meaning associated with it. In word recognition models activation is assumed to cascade continuously through the levels, rather than to wait for a clear winner at each level. Thus activation of the word form *plain* can pass activation on – in this case, of course, to several meanings rather than just one. The string *a plain* is ambiguous as to whether the word-form *plain* is noun or adjective, and which of several interpretations of either syntactic form might be intended. Empirical studies (e.g. with the priming tasks described above) have indeed shown that multiple meanings of a homophone can be simultaneously accessed. However, the integration of the word's meaning with the rest of the syntactic and semantic context is also assumed to be a continuous process, as a result of which the intended meaning can very rapidly be selected. In the context of a story about flight, the message interpretation component might very quickly select the noun *plane* in the sense of aircraft, on semantic grounds. Syntactic considerations would suggest that *A plain* followed by *introduction* is best interpreted with the adjectival meaning of *plain*.

Slips of the Ear

Errors can, again, arise at any point in the process of comprehending an utterance. Errors specifically in the process of lexical access imply that the outcome of the competition process is a word or sequence of words which does not correspond to what the speaker actually said. Such slips of the ear are particularly likely when the input is unclear – due to background noise, for example, so that weak acoustic support is provided for a number of possible candidate words. Thus an old popsong contained the words *she's a must to avoid*; very many listeners independently interpreted this as *she's a muscular boy*.

Slips of the ear often (as in this example) produce implausible results, and may produce reports of low frequency words or even nonwords (see Bond, 1999). This suggests that frequency and plausibility do not play a strong role in the activation and competition process.

The operation of the strategies constraining the competition process can be seen in the patterns of slips of the ear. In English, for instance, slips are much more likely to produce interpretations in which strong syllables are word-initial and weak syllables are not word-initial – as in the example, in which *must to avoid* (strong, weak, weak-strong) is thought to be *muscular boy* (strong-weak-weak, strong).

THE INDEPENDENCE OF LEXICAL ACCESS

A recurring question in research on language processing is whether the different components of the process are independent, or whether they can be influenced by processing decisions made by other components which are logically later in the processing chain. In models which preserve independence ('autonomous models'; e.g. Levelt *et al*., 1999 for word production, or Norris, 1994 for word recognition), information feeds forward only – in speaking, from conceptual formulation to articulation, and in listening, from acoustic-phonetic processing to message interpretation. In models which allow non-independence ('interactive models'; e.g. Dell, 1986 for word production, or McClelland and Elman, 1986 for word recognition), there is feedback, e.g. from phonological encoding to lemma selection in speaking, or from word activation to phonetic processing in listening.

This is one of the most controversial issues in cognitive science, and it is a subject of continuing debate. For lexical processing in both speaking and listening, however, strictly feedforward models have been proposed which adequately account for the known empirical evidence (Levelt *et al*., 1999; Norris *et al*., 2000). Considerations of parsimony suggest that the simplest model consistent with the evidence should be preferred; the proponents of these models therefore argue that lexical processes should not be held to involve feedback connections.

In speaking, considerations of added efficiency have not been invoked in favor of feedback; the strongest evidence which has been used to argue for feedback in fact comes from performance failure, i.e. from slips of the tongue. First, semantic errors are more likely if the error is similar in sound to the intended word; that is, *plane* is more likely as a semantic error for *train* than for *boat*. And second, single-phoneme errors tend to produce another real word rather than a nonword: *plane* is more likely to be mispronounced *plate* than *plake*. However, both of these tendencies also arise in Levelt *et al*.'s (1999) feedforward model. Errors which result in real words are more likely to be missed by the monitoring component in that model. The split-stage architecture in the model further provides a natural explanation for phonological similarity in semantic errors. If two equally active lemmas are passed on to the word-form level instead of one, the error word-form is more likely to be selected at that level if it is similar to (and its phoneme connections hence receive activation from) the intended word-form.

In listening, similarly, the performance of the lexical processor cannot actually be improved by feedback to prelexical processing. Suppose the input *plai-*, with co-articulatory information in the vowel, is enough to activate *plain* to such an extent that it is the most well-supported word in the ongoing lexical competition process. Feedback from the lexicon can then determine that phonetic processing identifies an [n]. But this offers no assistance to the recognition of *plain*, since *plain* is already the most activated word. It would also not assist word recognition to pass down information from a number of equally supported competing words; if *plain*, *place*, *plate* and *plague* all passed down activation to their separate terminal phonemes, the phonetic processing level would simply receive more incorrect than correct information. The information in the signal would ultimately have to determine the decision at the phonetic level, so that no useful role would be played by the feedback.

Lexical Development

Advanced article

Cecile Maxine McKee, University of Arizona, Tucson, Arizona, USA

CONTENTS

Lexical development refers to children's acquisition of meaningful and grammatical elements of the lexicon.

INTRODUCTION

What comes first? Many people think that words are children's first linguistic elements. This may be because words are the first meaningful units that we recognize in children's observable behavior. With the exception of scientists who study this topic, people rarely consider infants' production of well-formed but meaningless syllables like 'bababa' as evidence of language knowledge. However, words are not first in any scientifically interesting sense. Children develop multiple aspects of linguistic knowledge simultaneously, and they do so well before producing their first words. (*See* **Phonology and Phonetics, Acquisition of**)

One theme in this encyclopedia is information; another is information processing. The study of lexical development relates to both. First, lexical development refers to children's mastery of a kind of information. However, the evidence for such mastery is affected by information processing. This distinction between information and the processing of information is comparable to the distinction between competence and performance. Developmentalists face subjects who are clearly gaining both target competence (i.e. representation of information) and proficient performance (i.e. processing of that information). Limitations in either or both can be sources of error for learners. For example, the holophrastic stage when children emphasize one-word utterances may reflect processing limitations as much as or more than informational limitations. Language processing systems, including those governing production, are developing at the same time as children are learning the very language(s) that these systems manipulate. Crosslinguistic considerations bring home the point. Although some aspects of language processing may be the same across languages and therefore at least a candidate for early development or even hard-wiring, some are language-specific and therefore not determinable until the learner's target language is – at least partly – in place (for example, see Levelt, 1989). (*See* **Performance and Competence**; **Speech Error Models of Language Production**)

An example of the complex relation between competence and performance comes from Smith's study of his son Amahl (Smith, 1989), which shows how the study of lexical development relates to both the information theme and the information processing theme. There was a time in Amahl's linguistic development when he pronounced 'mouth' and 'mouse' the same. Having an interest in competence–performance questions, Amahl's father devised a test. He put pictures of a mouth and a mouse in one room. From another room, he asked Amahl to bring him one or the other picture. The child repeatedly performed perfectly, showing that his representation of these words was closer to target than his utterances suggested. Were that not true, Amahl could not have perceived the distinction that his father made. That Amahl's production error was systematic requires an explanation in terms of both listed knowledge (e.g. the arbitrary information about the pronunciation or form of these words) and procedural knowledge (e.g. the processes that relate the sounds in 'mouth' and 'mouse' and the production mechanisms that apply those processes). Interestingly, this example is a case in which the child was still learning relevant procedural knowledge. It also shows how research on lexical development can be done.

The study of learning also informs this area of cognitive science. Whether the relevant learning rests on general mechanisms or on mechanisms specific to language, lexical development forces us to consider questions such as what a learner can do with partial information and/or less-than-smooth processing routines. In other words, the lexical system – both in terms of the information it

represents and the processing of that information – changes over time. Children begin to use language before it is fully in place. Research on lexical development thus aims at a moving target. Description of the adult lexicon and explanations of lexical development in children must recognize that. (*See* **Learning, Psychology of**)

WHAT IS A WORD?
